Therefore, I tested the amount of ATP and ADP in platelet-rich plasma in seven normal patients, eight cases of Von Willebrand disease. five patients with Glanzmann thrombasthenia—one with (type I) and four without (type II) anomalies of glycolysis[4]—six patients with a congenital defect in a clotting factor: three AHG (VIII) deficiencies. one Christmas factor (IX), one proconvertin (VII) and one Stuart-Prower (X) deficiency. Lastly, I treated six normal plasmas with an antiserotonic drug inducing *in vitro* thrombasthenia[9].

Platelet-rich plasma was prepared as follows: blood was collected by venous puncture in silicone glassware at 4° C, centrifuged slowly (1,200 r.p.m. for 10 min) and the supernatant treated with perchloric acid (aqueous solution 6 per cent). The supernatant, after centrifugation, was neutralized and filtered. The methods used for ATP determinations were those of Biochemica test Bohringer *TC J* and for ADP the Biochemica test Böhringer *TC K*, except for the fact that I used 0·08 ml. of DPNH instead

Table 1. PLASMATIC ASSAYS (MEAN VALUES)

	No. of patients	ATP	ADP	ATP/ADP
Control	7	7·71*	6·23	1·24
Von Willebrand	8	*11·53*	6·23	1·85
Glanzmann disease:				
Type I	1	*1·7*	4·25	0·4
Type II	4	8·47	*4·16*	2·03
Various disorders of blood coagulation	6	8·80	5·57	1·57
Experimental thrombasthenia	6	8·23	6·51	1·26

* In mg for 10^{11} platelets.

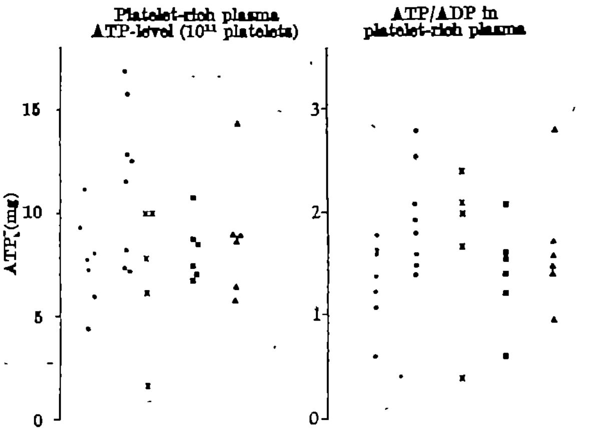

Fig. 1. ●, Control; ○, Von Willebrand; ×, Glanzmann disease; □, drug-induced thrombasthenia; △, blood coagulation disorders

of 0·1 ml; all the measurements were made in a Jobin Yvon Maroc II spectrophotometer at 366 Å. Results are expressed in mg for 10^{11} platelets (Fig. 1); the ratio ATP/ADP is on the right side in Fig. 1.

The mean values (normal and pathological) are given in Table 1. The difference of the ATP amount between normal subjects and patients with Von Willebrand disease is significant, and the coefficient of correlation is 2·36 (*S.E.* < 5 per cent). The amount of ADP is the same in both (Table 1). In Glanzmann disease with anomaly in glycolysis (type I), ATP is depressed; in the other one (type II), ADP is decreased; in any event the ratio ATP/ADP is abnormal. In experimental thrombasthenia and in patients with blood coagulation disorders, the level of ATP and ADP is normal except the increased amount of ATP in the platelet rich plasma of one case of Stuart (factor X) deficiency.

The significance of these results is still unknown, but it can be seen that the ratio ATP/ADP is abnormal (higher or lower than normal) in the cases with an anomaly in the cohesion of the platelets to the vessel wall[4,9,10]. The site of action of ADP on platelets, the opposite role of ATP, higher than normal in Von Willebrand disease, merits further consideration.

PATHOLOGY

Characters of Mammary Tumours in *BALB/c* Female Mice Foster-nursed by *C3H* and *RIII* Mothers

ANALYSIS of mammary tumours occurring in *C3H*, $BALB/c_f$, and *RIII* mice has indicated the existence of strain differences in the characters of neoplasms[1–10] (Table 1).

Table 1. CHARACTERIZATION OF THREE HIGH-CANCER-STRAIN MICE BY MEANS OF THE DOMINANT TUMOUR CHARACTERS

Tumour characters	Strains *C3H*	 $BALB/c_f$	 *RIII*
Clinical duration	short	short	long
Growth-rate	high	high	low
Partial regressions	rare	rare	frequent
Type of growth	regular*	regular*	irregular
Responsiveness to pregnancy	absent(?)	rare	frequent
Histological origin	nodules†	nodules†	plaques
Morphological picture	pure	pure	varied

* Sigmoidal, linear, parabolic or exponential curves.
† Hyperplastic alveolar nodules.

The question therefore arises: What causes the difference found in tumour behaviour in various strains? The causes might be only genetic, but it is interesting to note that in *C3H* and $BALB/c_f$ strains, though their genetic origin is different, the behaviour of tumours is parallel. In order to explain the results found, three facts deserve special consideration, namely: (*a*) *C3H* and $BALB/c_f$ mice, which grow tumours with similar behaviour, carry the same milk agent (the $BALB/c_f$ strain is *BALB/c* foster-nursed by *C3H*), whereas another type of agent is responsible for tumours in *RIII* mice; (*b*) mammary tumours showing the same characters as *RIII* tumours have been observed in *RIII* × *C57b* and reciprocal hybrids, which bear the same milk agent as their *RIII* parent[11,12]; (*c*) the existence of differences in behaviour between the *RIII* milk agent and that of other strains of mice has also recently been noticed by other investigators in different laboratories[13–15]. This leads one to suppose that the mammary tumour agent, like a true genic particle, might be the carrier of a number of specific tumour characters. In order to test this hypothesis foster-nursing experiments are being performed.

Two new lines of inbred mice have been established by crossed foster-nursing, namely: *RIII* foster-nursed by $BALB/c_f$, and *BALB/c* foster-nursed by *RIII*. Preliminary results from the former line have been published elsewhere[16]. The results obtained were in agreement with the working hypothesis suggested here. In fact, the behaviour of mammary tumours occurring in *RIII* mice foster-nursed by $BALB/c_f$ closely approached that of $BALB/c_f$ tumours. The data so far available on the behaviour of tumours in the *BALB/c* line foster-nursed by *RIII* are given here.

A litter of five *BALB/c* mice removed from its mother at birth was transferred to an *RIII* mother for suckling. At weaning, four $BALB/c_{f(RIII)}$ mice were still living, two females and two males. Both the females were mated and the line was then maintained by brother to sister mating. Now it has reached the seventh inbred generation and shows a high incidence of mammary tumours. Data concerning mammary tumours in breeding females already dead are given here.

Of 52 breeding female mice, either normally or forcibly bred, 49 or 94·2 per cent developed mammary tumours at an average age of 233 days. The average number of tumours per mouse was two. All the animals with or without mammary tumours delivered litters. The average number of litters per mouse was 4·8 in mice normally bred and 7·2 in those forcibly bred.

The behaviour of mammary tumours in *BALB/c* mice foster-nursed by *RIII*, compared with that in *BALB/c* mice foster-nursed by *C3H*, is summarized in Table 2. On the right and left sides of Table 2 are recorded the characters of tumours grown in the *RIII* and *C3H* strains, which provided the respective milk agents to the $BALB/c_f$ lines.

Table 2. CHARACTERS OF MAMMARY TUMOURS IN *BALB/c* FEMALE MICE FOSTER-NURSED BY *C3H* AND *RIII* MOTHERS

	C3H (donor) →	$BALB/c_f$ (*C3H*)	$BALB/c_f$ (*RIII*)	← *RIII* (donor)
Clinical duration (days)	49	59	104	103
Growth-rate (cm per week)	0·238	0·231	0·125	0·135
Partial regressions (per cent)	27	34	60	59
Type of growth (regular: per cent)	64·3	61·5	25	30
Responsiveness to pregnancy (per cent)	0*	19	83	80·3
Histological origin (prevalent)	nodules	nodules	plaques	plaques
Morphological picture (prevalent)	pure	pure	varied	varied

* Due to the low fertility of these animals at the age of tumour appearance, this figure concerns only a few tumours. A larger group of *C3H* mice is now under investigation for this character.

In *BALB/c* mice foster-nursed by *RIII* the clinical duration of tumours was 104 days, on average, and the average rate of tumour growth was 0·125 cm per week. Partial regressions were observed in 60 per cent of tumours. The type of growth was regular in 25 per cent of tumours. Responsiveness to pregnancy was observed in 82 per cent of tumours. Preliminary histological studies have shown that tumours in these mice arise frequently in plaques and present varied pictures.

The results presented here show that the behaviour of mammary tumours occurring in *BALB/c* mice foster-nursed by *RIII* closely approaches that of *RIII* tumours. By contrast, a striking difference in behaviour has been found between tumours which grow in the same strain (*BALB/c*) foster-nursed by different mothers (*C3H* and *RIII*). These results indicate that the tumour characters may be transferred from one strain to another by means of foster-nursing.

Asbestosis in Non-Experimental Animals in South Africa

Asbestosis has been produced in monkeys, rabbits and guinea pigs exposed to crocidolite, amosite and chrysotile asbestos dusts in experimental dust rooms[1]. No record of asbestosis occurring in non-experimental animals has been found, although Kiviluoto found anthophyllite asbestos fibres in the lungs of a cow from the vicinity of an asbestos mine[2]. He suggested that this finding supported his contention that the mining process was not directly responsible for the inhalation of asbestos dust in those cases of bilateral pleural calcification in which there was no history of an industrial exposure to asbestos dust.

Recently it has been possible to examine the lungs of different animals which have lived in the vicinity of an asbestos mine or associated process.

Donkeys. Two donkeys had worked on an amosite asbestos mine in the northern part of the Transvaal Province hauling ore from the mine to the reef picking plant. At autopsy the lungs and heart of one of these which had worked for ten years were removed and sent to this Unit for examination. Histological examination showed the presence of an interstitial fibrosis associated with asbestos bodies and asbestos needles. A small part was taken from one of the lungs of the other donkey—the length of service of which is not known—and although preservation of the tissue was not good, numerous asbestos needles were found in histological sections after micro-incineration at 600° C.

The finding of asbestosis in these donkeys is of interest. Although Heppleston[3] found reticulin fibrosis in the small foci of dust deposits in the lungs of pit ponies from the steam coal mines in South Wales, the examination of the lungs of mules which had worked in the haulage ways of one of the South African gold mines did not show silicotic lesions. A considerable amount of dust, however, had accumulated in the tracheo-bronchial lymph glands.

Baboon. A troop of baboons lives in the hills near one of the crocidolite asbestos mills in the Kuruman area of the north-west part of the Cape Province, and has been seen near the mill on a number of occasions. One of this troop was shot after killing some of the livestock on a neighbouring farm, and the lungs and heart were submitted for examination. Macroscopically the lungs felt firmer than those of a normal laboratory monkey, and on histological examination there were focal areas of interstitial fibrosis associated with asbestos bodies and fibres.

Rattus namaquensis. In furthering the investigation which this Unit is undertaking into the relationship of the inhalation of asbestos dust to the development of malignancy in general and mesothelioma of the pleura in particular, an examination of the rodent population of different areas is being carried out. Twenty-three field rats of this species were trapped around the mill already mentioned and sent to this Unit by a member of the Department of Health. The rats were killed, and the thoracic organs removed. Histological examination of sections from the right lung showed definite evidence of asbestosis in eighteen and probable asbestosis in three rats.

These rodents do not normally move more than 25 yards from their burrows[4]; but it was noticeable that there were far fewer trapped than was expected from the number of nests found. The mortality rate in this colony appears to be high, but this is probably not due to asbestosis.

I thank Messrs. C. G. Coetzee and A. J. Prinsloo of the Department of Health for trapping the smaller animals and for the care taken to preserve the specimens.

Tissue Mast Cells

While examining the histology of tuberculoid and lepromatous skin lesions of leprosy, we noted that there were many cells containing acid-fast granules in the cytoplasm, around the granulomatous collections, in the connective tissue and in relation to small capillaries in both types of the disease. These granules were spherical, and stained somewhat paler red than the acid-fast *Myco. leprae* with the Fite-Faraco modification of Ziehl-Neelsen stain using Harris's hæmatoxylin as counter-stain. These cells were rounded, oval, stellate or spindle-shaped with oval, rounded or bean-shaped nucleus. The cell membrane was indistinct, and in some cells the granules appeared extracellular.

On staining the sections made from the same tissue blocks with Lison's toluidine blue (differentiated and dehydrated with alcohol, cleared in xylol and mounted in balsam), it was found that the above cells corresponded morphologically and in distribution to the mast cells which were prominently shown by the red coloration of the cytoplasmic granules due to their alcohol-fast γ-metachromasia with the dye.

Afterwards, we stained by toluidine blue and Fite-Faraco-hæmatoxylin respectively consecutive sections of various tissues containing fairly large numbers of mast cells, namely, post-kala-azar dermal leishmaniasis, lupus vulgaris, chronic dermatitis of non-specific ætiology, dermatitis herpetiformis, acne vulgaris, lichen planus, adenoma sebaceum, porokeratosis, psoriasis, metastatic carcinoma of the omentum, portal cirrhosis, and mesenteric spreads from guinea pigs. In these conditions most of the mast cells, the distribution of which was demonstrated by toluidine blue stain, showed acid-fast granules in the corresponding sections stained by Fite-Faraco-hæmatoxylin stain.

Morphology, evolution, cytochemistry, functions in health and disease, etc., of the mast cells have been reviewed by Asboe-Hansen[1] and Riley[2]. It is generally agreed that the mast cell granules contain an acidic mucopolysaccharide and substances closely related to hyaluronic acid and heparin. These cells are also believed to contain histamine. The present investigation shows that the granules contain a substance that shows an acid-fast character with the Fite-Faraco stain.

In the course of his work on the early lesions of leprosy, Khanolkar[3] was the first to record the presence of certain cells that showed acid-fast granules (fuchsinophil cells) in sections stained by the Fite-Faraco method. The morphology and distribution of these cells as described by him and illustrated with drawings in colour in his paper appear to be identical with the mast cells seen in our tissue sections. Khanolkar regarded these granules as partly digested *Myco. lepræ* and the cells as adventitial cells or macrophages.

Our observations indicate that these cells are tissue mast cells, the granules of which have now been shown to contain among other substances an acid-fast material and that such mast cells are seen in a wide variety of conditions unrelated to mycobacterial infection.

Utilization of Cell Chromosome Number for diagnosing Cancer Cells in Effusion

THE karyological study of cancer cells has recently been a field of increased interest. While noting that most human cancer cells have abnormal idiograms, the various contributions have been concerned largely with the theoretical nature of cancer and have provided only a minimal amount of clinically useful information[1-5]. Jacob[6] has suggested that malignancy may be diagnosed by chromosome counts. It therefore appears worthwhile to emphasize that determining the approximate number of chromosomes of cells frequently will provide accurate diagnoses of cancer.

In the work reported here 49 effusions from pleural or peritoneal spaces were analysed for chromosomes. The absolute diagnosis in each instance was determined by the patient's hospital course. The cancerous effusions were primarily those with ovarian or uterine tumours, but also included are effusions from patients with cancer of the stomach, lung and breast.

The laboratory technique requires minimal experience. The effusion fluid is slowly centrifuged, and the cell button is resuspended in 0·5 per cent sodium citrate for 20 min, the cells then fixed in 50 per cent acetic acid. The cell suspension is stained with acetic orcein and a drop of fluid then squashed between cover-slip and slide. Using a phase microscope, the preparation is searched for cells and a minimum of 10 cells must be counted.

For the purposes of 'marker' chromosome examination and stem line determination, it is necessary to photograph the better chromosome figures and prepare idiograms. This laborious step is not required if the purpose is only to determine the presence of cancer. Most cancer cells are readily identified because of their abnormal chromosome patterns.

Cancer cell chromosome counts in this work have ranged from 24 to more than 250. The majority have been between 54 and 84. In these human cancer preparations, many different chromosome numbers were found and there was frequent absence of a clear-cut model number (stem line) of chromosomes. Idiogram analysis will often show unusually long acrocentric chromosomes which are apparently associated with cancer.

The fluids were evaluated at the same time with standard cytological techniques for cancer cells. The results are shown in Table 1. In 5 out of 16 examples of benign effusion, inadequate chromosome preparations were found and no diagnosis could be made. In only 2 of the 31 cancerous effusions was this true.

Table 1. DIAGNOSIS OF CANCER CELLS IN EFFUSIONS, USING CHROMOSOMAL AND CYTOLOGICAL TECHNIQUES

Source	Total cases studied	Chromosome study Correct diagnosis	Chromosome study Incorrect diagnosis	Cytological study Correct diagnosis	Cytological study Incorrect diagnosis	Preparations inadequate for chromosome study
Non-cancer effusions	16	11	0	16	0	5
Cancer effusions	33	26	5	31	2	2

Five out of 33 chromosomal preparations of malignant cells were incorrectly diagnosed, either because the tumour had nearly normal chromosome patterns or because poor karyological technique obscured the total number of chromosomes. Fluids from two patients were incorrectly diagnosed as showing 'no malignant cells' by the cytological technique but were correctly diagnosed as cancer by chromosome analysis.

Improved results could be obtained by short-term culture techniques and by more detailed analysis of the cell preparations. But such modifications change a simple technique into an expensive and laborious procedure which can offer no competition for the standard cytological techniques. While a significant number of malignant effusions were called benign, no false positive diagnoses were made.

In addition to adding a simple collaborative technique to the usual cytological procedures, chromosome study has the advantage of contributing knowledge to our understanding of cancer.

This work was supported in part by a grant from the American Cancer Society Institution.

IMMUNOLOGY

A Freezing-thawing Technique for Concentrating Antibodies in Serum

WHEN frozen serum is centrifuged, thawing due to air friction takes place and the heavier molecules are precipitated. By this means it is possible to concentrate the proteins and electrolytes present in serum.

Bovine serum containing *Brucella abortus* agglutinins was placed in 10-ml. amounts in 10-ml. conical centrifuge tubes and the tubes were frozen overnight at −10° C. The tubes were then centrifuged at 3,800 r.p.m. for 30 min at

Table 1

Fraction	1/40	1/80	1/160	1/320	1/640	1/1,280	1/2,560	1/5,120	1/10,240	1/20,480	1/40,960	Sodium content (m.equiv./l.)
						Serum dilutions						
1	++++	+										20
2	++++	++++	++++	+								20
3	++++	++++	++++	++++	++							47
4	++++	++++	++++	++++	++++	++++	++++	++++	++++	++		115
5	++++	++++	++++	++++	++++	++++	++++	++++	++++	++++	+	272
Control	++++	++++	++++	++++	++++	++++	+++	+				136

room temperature. A water clear, supernatant fraction was then removed (Fraction 1) and the remaining portion again frozen overnight at the same temperature. The procedure was repeated on two occasions (Fractions 2 and 3) and a thick viscous layer remained. This fraction was then divided on the basis of colour into an upper light yellow fraction (Fraction 4) and a lower deep amber fraction (Fraction 5).

Fractions obtained from 2 × 10 *ml. quantities of serum:* Fraction 1, 7·2 ml. after 30 min at 3,800 r.p.m.; Fraction 2, 4·2 ml. after 30 min at 3,800 r.p.m.; Fraction 3, 2·0 ml. after 30 min at 3,800 r.p.m.; Fraction 4, 2·4 ml. = upper light yellow layer of sediment; Fraction 5, 1·8 ml. = lower deep amber layer.

The serum fractions were kept at −10° C until used. These and a frozen control serum were allowed to thaw at room temperature and were then well shaken and submitted to a *Brucella abortus* agglutination test. The control serum had been taken from the same batch of serum and had been kept frozen at −10° C for 5 days. The *Brucella* antigen was standard concentrated Weybridge antigen diluted 1 in 10 with normal saline. Twofold dilutions of serum were made starting at 1 in 40. Readings were made after 24-h incubation at 37° C in a hot-air incubator.

An analysis of the sodium content of each fraction and the control serum was carried out using a Beckman flame spectrophotometer. The results are contained in Table 1.

By this method there was approximately an eight-fold increase of agglutinins in the 5th fraction over the control serum. The sodium content was doubled. The length of time chosen for centrifugation was that required to ensure complete thawing of the sample. Rubber liners were used in the centrifuge buckets and these influenced the thawing time.

The rate of thawing and the speed of centrifugation are factors which are likely to influence the rate of precipitation of the molecules, and these factors require further investigation. This technique may have an application in the concentration of toxins.

Type-specific Immunity against Intracerebral Pertussis Infection in Mice

It has been generally assumed that smooth strains of *Bordetella pertussis*, recently isolated from human cases of whooping cough, belong to a single antigenic type[1]. But Andersen[2] showed that these freshly isolated strains may be divided into serologically different types. This heterogeneity of the heat-labile agglutinogens, enabling type-differentiation of strains, has been confirmed by Eldering *et al.*[3], by Lacey[4], and by Preston and Te Punga[5]. All strains possess a common heat-labile agglutinogen which Andersen designated 1; and they may possess also one or more of a series of similarly heat-labile antigens which she numbered 2, 3, 4, 5. Andersen and Bentzon[6] attempted unsuccessfully to demonstrate a relationship between agglutinogen-type of vaccines and their protective potency in mice. But their experiments were handicapped in two ways: first, their strains were of low virulence for mice; and secondly, they were using active immunity, so that specific immunity to each sero-type would be partially masked by cross-immunity due to the common (1) antigen.

However, it seemed to us likely that one or more of these agglutinogens may be concerned with immunity, since there is usually a close correlation between the protective potency of pertussis vaccine and its ability to produce agglutinin in mice[7]. But, like Andersen, we found that strains freshly isolated from children were all of low virulence for mice. In fact, we had only two strains which were virulent for mice, by intra-cerebral injection: the Kendrick strain (*W*.18–323), which is widely used for intra-cerebral challenge, and possesses antigens 1,2,3,4; and a unique strain (353/*Z*), which came to us originally from Dr. Standfast, Lister Institute, and which we had made sufficiently virulent by serial passage in mice—this strain was unique in that it possessed only the common (1) antigen.

We were anxious to attempt cross-immunity experiments with sero-types frequently isolated from children, for example, 1,3; and 1,2,4; but we were unable to enhance the mouse-virulence of these by passage. However, we eventually succeeded in producing a mouse-virulent strain possessing antigens 1,3 by exposing a freshly isolated strain of this sero-type, in log-phase, to each of the following mutagenic agents successively: 5-bromo-uracil (1/250), ultra-violet light, and proflavine (1/35,000). In conjunction with the unique type-1 strain, this type-1,3 strain provided the possibility of determining the importance of the 3 antigen in immunity. Mice were passively immunized with type-specific (absorbed) antiserum containing either 1 or 3 antibody, and then challenged 2 h later with one or other sero-type as shown in Table 1.

Table 1. Passive Protection of Mice with Type-specific (Absorbed) Antiserum containing Either 1 or 3 Antibody

Sero-type of challenge strain	Antibody in serum	No. of deaths/No. challenged Exp. 1	2	3	4	5	Total	(%)
1	(normal serum)	·	12/15	13/15	10/14	8/14	43/58	(74)
	1	0/14	1/15	1/14	4/15	2/14	8/72	(11)
	3	14/14	5/14	8/15	8/15	8/14	43/72	(60)
1,3	(normal serum)	·	13/15	7/15	10/15	7/14	37/59	(63)
	1	2/14	15/15	3/15	3/14	3/14	26/72	(36)
	3	5/14	3/15	2/14	7/15	1/14	18/72	(25)

It is clear that 1 antibody gave significant protection against challenge by the type-1 strain, whereas 3 antibody did not. Conversely, both 1 antibody and 3 antibody protected significantly against the type-1,3 strain. (The mortality in mice which were pre-treated with normal serum was not significantly different from that in untreated mice; the challenge inoculum was deliberately chosen to give a mortality of 60–70 per cent so as to provide the greatest chance of detecting significant protection.)

While these immunity experiments were being performed, we succeeded in producing a mouse-virulent mutant from a type-1,2,4 strain. This was compared with the type-1,3 strain in a similar series of passive immunity experiments, the results of which are shown in Table 2.

Clearly, both 1 antibody and 3 antibody significantly reduced the mortality from challenge with the type-1,3 strain, whereas 2,4 antibodies did not. Conversely, both 1 antibody and 2,4 antibodies protected significantly against the type-1,2,4 strain, whereas 3 antibody did not.

It is evident from Tables 1 and 2 that, although there is cross-immunity between pertussis sero-types because of the common (1) antibody, there is also type-specific immunity determined by the type-specific (2,3,4) antibodies.

Table 2. Passive Protection of Mice with Type-specific (Absorbed) Antiserum containing Either 1 or 3 or 2,4 Antibodies

Sero-type of challenge strain	Antibody in serum	No. of deaths/No. challenged Exp. 1	2	3	4	5	Total	(%)
	(normal serum)	·	13/15	7/15	10/15	7/14	37/59	(63)
1,3	1	2/14	15/15	3/15	3/14	3/14	26/72	(36)
	2, 4	6/14	10/15	9/15	11/14	6/14	42/72	(58)
	3	5/14	3/15	2/14	7/15	1/14	18/72	(25)
	(normal serum)	·	·	9/14	10/15	8/14	27/43	(63)
1,2,4	1	·	·	1/12	0/15	2/14	3/41	(7)
	2, 4	·	·	6/14	4/14	6/14	16/42	(38)
	3	·	·	5/15	12/15	8/14	25/44	(57)

Considering the possible application of these findings to immunity in children, we direct attention to the fact that unabsorbed immune sera may contain much higher levels of type-specific antibody than of common (1) antibody[5,9]. A child immunized with type-1,2,4 strains may therefore develop very little immunity to type-1,3 infection. This may possibly account for the increase in the proportion of type-1,3 strains isolated in recent years[4,9]. Moreover, type-specific immunity may account for the different potencies of a single vaccine used in different localities[7], depending on the sero-type of the local epidemic strain.

RADIOBIOLOGY

Irradiation of Fruit and Simultaneous Measurement of Respiration

Fruit has often been irradiated for the purpose of examining the extension of storage life through control of infective organisms[1,2]. Fruit tissues, however, also lend themselves for studies in radiobiology; especially when high dose-levels are desirable to accentuate the primary cellular responses. Doses several orders of magnitude higher than those normally found to be lethal to animal systems can be tolerated by the fruit tissues, albeit with consequent manifestations of an altered metabolism.

The respiratory rate of the whole fruit serves as a measure of the metabolic response induced by irradiation. Limitations in the physical facilities have often necessitated a delay in the respiration measurements to various times after the exposure[3]. This may not only result in a misleading estimate of radiation response but also impose a severe limitation in studies of radiobiology where the critical need is to assess the initial radiation effect[4].

A recently installed 32,000-c. cobalt-60 facility designed by the U.S. Atomic Energy Commission to deliver a uniform dose of radiation under controlled temperature conditions has been adapted for the simultaneous measurement of respiration during the exposure period. This is achieved by attaching twelve air lines to a water-tight chamber into which the samples are placed to be lowered into the irradiation field. Air in-flow and return lines may then be attached to six containers of fruit and the respiratory rate followed with the standard Claypool–Keefer[5] technique. Temperature is normally maintained at 20° C, before, during, and after irradiation. Dose distribution as measured with Fricke dosimeters was found to be within ± 10 per cent with a dose rate of 295,000 rads per hour.

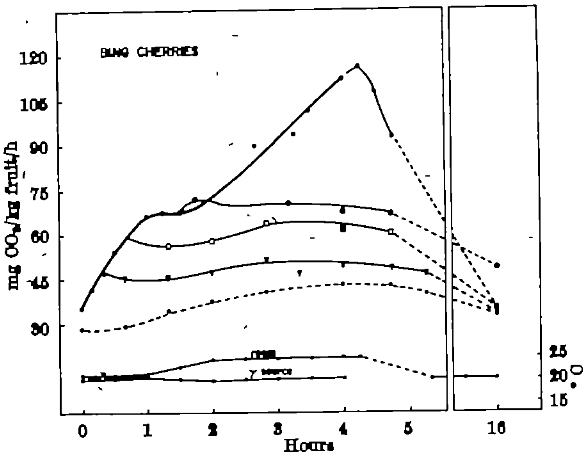

Fig. 1. Respiration of cherries during and immediately after irradiation. Simultaneous radiation and respiration period is indicated by the bold trace. ● - - - ●, Control; ▽ —— ▽, 100,000 rads; □ —— □, 200,000 rads; ○ —— ○, 500,000 rads; ● —— ●, 1,000,000 rads

An example of fruit respiration during irradiation is that elicited from Bing cherries as indicated by the bold trace in Fig. 1. The respiration rate rises with increasing dose excepting a plateau area near 500,000 rads. It is of interest to note that fruit receiving doses above the plateau-level decrease faster in post-irradiation respiration in contrast to the fruit receiving lower doses. Similar responses have been observed for oranges and lemons but with differing transition or 'plateau'-levels of irradiation. As a possible explanation of this effect one may assume that the higher doses cause irreparable damage to the respiratory mechanism, whereas at lower doses the resultant stress elicits a continued, elevated respiration commensurate with repair reactions. Experiments now in progress are directed towards the discernment of some of the intracellular changes which underlie this metabolic response.

The research is supported by the U.S. Atomic Energy Commission, contract No. AT(11–1)–34.

Increase of Strontium-90 and Caesium-137 in Japanese Leafy Vegetables due to the Russian Nuclear Tests, 1961

Fall-out radioactivity derived from tropospheric origin was detected soon after the Russian nuclear tests of September and October, 1961, in the northern hemisphere. Contamination of milk and fresh vegetables by short-lived radionuclides such as iodine-131, zirconium-95 and ruthenium-103 was reported in Japan[1].

In the case of strontium-90 and caesium-137 also, fresh leafy vegetables are fairly sensitive to reflect a change of contamination-level because of their direct foliar uptake of radionuclides besides root absorption from soil. Spinach, cabbage, hakusai (Chinese cabbage) and some other kinds of leafy vegetables were sampled from about ten locations widespread over the country in May–June (before resumption of tests) during October in 1961, January and March in 1962. These samples were analysed for strontium-90 and caesium-137 by the fuming nitric acid separation method and dipicrylamine–caesium chloroplatinate method respectively.

Table 1. STRONTIUM-90 AND CAESIUM-137 CONTENT OF JAPANESE LEAFY VEGETABLES DURING MAY 1961–MARCH 1962 (pc./kg FRESH WEIGHT)

Sample	^{90}Sr (pc./kg) May–June 1961	Oct. 1961	Jan. 1962	Mar. 1962	^{137}Cs (pc./kg) May–June 1961	Oct. 1961	Jan. 1962	Mar. 1962

	16		102	57	58		138	25
	8		97	229	30		132	155
			90	72			126	42
Miscellaneous		41	93	54		34	70	33
		46	87	128		48	39	67
				123				37
Average	24	32	71	99	41	44	92	70

Results obtained are shown in Table 1. May–June samples in 1961 can serve as a background-level of contamination before resumption of nuclear tests in the autumn of 1961. As a rule, strontium-90 content of leafy vegetables shows considerable variation in most cases reported so far[2]. This seems to be caused by the variability of morphology, physiological conditions and environmental factors such as soil character, climate and fall-out pattern. As seen in Table 1, strontium-90 content of the May–June sample in 1961 shows fairly narrow range of about 5–20 pc./kg fresh weight except one, probably because of low strontium-90 fall-out rate during winter and spring in 1961. The October 1961 sample taken just after the resumption of nuclear tests by the U.S.S.R. shows fairly higher value and wider range of strontium-90 content (10–60 pc./kg fresh weight) than the sample in May–June caused by a sudden increase of strontium-90 fall-out in October 1961. In 1962 also, the similar tendency of increase is observed in January sample (10–110 pc./kg fresh weight) and March sample (40–230 pc./kg). Range of strontium-90 contamination-level becomes progressively larger and much higher values can be found more frequently than in 1961. Cæsium-137 content of fresh leafy vegetables in October 1961 does not seem to differ from that in May–June significantly. But, in January and March 1962, the level of cæsium-137 contamination of the sample had markedly increased when compared with that of the preceding year (Table 1). These significant increases of strontium-90 and cæsium-137 in fresh leafy vegetables should be due to the addition of the recent fall-out radioactivity which has produced direct contamination of the aerial part of these plants besides the accumulated deposition of strontium-90 and cæsium-137 in soil.

We thank members of the Prefectural Hygienic Laboratory for their help in sampling.

BIOLOGY

Protection of the Skin Homografts by ε-Acetamide Caproic Acid

ε-AMINOCAPROIC acid has recently attracted a great deal of interest, mainly for its marked antifibrinolytic activity: it seems that it acts as an inhibitor of the transformation of profibrinolysin into fibrinolysin, or as an antagonist of the latter[1-3].

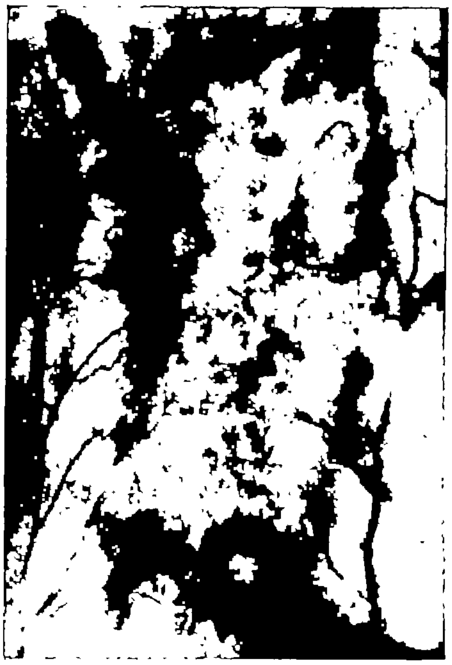

Fig. 1 Homotransplant in the seventh day in untreated control rat. Areas of diffuse necrosis and no vascularization are present in the graft

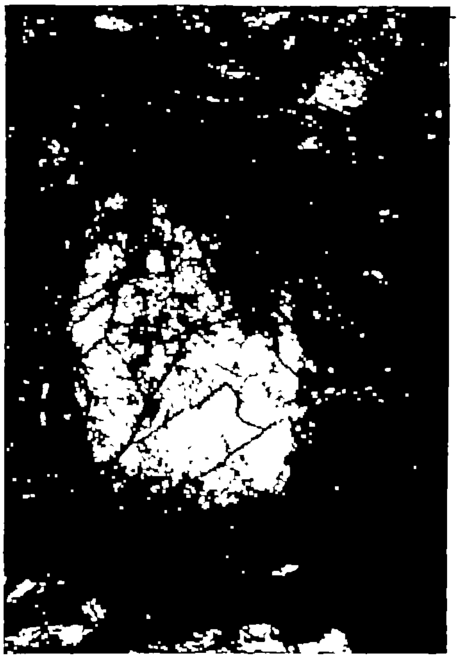

Fig. 2. Homotransplant in the fourteenth day in rat treated with ε-acetamide caproic acid. Diffused vascularization is evident and no necrosis appears

It has been shown here that ε-aminocaproic acid can prevent anaphylactic shock in the guinea pig[4], œdema from dextran, egg albumin and kaolin, agar granuloma and histamine wheals in the rat[5] and, in a particularly striking manner, the Sanarelli–Schwartzmann reaction in the rabbit[6].

One of us has been interested for some time in the problem of grafts, and especially of skin grafts, in the rat[7].

The technique used for such grafts, which is now well standardized, is as follows: careful depilation of the abdomen surface of the rat (female rats Sprague–Dawley strain, weighing about 250 g, of homogeneous strain, bred in this Institute, fed on standard diet); a rectangle of skin of full thickness measuring 2·5 × 2 cm is removed; this is substituted with another skin rectangle of identical dimensions removed from the same or from another animal. The extremities of the transplanted skin are sewn with silk No. 00. Some extra thread is left at the four angles; these threads are knotted together above a cotton wool pad, damped with physiological solution, which compresses the transplant.

The operated area is protected by raising two folds of skin from the sides and by sewing the edges with silk No. 2.

The rats are narcotized with 'Nembutal' (25 mg/kg 'Nembutal' intraperitoneally). The protecting cover may be opened whenever an inspection of the transplant is desirable.

With such a technique the homotransplants are rejected in about 6–7 days.

Practically all the autotransplants survived very well.

Different groups of rats bearing skin homografts are treated with ε-acetamide caproic acid intraperitoneally, repeating the administration twice a day. The doses were progressively increased. The starting dose was 300 mg/kg, with a daily increase of 100 mg/kg, until a final dose of 1·5 g/kg/day is reached. The animals do not seem to suffer at all for this treatment and show no signs of being inconvenienced by the drug; in any event, the quantity administered is 10 times lower than the LD_{50}.

The results are very evident: the homotransplants were observed until the 14th day and appeared healthy. The skin has a pale pink colour, soft and elastic under pressure; the adherence of the extremities is also excellent.

The veins of the homotransplant were observed after administration of China-ink in a femoral vein, and much better vascularization was observed than that of the homotransplant of a control not treated at the 6th or at the 7th day, when it was practically eliminated.

Similar results, although less striking, are obtained when ε-aminocaproic acid is used instead of ε-acetamide caproic acid.

The effects of ε-acetamide caproic acid and ε-aminocaproic acid on homotransplants of kidneys of the dog are now being investigated.

Influence of the B Blood Group-histocompatibility Locus in Chickens on a Graft-versus-Host Reaction

PRODUCTION of nodular lesions on the chorioallantoic membrane of chick embryos after inoculation with adult fowl leucocytes has been described by Boyer[1]. These lesions, appearing as raised yellow or white foci, are considered to arise from the interaction of donor lymphocytes with foreign antigenic determinants present in the tissues of the embryonic host. The number of foci produced depends on the number of large lymphocytes in the inoculum[2] although immunization of the donor with embryonic tissue does not enhance the ability to produce foci[3]. Two independent experiments with inbred lines indicated that single gene differences between donor and host could account for chorioallantoic membrane foci production[4] as well as splenomegaly[5].

Skin-graft investigations reported from this laboratory have shown that the B blood group locus is also a major histocompatibility locus[6]. The experiment reported here was designed to determine if the B locus controls chorioallantoic membrane foci production, and if so, to make a quantitative study of its effect. Peripheral blood leucocytes from mature birds of White Leghorn inbreds (line *G*) were deposited on the chorioallantoic membrane of 14-day line *G* embryos. The technique used was similar to that described by Burnet and Boyer[7]. The inoculation consisted of 0·1 ml. of a leucocyte suspension prepared by resuspending the buffy layer of donor blood in Hanks's balanced salt solution to give a concentration of approximately $3·5 \times 10^4$ leucocytes per mm.^{3}. After four days, counts were made of the number of chorioallantoic membrane foci produced. The embryos and adult leucocyte donors had blood-group genotypes designated B^1/B^1, B^2/B^2 and B^1/B^2 so that nine donor-host combinations were used. 77 embryos from 13 hens were tested with leucocytes from eight donors. The results indicate that production of chorioallantoic membrane foci is due principally to B locus incompatibility, that is, when the embryo has a B allele (thus antigen) not also represented in the leucocyte donor. Membranes from the four B-incompatible combinations yielded an average of 65 foci. These foci were opaque and large enough to be easily recognized macroscopically. No foci of this nature were observed when donor and host were B-compatible. On close inspection, however, a number of the membranes were found to contain some small and relatively translucent lesions, presumably due to 'weak' histocompatibility antigens controlled by genes at other loci.

Further evidence for B locus control of the graft-versus-host reaction was shown by marked splenic enlargement in the B-incompatible embryos. Spleens from 10 B-compatible embryos averaged 17·6 mg compared with an average of 33·8 mg for 10 B-incompatible embryos.

The second part of the experiment was carried out by using host embryos of the same B genotypes as before (B^1/B^1, B^2/B^2 and B^1/B^2), but with two adult leucocyte donors from line *G* previously blood typed as B^3/B^3. A total of 220 membranes were examined in five replicates. All membranes exhibited the nodular foci previously described, although some low foci counts were observed in two of the five replicates. The mean foci count for B^1/B^1, B^2/B^2 and B^1/B^2 embryos was 69, 66 and 90, respectively. Mean differences due to host genotype proved to be statistically significant at the 0·05 level of probability.

An additional comparison of foci counts from 53 embryos produced by five hens is of interest. By shifting males in the breeding pens, embryos of the B^1/B^1 genotype were produced in one replicate and B^1/B^2 genotype in another. Mean foci counts (Table 1) for embryos of Dam group *a* (two hens) and Dam group *b* (three hens) appeared to be dependent on the B genotype being produced. Within each replicate the B^1/B^2 membranes yielded a considerably higher number of foci than the B^1/B^1 membranes. This difference is statistically significant at $P < 0·01$ for each donor.

Table 1. AVERAGE NUMBER OF CHORIOALLANTOIC MEMBRANE FOCI FOR B^1/B^1 AND B^1/B^2 HOST EMBRYOS OF THE SAME DAMS WITH B^3/B^3 LEUCOCYTE DONORS

	Host genotype B^1/B^1			Host genotype B^1/B^2		
	Dam group	Donor 1	Donor 2	Dam group	Donor 1	Donor 2
Replicate 1	*a*	65	113	*b*	149	175
Replicate 2	*b*	74	68	*a*	147	100

A possible explanation for the greater number of foci on B^1/B^2 membranes, following an 'elective' theory of antibody formation, is that the leucocyte inoculum from the B^3/B^3 donors contained immunologically competent cells with preformed patterns, some corresponding to B_1 and others to B_2 antigenic determinants of the chick embryo. An 'instructive' or template theory interpretation must, on the other hand, presume that the B^1/B^2 host antigens, being more foreign, stimulate proliferation of a greater number of donor cells which are analogous to each other. Further studies with chick embryos of known genetic constitution may provide evidence to support or invalidate certain assumptions basic to the two opposing theories.

Effect of Certain Environments on the Carapace of the Freshwater Ostracod *Cypridopsis vidua* (Müller)

A FREQUENTLY occurring problem in quantitative palæontology concerns the effect of environment on the shell of an organism. In an attempt to elucidate a micropalæontological aspect of this question the effects on the carapace dimensions of *C. vidua* of the two environmental types 'lime-rich, freshwater' and 'stagnant, freshwater' were investigated by laboratory experiments, backed up by biometrical analysis. As a standard of reference observations were also made on a population kept under 'normal' conditions.

The original material of the parthenogenetic species *C. vidua* was obtained from Lake Rönningen, Parish of Täby, Uppland, Sweden, on August 7, 1958. Throughout the experiments *p*H and redox potential were controlled with a Beckman *p*H-meter (model *N*). The investigations were based on the dimensions—length, height and breadth of carapace.

The calcium carbonate of the shell of *C. vidua* is composed of calcite[1]. A chemical analysis made by F. Manheim and B. Brännström of the inorganic residue of the shells from the three environments is given in Table 1.

Table 1

Environment	$CaCO_3$	$MgCO_3$	Undetermined
Normal	89%	6%	5%
Stagnant	76%	7%	17%
Lime-rich	82%	10%	8%

An appreciable difference in the relative variability for the three dimensions for the samples from each of the environments could be established. This is here indicated by the coefficients of variation for adult carapaces (Table 2).

Table 2. COEFFICIENTS OF VARIATION FOR ADULT CARAPACES

Environment	No. in sample	Length	Height	Breadth
Normal	365	2·94 ± 0·11	4·94 ± 0·18	6·02 ± 0·22
Stagnant	308	3·78 ± 0·24	5·28 ± 0·21	5·89 ± 0·24
Lime-rich	581	6·93 ± 0·21	8·06 ± 0·24	11·32 ± 0·34

These results suggest the possibility of heterogeneity in the respective variances. This could be confirmed by *F*-tests for pairs of samples and by subjecting the trivariate covariance matrices of the adult samples and the samples of the final larval stage to a multivariate test for homogeneity of covariance matrices. The highly significant value of $\chi^2 = 1{,}128{\cdot}22$ does not support the hypothesis of equal covariance matrices. Hence, the carapace–morphologic covariance matrix of ostracoods would seem to be sensitive to environmental factors.

Highly significant *t*-values for the differences in means between the respective growth-stages of the stagnant and normal environments and the lime-rich and normal environments could be shown. The differences in means between the corresponding growth-stages of the stagnant and lime-rich environments do not give significant values. Nor are the multivariate T^2-values for differences in the mean vectors of these samples significantly different. This suggests the interpretation that the freshwater species *C. vidua* is morphologically equally affected by both an excessive calcium content in its environment as well as excessively stagnant conditions. This is expressed by a significant decrease in the carapace dimensions. (However, the 'saturation density' for the populations living in the lime-rich environment was found to be three times that for the stagnant environment.)

A reflexion of the variability in magnitude of the elements of the carapace-morphological covariance matrix is provided by the results of the principal component analysis. This discloses that there is but slight stability in the components of eigenvectors for the samples of the stages of growth from the three environments. The study suggests that not only the first principal components of a carapace–morphological covariance matrix for ostracoods is representative of the influence of environment on size, but also that in some way or other the second principal component is also correlated with environment.

The morphological closeness of the samples from the lime-rich and stagnant environments, compared with the samples from the normal environment, could be well brought out by canonical analysis of the entire data and by a generalized distance study.

The complete investigation by R. A. Reyment and B. Brännström is to be published in *Stockholm Contributions in Geology* (9, Pt. 5). The work was partially supported by a grant from the Swedish Natural Science Research Council; free computer time was made available by the Swedish Board for Computing Machinery.

Abbreviated Pelagic Life of Chilean and New Zealand Oysters

OYSTERS of the genus *Ostrea* incubate their larvæ. In *O. edulis*, for example, veligers are released from the female when 0·15–0·17 mm long, and afterwards undergo pelagic development, usually of 6–14 days, according to water temperature and food supply, before settling and metamorphosing[1-3]. In *O. chilensis* Philippi from Chile, however, larvæ from incubating females collected by the Lund University Chile Expedition 1948–49 were examined by one of us (R. H. M.), through the courtesy of Dr. T. Soot-Ryen and Prof. H. Brattstrøm, and were found to be 0·45–0·49 mm long and to possess the eye spots and foot which other species develop only at the end of their pelagic life. The other (P. J. H.), who is publishing elsewhere a fuller account of the life-history of the New Zealand mud oyster, *O. lutaria* Hutton, has observed similar larvæ in that species. These larvæ, when released by the female in laboratory experiments, settled almost immediately. In both species this probably also happens in Nature.

Elimination of the usually wasteful pelagic phase is biologically useful, particularly in the low temperature and strong-tidal currents of areas like Foveaux Strait, New Zealand, where large oyster beds exist.

The introduction of the New Zealand species to Britain could be commercially important, as it might breed more successfully than *O. edulis* and certainly does so at lower temperatures. Repopulation may even be possible of the exhausted Scottish beds, such as those in the Firth of Forth, where formerly there may have been a local race of *O. edulis* adapted to breeding at relatively low temperatures. Experiments, including laboratory breeding, are in progress at the Marine Station, Millport with oysters flown from New Zealand, to test this possibility. Precautions are being taken to avoid the introduction of associated organisms.

Relation of Arbutin–Hydroquinone in Pear Blossoms to Invasion by E. *amylovora*

Infection of plants by certain virus and fungus pathogens results in an increase in polyphenol synthesis and oxidation[1,2]. This has been interpreted as a possible defence reaction by host tissue. Investigations of resistance of specific varieties of pear, *Pyrus communis*, to invasion by *Venturia pirina* indicated that polyphenol metabolism might be associated with resistance[2]. A project was initiated to determine whether the location and concentration of phenolic substances in pear might be of possible significance in influencing the channels of infection and relative susceptibility of specific pear tissues to fire blight caused by *Erwinia amylovora*. The relation of the arbutin–hydroquinone complex in pear blossoms to invasion by the fire blight organism is herein reported.

Aqueous extracts of pear tissues were highly toxic to *E. amylovora*. A substance inhibitory to *E. amylovora* on bioassay plates was purified by extracting aqueous extracts with ether. The ether residues were extracted with benzene, and the benzene residues sublimed at 173° C. Final identification of the purified substance on the basis of an infra-red analysis showed it to be hydroquinone, which is toxic presumably as a semi-quinone. Hydroquinone occurs in pear principally in the form of the glucoside arbutin, which is readily hydrolysed into hydroquinone and glucose by a β-glucosidase on injury to the tissue. Chromatograms of aqueous extracts were made according to Kirkham's method[3] to determine whether other phenolic materials were present in concentrations toxic to *E. amylovora*. Strips were cut from the chromatograms and bioassayed using *E. amylovora* as the test organism. Inhibition zones were formed only at the region corresponding with the R_F value of hydroquinone.

Blossoms of *P. communis* were collected shortly after opening and tested for antibiotic activity. The stamens and petals were removed and longitudinal sections 100–150μ thick cut from the median part of the blossoms. These sections were bioassayed on potato–dextrose–peptone agar seeded with a standardized suspension of *E. amylovora*. Also bioassayed were pieces of tissue approximately equal in size cut from both the nectarial region and the exterior region of the receptacle. After cutting, all tissues were frozen for 10 min, placed on seeded bioassay plates, and incubated at 28° C for 24 h. Antibiotic activity was measured by the width of the inhibition zone adjacent to the tissue.

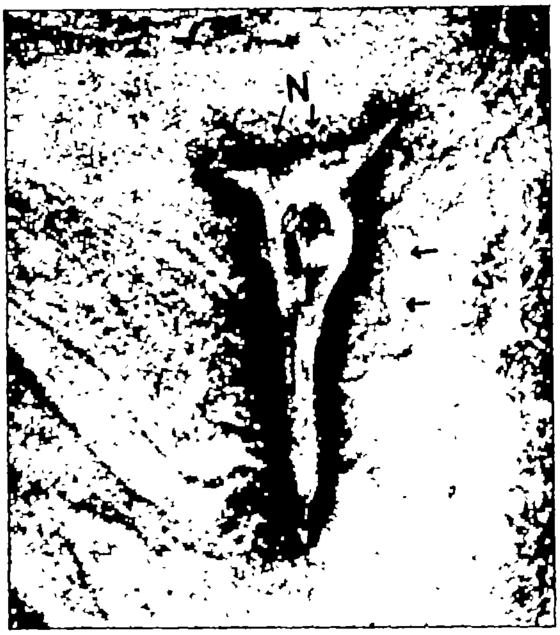

Fig. 1. Bioassay of a median longitudinal section of a pear blossom on agar seeded with *E. amylovora* showing the broad zone of inhibition except around the nectarial region (*N*). Arrows designate points of measurement used in preparing Table 1

The bioassay of the longitudinal sections of the blossom showed that the zone of inhibition was much narrower around the nectarial region than around other parts of the blossom (Fig. 1, Table 1). Often no zone could be detected around the nectarial region. The bioassay of equal-sized tissue segments cut from the nectarial and the exterior tissues of the receptacle gave results similar to those using longitudinal sections; slight or no zones of inhibition were detected around nectarial tissue pieces, whereas broad zones surrounded the exterior tissues. A chromatographic comparison of the arbutin concentration in nectarial and exterior tissues was made to determine whether antibotic activity was related to differences in arbutin concentration. No significant difference in arbutin concentration was noted. This suggests that antibiotic activity may be a function of the distribution and activity of the enzyme, β-glucosidase, rather than differences in the amount of arbutin.

Although many other natural openings occur on the blossom, *E. amylovora* usually enters through the nectaries. Here invasion and infection is so rapid that often the entrance of the organism through other natural openings is obscured[4]. This correlates with the findings that antibiotic activity is lower in nectarial tissue than in other exterior tissues. It is suggested that the arbutin–hydroquinone complex may be one of the factors which influences the progress of invasion and infection.

Table 1. INHIBITION ZONES AROUND THE NECTARIAL REGION AS COMPARED WITH THE EXTERIOR OF THE RECEPTACLE OF MEDIAN LONGITUDINAL BLOSSOM SECTIONS FROM THREE VARIETIES OF PEAR BIOASSAYED ON AGAR SEEDED WITH *E. amylovora*

Variety	Nectarial region	Receptacle exterior
D'Anjou	0·1 mm*	0·5 mm
Bartlett	0·2	0·6
Hardy	0·1	0·7

* Each value is the mean for six replications. Zones were measured at largest and smallest points and averaged. Points of measurements are indicated by arrows in Fig. 1. Mean differences are all significant at the 1 per cent level.

Effect of Didecyldimethylammonium Bromide against Powdery Mildews and other Fungal Plant Diseases

CATIONIC surface-active agents are widely used as bactericides, and in recent years have been applied against a number of fungi of medical importance[1]. Certain agents of this type have been included in investigations at this Station of chemicals of potential value for the control of fruit diseases, especially apple mildew, *Podosphaera leucotricha* (Ell. and Ev.) Salm. Among these, didecyldimethylammonium bromide (DDAB) was outstanding both for wetting of foliage and for disease control. In all experiments, it was used as the commercial 50 per cent liquid preparation that is already widely used in the food and beverage industries, but concentrations quoted here are in terms of active ingredient for all materials.

Using a settling-tower procedure for inoculation of apple rootstocks with powdery mildew[2], we have found that protection of young foliage against this disease is related to the wetting power of the cationic surface-active agent used. Thus the well-known agent, cetrimide (cetyl tetradecyl trimethylammonium bromide), at 0·025 per cent, wets apple rootstock foliage only moderately and gives little protection against mildew. DDAB, at the same concentration, wets such foliage extremely well and provides a high level of protection against this disease.

In a comparison of DDAB with the phenolic material DNOP, obtained by hydrolysis of crude dinocap extracted from the American commercial wettable powder, DDAB was intrinsically inferior as a protective agent. However, the curative (post-infection) control given by 0·025 per cent DDAB applied 5 days after inoculation was virtually complete.

Experiments late in the season with heavily infected rootstocks have shown that one application at 0·05 per cent was sufficient to eliminate visible signs of sporulating mycelium for more than two weeks.

In the field a programme of DDAB at 0·05 per cent applied at intervals of 10–14 days until the end of June to Cox's Orange Pippin trees gave significantly ($P < 0{\cdot}01$) better control of apple mildew, as judged by secondary infections recorded in August, than one of captan plus dinocap, but produced more russet-blemish on some of the fruits.

With the settling-tower technique on potted seedlings of barley, var. Plumage Archer[2], more than 90 per cent control of mildew, *Erysiphe graminis* DC, was given without damage by protective applications of DDAB at 0·05 per cent, dinocap at 0·005 per cent, and the organophosphorus fungicide, 'W.P. 155', at 0·02 per cent.

In glasshouse tests, DDAB gave superior control of strawberry mildew, *Sphaerotheca macularis* (Wallr. ex Fries) Jaczewski, to that given by DNOP, dinocap, cetrimide, lime-sulphur, or actidione oxime. But in a late-season, small-scale field trial on the variety Cambridge Rearguard, lime-sulphur and dinocap gave more lasting control.

As sprays for control of apple mildew are usually combined with those for control of apple scab, experiments were also begun with DDAB for control of this disease. In a glass-slide test with conidia of *V. inaequalis* (Cke.) Wint., germination was inhibited almost to the same extent as by captan at the same concentrations. In a test of curative action in the glasshouse on potted MM. 109 apple rootstocks sprayed with various concentrations of DDAB 24 h after an optimal period for infection had been given, control at 0·05 per cent was fully comparable with that to be expected from 0·0015 per cent mercury as phenylmercuric chloride (PMC).

Of the compounds examined by a glasshouse technique developed for examining the action of fungicides on sporulating lesions of *Gloeosporium perennans* Zeller and Childs, DDAB has shown great promise, and at 0·05 per cent was almost equal to 0·1 per cent PMC in suppressing spore production. The field trial on apples already mentioned is designed to give evidence of field performance against mildew, scab and *Gloeosporium*.

There was no indication that DDAB damaged apple foliage in the field, and in glasshouse tests on rootstocks concentrations up to 0·2 per cent were safe; the problem raised by the russeting of apple fruits will be examined further, in view of the apparent promise of DDAB (and perhaps of related compounds) as a field fungicide.

A Nematotoxin produced by the Nematophagous Fungus *Arthrobotrys oligospora* Fresenius

THE nematopagous fungus, *Arthrobotrys oligospora* Fres., captures nematodes by means of adhesive hyphal networks. When a nematode has been snared, the fungus pierces the animal's integument and produces a bulbous structure from which trophic hyphae grow throughout the body of the worm. Drechsler[1] attributes the death of the nematode to the partial severance of its body by the infection bulb of the fungus. This view is not shared by Shepherd[2], who found that the captured nematode becomes inactive before the infection bulb has completely developed. Duddington[3] supports Shepherd's view and suggests that a toxin, capable of paralysing or killing, may be secreted by the adhesive trapping organs and act externally, or that such a substance may be transported internally by way of the fine penetration peg through the nematode cuticle. Soprunov and Galiulina[4] claim to have detected a secretion by a hyphal network-forming species which paralyses nematodes.

In view of the conflicting reports and opinions regarding the actual cause of death of the captured nematode, it was decided to investigate this aspect of the nematode host–fungus parasite relationship.

The fungus, *A. oligospora*, was cultured in a 0·3 per cent yeast-extract amended Czapek's broth at 26° C. Seitz filtered, sterile extracts of this fungus had no apparent effect on the vitality of nematodes of *Rhabditis* sp. when they were immersed in the filtrate for periods up to 24 h. Sterile filtrates from crushed nematodes also had no adverse effect on living nematodes which were immersed in various concentrations of them for similar periods. But, when living nematodes were placed in a filtrate obtained from crushed nematodes which had been parasitized by the fungus, many of them became inactive and appeared to have been killed by some substance in the filtrate. After transferring the inactivated nematodes to tap-water a number of them revived.

In repetitions of the experiment it was found that about 30 per cent of the nematodes became inactive during a 2-h period of immersion in filtrates from fungus-parasitized nematodes and that practically all of these revived when placed in tap-water. If the nematodes were in the filtrate for 12–24 h, approximately half of them became inactive, and about 30 per cent of these were found to have died. They did not revive when placed in tap-water.

Since the osmotic pressure of the lethal filtrate was far below levels known adversely to affect nematodes[5], it is postulated that the extract contained a nematotoxic substance. It is assumed that the fungus secretes a chemical substance which paralyses or kills nematodes after they are caught by its adhesive trapping organs, because only the filtrates from fungus-parasitized nematodes contained the nematode-inactivating substance. The relatively low toxicity of the filtrates may be attributed to dilution effects. This, apparently nematotoxic, substance is probably an unstable chemical compound because a nematode population in a Petri dish culture with *A. oligospora* will usually build up again soon after the natural decline of the nematophagous activity of the fungus.

Isolation and Maintenance of Single Spore Lines of *Peronospora tabacina* (Adam.)

While germination of conidia of the obligate parasite *Peronospora tabacina* Adam. has been effected on tobacco leaf disks[1,2], it has not previously been possible to complete the life cycle of the fungus on such disks, because of their rapid deterioration. Sporulation investigations have been possible only by taking disks from leaves which had been infected previously and in which mycelium was well established[3]. Izard[4] has described a method for the growth of *P. tabacina* on leaves and leaf disks in the laboratory, but in our experience this method has been unsuccessful with the Australian varieties of host and pathogen. Accordingly, we have devised the following technique.

Following the report by Richmond and Lang[5] on the effect of kinetin on the survival of detached leaves of *Xanthium pennsylvanicum*, leaf disks (15 mm diam.) from *Nicotiana tabacum* cv. Virginia Gold were floated, ventral side uppermost, on an aqueous solution of 1 μg/ml. kinetin. On this medium, the disks remain green and apparently healthy for approximately three weeks in the absence of infection. When kinetin is omitted from the medium, the disks show discoloration and yellowing after 5–7 days. Approximately 2×10^8 conidia of *P. tabacina* were applied in a drop of water to the centre of each disk. The disks were then incubated at 20° C under 800 ft.-candles of fluorescent illumination and a daily light regime of 16 h light and 8 h darkness.

Some necrosis occurs under the drop of conidial suspension after 2 days incubation and this afterwards extends over the leaf disk surface in an irregular manner. This necrotic reaction does not occur on control disks under a water droplet and in the absence of conidia. Sporulation occurs after 6–7 days, the number of conidiophores produced increasing to a maximum over a period of 2–3 days from their first appearance. The conidiophores appear to be confined to the green portions of the disk and have not been observed to emerge from the necrotic areas.

After 7, 8 and 9 days incubation at 20° C the average number of conidiophores produced per leaf disk was 5·6, 20·9 and 49·6 respectively (averaged over 48 disks). After incubation of a similar number of disks for 9 days at 15° C and 25° C, the average number of conidiophores per disk was 0·3 and 19·0 respectively.

When 2 μg/ml. each of *p*-aminobenzoic and nicotinic acids were added to the kinetin solution, the number of conidiophores finally produced was approximately double that occurring when these vitamins were omitted.

The infection of disks from single spores was achieved following the isolation of single conidia on agar, using a De La Rue cutter. The percentage of successful 'takes' was increased from 21 per cent to about 50 per cent when such spores were applied to leaf disks in a drop of the complete medium described by Shepherd and Mandryk[6]. Clones, isolated in this manner, have been passaged three times successfully, but some loss of viability of the organism as measured by a reduction in the number of conidiophores produced appears to occur during such serial passage on to leaf disks. This difficulty has been overcome by transferring the first leaf disk infected by the original single spore isolate to the ventral side of a tobacco leaf. If the disk is attached closely to the leaf surface by means of a thin layer of 1 per cent Difco 'Bacto' agar, the mycelium from the disk grows readily into the leaf and abundant sporulation occurs afterwards on the leaf surface. Alternatively, the first crop of conidia produced on a leaf disk following single spore isolation may be used to inoculate tobacco seedlings grown in sterile culture according to Steinberg[7].

This technique allows the ready isolation and maintenance of clonal lines of the pathogen. It opens the way to studies on the occurrence of physiological strains and to the possible isolation of biochemical mutants of this organism.

MICROBIOLOGY

Lysogeny in *Providence* Strains and the Host-range of *Providence* Bacteriophages

Biochemically *Providence* strains are closely related to *Proteus* organisms, especially *P. rettgeri*, and on these grounds the name *Proteus inconstans* has been suggested for them[1]. The guanidine + cytosine content of *Providence* strains is very similar to those of *P. hauseri* and *P. rettgeri*[2], and recently it was found that many *Proteus* (especially *rettgeri*) phages productively lyse *Providence* strains[3]. It was decided to investigate the reciprocal relationships, that is, to test phages primarily isolated on *Providence* strains for action on *Proteus* organisms. Media used were those previously used[4]. Thirty-seven *Providence* cultures comprising 25 different serological groups were used. They are all National Collection of Type Culture strains and were kindly supplied by Miss Shona Wright of the Department of Bacteriology, University of Edinburgh. In addition, 25 *P. rettgeri* cultures (17 locally isolated, 8 N.C.T.C. strains) 17 *P. morgani* cultures (11 locally isolated, 8 N.C.T.C. strains) and 31 *P. hauseri* strains previously described[5] were used in host-range experiments. The *rettgeri* strains can all be differentiated on the basis of susceptibility to a series of *P. rettgeri* phages. The *hauseri* strains were in the *A* morphological phase and all showed a positive Dienes phenomenon when matched against one another[3].

Using each of the 37 *Providence* strains individually in an enrichment technique of sewage[5], 34 phages were isolated against a corresponding number of the strains on first attempt. The properties of these phages are still being examined, but they can all be differentiated on the basis of their host-range.

The demonstration of lysogeny in the 37 *Providence* strains was attempted by the use of the 3 methods previously described[6]. The only modification was that supernatants obtained by centrifuging the cultures were treated with 0·1 volume of chloroform instead of heating to inactivate bacteria. All 37 strains were used as possible indicators of phage activity. Twenty-three of the 37 strains (62 per cent) proved lysogenic for other *Providence* strains by one or more of the 3 methods of induction used. The 23 strains represent 19 of the 25 serological groups. Strain N.C.T.C. No. 9211 is susceptible to all 23 temperate phages. All phages were purified by repeated single-plaque propagation in broth cultures of the host organism. Phage suspensions were stored above 0·1 volume of chloroform and before use the latter was removed by bubbling the suspensions with sterile air at 45° C.

The host-range of the phages was determined by spotting drops of the suspensions on agar plates which had been layered with soft-agar seeded with enough test organism to give a lawn of growth. The phage suspensions contained about 10^7 plaque-forming particles/ml. Plates were incubated at 37° C for 4 h and then left at room temperature overnight before reading. Phages which showed reactions were then titrated simultaneously on the original host organism and on the new strain and the relative efficiency of plating calculated.

Sixteen of the 34 phages isolated from sewage productively lysed a total of 20 *P. hauseri* strains. Most of the 16 phages attacked a couple of the strains and the phage isolated on N.C.T.C. strain No. 9297 lysed 8 of the *hauseri* cultures. In contrast only one of the temperate *Providence* phages (phage from N.C.T.C. No. 9294) caused productive infection in *hauseri* strains. This phage lysed 5 different cultures. The efficiency of plating of the foregoing systems varied between 10^{-3} and unity with most near the latter value. Six of the 17 *P. morgani* cultures were productively lysed by one or more of the sewage phages. Some of the N.C.T.C. *morgani* strains were remarkably sensitive to these phages and strains Nos. 2815, 5845, 7381 and 10041 were susceptible to 28, 21, 20 and 4 of the 34 phages respectively. The efficiency of plating was often unity. None of the temperate *Providence* phages had any action on the *morgani* strains. Twenty-five of the sewage phages and 9 of the 23 temperate phages formed plaques on one or more of 21 of the *P. rettgeri* cultures. Six of the 8 N.C.T.C. *rettgeri* strains were susceptible to one or more of the temperate phages and the efficiency of plating varied between 10^{-3} and unity.

The phage relationships of the kind demonstrated here have been taken[7] to indicate close taxonomic relationships between the hosts involved and should strengthen the claim[1] for inclusion of *Providence* strains within the *Proteus* group of organisms.

This work was aided by grants from the South African Council for Scientific and Industrial Research.

An Endotoxin-like Fraction extracted from the Cells of *Candida albicans*

ENDOTOXINS are incompletely characterized cell surface complexes which account for some of the pathogenic properties of Gram-negative bacteria. Material with similar biological characteristics has been identified in certain Gram-positive bacteria and in several plant and animal tissues[1]. The existence of a 'toxic principle' in virulent strains of *Candida albicans* has been suspected for about a decade[2]. A recent report by Hasenclever *et al.*[3] strongly supports the presence of such a fraction. Our studies of surface and subsurface antigens of this yeast suggest that several surface materials contained in the aqueous fraction after ethanol-ethyl ether[4] or phenol[5] extraction of intact yeast cells included a substance or substances with toxic activity comparable with that observed by Hasenclever *et al.*[3]. This communication presents evidence that this is indeed the case.

Antibodies produced in rabbits against intact cells of *Candida albicans* variants 1529, an old avirulent laboratory strain, and the mouse-virulent strains of *B*311 and 207 produced equivalent agglutination and cross-agglutination. (Strains *B*311 and 207 were kindly supplied by Dr. H. F. Hasenclever, National Institutes of Health, Bethesda, who also gave us details of his investigations prior to publication.) When cells which had been extracted with either ethanol-ethyl ether or phenol were used as antigens, the corresponding antibodies agglutinated homologous extracted cells to a greater degree than the heterologous strains. Antisera against untreated cells agglutinated extracted cells to the same extent as whole cells. In addition, Ouchterlony precipitin methods were used. The various antisera were reacted with the aqueous solvent-free extracts, which by themselves did not promote antibody production even with adjuvants. Antibodies against intact cells formed 2 precipitin lines with ethanol-ethyl ether as well as with the phenol extracts. These bands always displayed coalescence signifying the identity of the antigens derived from intact cells. When the immunodiffusion test was carried out with antibodies against extracted cells, 6 additional precipitin bands formed when ethanol-ethyl ether extracts were used, and 7 with the phenol extracts. Six of the ethanol-ethyl ether precipitin arcs were identical with 6 of the phenol extract bands. The phenol extract always formed an additional and distinct precipitin line with antibodies produced against the phenol-extracted cells. Chemical analysis of the extracts indicates the presence of protein and polysaccharides in proportions shown in Table 1.

The endotoxin-like nature of the complex haptens extracted from mouse virulent strains *B*311 and 207 became apparent clinically during the immunization procedures. Rabbits which received intravenous solvent-free preparations of both the ethanol-ethyl ether and phenol extracts and the extracted cells themselves manifested extensive necrosis of the skin around the sites of injection within 48 h. Similar severe skin reactions were

Table 1. COMPARISON OF EXTRACTS FROM MOUSE-VIRULENT AND AVIRULENT STRAINS OF *Candida albicans*

observed when mice were treated with the same materials. When 0·2 ml. of the phenol extract of the mouse-virulent strains were injected into the tail veins of mice, 50 per cent died within 12 h. The survivors did not succumb when challenged intravenously with 10 million cells of the homologous strain, a uniformly lethal dose in unprotected controls. Corresponding doses of the ethanol-ethyl ether extracts were not lethal to mice; but all animals so treated were severely ill for at least 2 days and subsequent challenge with the number of yeasts fatal to unprotected controls failed to kill. The mouse-avirulent strain did not elicit any response in controls nor did extracts and extracted cells produce any ill effects. These findings, which are summarized in Table 1, suggest that material resembling endotoxin is elaborated by strains of *Candida albicans* virulent to mice.

We thank Dr. Edgar Ribi, U.S. Public Health Service, Rocky Mountain Laboratory, Hamilton, Montana, for advice.

Cytochromes of *Pseudomonas saccharophila*

LIQUID cultures of autotrophically grown *Pseudomonas saccharophila*[1] are pink and when gassed with hydrogen the colour is intensified. On examination of spectra of cells reduced with hydrogen, using a Cary No. 11 recording spectrophotometer and the opal glass technique[2] the difference spectra showed a Soret band, flavin trough and a single peak at 550 mμ. Breaking the cells and fractionating the extract into a soluble fraction and washed small particles[1], resulted in finding a spectra characteristic of a cytochrome *c* in the soluble fraction and the presence of cytochromes of the *b* and *c* type in the particles. Comparison of the optical density of reduced-oxidized preparations at 550 mμ, shows the distribution of cytochrome *c* to be 77 per cent in the soluble fraction and 23 per cent associated with particles. Difference spectra of the particles are shown in Fig. 1. No other cytochrome peaks were ever observed in cells and extracts of *P. saccharophila*. Hand spectroscopic examination of particles in 50 per cent glycerol at the temperature of liquid nitrogen, as described by Keilin and Hartree[3], showed only three bands, one ascribed to cytochrome *b* and the other two due to the splitting of the cytochrome *c* α-band into two components. The two bands for cytochrome *c* were also observed with partially purified cytochrome *c* from the soluble fraction. Packer[4] examined another hydrogen bacterium, *Hydrogenomonas ruhlandii* and only found a cytochrome *b* and *c* in whole cells.

On fractionating the soluble extract with ammonium sulphate, 18 per cent of cytochrome *c* precipitated in the 80–100 per cent saturated ammonium sulphate fraction and the rest was soluble in saturated ammonium sulphate solution. The second fraction was dialysed and lyophilized. Absorption maxima for this fraction were 550, 523 and 417 mμ and in the case of the pyridine hæmochromogen 550, 521 and 417 mμ. Redox potential was measured using a ferrous–ferric oxalate couple[5] and E'_0 at *p*H 7·8 was + 0·08 mV. This cytochrome *c* preparation is slowly autoxidized. Only two other cytochrome *c*'s have been observed with lower redox potentials, that of *Chromatium* which has 2 hæm groups[6] and *Desulfovibrio desulfuricans* which has 2 hæm groups per molecule[7]. The other unusual property of cytochrome *c* of *P. saccharophila* is solubility in saturated ammonium sulphate solution which has also been observed with cytochrome b_3 of higher plants[8].

Physical and Chemical Properties of Two New Small Bacteriophages

IN recent years, several investigators have reported new bacteriophages which have a molecular weight about 100 times less than the classical *T*-series of phages[1,2]. Those small phages which have been physically characterized are roughly spherical and have a molecular weight of 4–6 × 10^6, of which 20–30 per cent is nucleic acid. The nucleic acid is either single-stranded DNA[3] or RNA[4].

We have been studying two small phages which infect only male (F^+ or *Hfr*) strains of bacteria. The phages were isolated from sewage and grown and purified using conventional methods. Both phages are resistant to DNase and RNase. One of the phages (*fr*) contains RNA and seems in many respects similar to *f*2 phage[4]. The other (*fd*) contains single-stranded DNA. It seems to have an unusual physical form.

The *fr* phage is spherical in electron micrographs, with a diameter of 200–220 Å. Its physical properties in solution are given in Table 1. Its molecular weight is calculated as

4·1 × 10⁶ using sedimentation and viscosity (assuming a perfect sphere) and 4·4 × 10⁶ using sedimentation and diffusion. The phage has 1·1 g water of hydration per gram phage from viscosity or 1·3 g water per gram phage from diffusion. Taking a mean molecular weight of 4·25 × 10⁶ the unhydrated phage would have a diameter of 210 Å. The RNA content is 28·4 per cent (orcinol method) which accounts for 97 per cent of the total phosphorus. Thus the phage contains 1·2 × 10⁶ mol. wt. RNA. The physical constants of the RNA isolated by a detergent–phenol method are shown in Table 1. The molecular weight calculated according to Scheraga and Mandelkern[4] with $\beta = 2{\cdot}25 \times 10^6$ and $\bar{v} = 0{\cdot}55$ c.c./g (c.f., ref. 5) is 1·3 × 10⁶. The RNA is therefore present as a single piece in the phage. The base percentages are: $A = 24{\cdot}3$ per cent, $U = 23{\cdot}7$ per cent, $G = 27{\cdot}1$ per cent, $C = 24{\cdot}9$ per cent. They are sufficiently distinct from those of *f2* phage to suggest that *fr* is a different phage.

Early electron micrographs of *fd* phage showed spheres embedded in a matrix of tangled fibrous material. On a macroscopic scale, infective preparations were very viscous due to the presence of those fibres. It was assumed that these fibres were pili (fimbriæ)[6] detached from the bacterial cell walls. However, during extensive attempts to clean the phage preparations by density gradient centrifugation, ion exchange chromatography, and shaking with a fluorohydrocarbon, infectivity was always found associated with high viscosity. Furthermore, it proved impossible to prepare pili from uninfected cells using methods which had been applied to prepare phage; and phage grown on pili free strains still showed high viscosity. We were therefore led to the conclusion that these fibres are in fact the phage.

To test this hypothesis we submitted mixed solutions of *fd* and *fr*, or *fd* and φ*X*174, to ultrasonics for varying lengths of time. As can be seen from Fig. 1, the infectivity of *fd* fell off extremely rapidly, while that of *fr* or φ*X*174 was scarcely affected. This sensitivity to ultrasonics is what one would expect for a long rod-shaped molecule.

Electron micrographs of carefully cleaned preparations of *fd* show long flexible rods, reminiscent of certain plant viruses[7]. (The spheres present in earlier preparations were probably contaminating ribosomes.) The rods are about 7000 Å long and about 50 Å diameter. The physical constants of *fd* in solution are listed in Table 1. For a rod-shaped molecule the mass per unit length is a function almost solely of the sedimentation constant[8]. The mass per unit length for *fd* is calculated as 1,400 mol. wt./Å. Using a length of 7000 Å as determined from electron micrographs, the molecular weight of *fd* is 9·8 × 10⁶. The molecular weight calculated from sedimentation and viscosity[4] is 11·8 × 10⁶. The total weight of infective preparations divided by their infectivity titre gives a maximum molecular weight of 16 × 10⁶ for the phage. Hence most particles are infective.

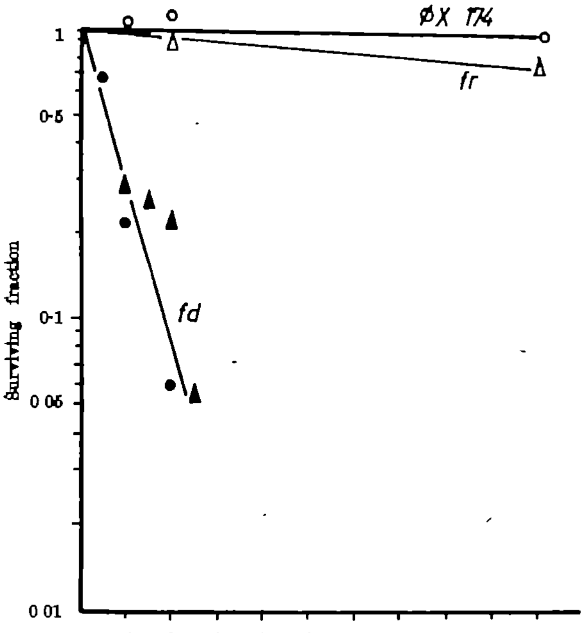

Fig. 1. Inactivation of *fd* phage by ultrasonics as compared with inactivation of spherical coli phages of comparable size. Mixtures of *fd* and φ*X*174 or *fr* (10^{11} – 10^{12} P.F.U./ml. each) were sonicated for the times indicated and plated on an F^+ sub-strain of *E. coli* *C*

Table 1. PHYSICAL CONSTANTS OF *fr* AND *fd* AND THEIR NUCLEIC ACIDS
Measurements were made at 20° C in 0·1 M sodium chloride, 0·02 M *tris* *p*H 7·3, except for *fr*-RNA, which was studied in 0·02 M sodium citrate *p*H 7·3. The estimated error is subjective and intended only as a rough guide

	fr	*fr*-RNA	*fd*	*fd*-DNA	Estimated error (%)
$S^0_{20,w}$ (Svedbergs)	79	21·0	40	24·4	± 2
[η] (dl./g)	0·044	0·80	9*	1·5	± 5
$D^0_{20,w}$ (× 10⁷ cm²/sec)	1·4	—	—	—	± 5
$\bar{v}$ (c.c./g)	0·69	—	0·71	—	± 2

* Roughly extrapolated to zero rate of shear; estimated error ± 20 per cent.

The phage contains 11·6 per cent DNA (diphenylamine method), which accounts for 83 per cent of the phosphorus; the phage therefore contains 1·3 × 10⁶ mol. wt. DNA (using a mean phage molecular weight of 10·8 × 10⁶). The physical constants for the DNA isolated by a detergent–phenol method are given in Table 1. From the Scheraga–Mandelkern equation, using β as for RNA and $\bar{v} = 0{\cdot}58$ c.c./g (ref. 9) one calculates a molecular weight of 2·3 × 10⁶. However, several considerations suggest that single-stranded DNA in solution is a more extended molecule than RNA under similar conditions; thus a larger β should be used and a smaller calculated molecular weight would result. The sedimentation constant of the DNA is similar to that found at the same ionic strength for φ*X*174 DNA[3], which has a molecular weight (from light scattering) of 1·6–1·8 × 10⁶. The measurements indicate that the DNA is present as a single piece in the phage. In low salt concentrations the DNA shows two ultracentrifuge bands of about 13*S* and 15*S*; the bands are replaced by a single band of higher sedimentation constant in high salt. This effect is similar to that found for φ*X*174 DNA. The melting curve as followed by ultra-violet absorption is typical of single-stranded nucleic acid. The base percentages are: $A = 24{\cdot}4$ per cent, $T = 34{\cdot}1$ per cent, $G = 19{\cdot}9$ per cent, $C = 21{\cdot}7$ per cent. These are clearly not consistent with Watson–Crick base pairing.

Preliminary X-ray diffraction patterns of partially oriented gels of *fd* show a strong meridional spacing at about 10 Å and a suggestion of a 60 Å layer line spacing. The diffraction patterns can be interpreted in terms of a helical structure with a 60 Å pitch and about six repeating units per turn.

We thank Dr. A. Gierer for his constructive criticism throughout this work. One of us (D. A. M.) was supported by a U.S. National Science Foundation postdoctoral fellowship.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk are open to the public*)

Monday, February 4

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. Donald W. Tull: Presidential Address.

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. L. F. Boyd: "Celestial Laboratories".*

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. M. Stacey, F.R.S.: "Recent Investigations on Immuno-Polysaccharides".

Tuesday, February 5

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. E. C. F. Bird: "Coastal Lagoons".*

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. C. G. Phillips: "Functions of Central Neurones".* (Eighth of twelve lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Institution of Mechanical Engineers, Automatic Control Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Resilience Problems in Hydraulic and Pneumatic Servo Systems".

Plastics Institute (at the Wellcome Building, Euston Road, London N.W.1), at 6.30 p.m.—Mr. R. P. Palmer: "Crystallinity in Polymers—Its Influence on Properties and Processing Techniques".

Polarographic Society (at the "Feathers" Restaurant, 36 Tudor Street, London, E.C.4), at 6.30 p m.—Discussion on "Documentation in Polarography".

Wednesday, February 6

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. A. G. Baikie: "Chromosomes and Leukæmia".*

Colour Group (Great Britain) (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 3 p.m.—Mr. R. N. Jackson: "Colour in a Television System"; Mr. R. N. Jackson and Mrs. M. L. Beeforth: "The Effects of Unmatched Taking and Reproducing Primaries in Colour Television Systems".

University of London (at Bedford College, Regent's Park, London, N.W.1), at 5.15 p.m.—Dr. F. N. L. Poynter: "Man and Nature at the Close of the Middle Ages".* (Second of three lectures on "The Passing of the Middle Ages".)

Institute of Petroleum (at 61 New Cavendish Street, London, W.1). at 5.30 p.m.—Dr. S. Reid: "Miscible Gas Injection for Flooding an Oil Reservoir—an Experimental Study of Phase Behaviour".

Society for Analytical Chemistry (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Meeting on "Particle Size Analysis—Some Methods Used in the Sub-Sieve Range".

Thursday, February 7

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. D. Hull: "Orientation Dependence of the Deformation of Single Crystals"; Mr. K. R. Allen and Mr. K. Phillips: "Electrical Breakdown in Gases".

Institute of Refrigeration (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 5.30 p.m.—Mr. H. S. Green: "Some Financial Aspects of Plant Selection for Industrial Refrigeration Installations".

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. J. Marshall: "Cerebral Circulation with special reference to 'Strokes' ".* (Ninth of twelve lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Institution of Mechanical Engineers, Nuclear Energy Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Techniques of Optimization in Basic Design".

Institute of Metal Finishing (joint meeting with the Institute of Metals, at 17 Belgrave Square, London, S.W.1), at 7 p.m.—Dr. G. L. J. Bailey: "Some Characteristics of Modern Nickel + Chromium Electrodeposits".

Royal Institute of Chemistry, London Section (joint meeting with the Kingston Technical College Chemical Society, at Kingston Technical College, Fassett Road, Kingston), at 7 p.m.—Dr. C. W. Rees: "Some Aspects of Heterocyclic Chemistry".

Institution of Mechanical Engineers, Steam Plant Group (at the Royal College of Science and Technology, Glasgow), at 7.30 p.m.—Mr. G. Nicholson and Mr. E. G. White: "The Disposal of Flue Dust from a Large Generating Station".

Friday, February 8

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. B. Lennox: "Chromosomes for Beginners".*

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. C. E. Lucas: "Fisheries Research and International Collaboration".

Monday, February 11

University of London (at Senate House, London, W C.1), at 5.30 p.m. —Dr. M. F. Perutz, F.R.S.: "Structure of Proteins"* (John Coffin Memorial Lecture).

Institution of Mechanical Engineers, Internal Combustion Engines Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The High-Speed Diesel Engine—Higher Performance or Lower Cost ?"

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"North America in the Making" (programme of award-winning films).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Chair of Philosophy—The Registrar, University of York, the King's Manor, York (February 8).

Turner and Newall Research Fellows in Engineering, Inorganic Chemistry, Physics and allied subjects—The Registrar, The University, Manchester 13 (February 14).

Lecturer and an Assistant in Moral Philosophy—The Secretary of University Court, The University, Glasgow (February 15).

Senior Lecturer in Education, with special reference to the teaching of geography—The Secretary, University of London Institute of Education, Malet Street, London, W.C.1 (February 15).

Senior Lecturer in Statistics—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (February 15).

Chair of Engineering Science; and Chair of Chemical Engineering —The Secretary, The University, Exeter (February 16).

Lecturer (with a good honours degree in mathematics and experience of teaching in schools) in the Department of Education—The Registrar, The University, Liverpool, quoting CV/219 (February 18).

Lecturers or Assistant Lecturers (preferably with interests in (*a*) marine biology or freshwater biology, (*b*) ecology, systematics or physiology of mammals, (*c*) ecology of the soil fauna, or (*d*) cytology and genetics) in Zoology at the University of Ghana—The Registrar, University of Ghana—P.O. Box 25, Legon, Accra, or The Assistant Registrar (Overseas), University of Ghana, 15 Gordon Square, London, W.C.1 (February 18)

Assistant Lecturer in the Department of Biochemistry—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (February 23).

Assistant Lecturer in European Prehistory in the Department of Ancient History—The Registrar, The University, Sheffield (February 23).

Lecturer or Assistant Lecturer in Pure Mathematics—The Registrar, University College of Swansea, Singleton Park, Swansea (February 23).

Nuffield Foundation Research Fellow in the History and Philosophy of Science—The Registrar, Clarendon Building, The University, Broad Street, Oxford (February 23).

Lecturer or Assistant Lecturer in Animal Husbandry at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square London, W.C.1 (February 24).

Assistant Lecturer in the Department of Philosophy—The Registrar, The University, Leeds 2 (February 25).

Senior Lecturer in Civil Engineering—The Registrar, The University, Sheffield (February 25).

Lecturer or Assistant Lecturer (preferably with special interests, teaching and research or research qualifications in one or more of the following fields: entomology, parasitology, or vertebrate zoology) in Zoology at Ahmadu Bello University, Northern Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 28).

Associate Professor (preferably with medical qualifications) in Clinical Bacteriology in the Faculty of Medicine, University of Sydney—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 1).

College Lecturer in Pure Mathematics—The Master, Emmanuel College, Cambridge (March 1).

Lecturer in Physiology—The Secretary, The Queen's University, Belfast, Northern Ireland (March 1).

Lecturers (2) (registered medical practitioners) in the Department of Pathology—The Secretary, The University, Aberdeen (March 1).

Lecturer in Atmospheric Physics—The Secretary of Faculties. University Registry, Oxford (March 2).

Chair of Geography (with special reference to Asia) at the School of Oriental and African Studies—The Academic Registrar, University of London, Senate House, London, W.C.1 (March 4).

Lecturer in Inorganic Chemistry at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 4).

Lecturer (preferably with a special knowledge of plant nematology) in Plant Pathology in the Department of Agriculture, University of Sydney—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 6).

Lecturer (with a degree in science or agricultural science, and qualified in biometry, agricultural statistics or mathematical statistics) in Biometry in the Department of Agriculture, University of Sydney—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House,. Pall Mall, London, S.W.1 (Australia and London, March 6).

Lecturer in Veterinary Medicine at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 12).

Associate Professor in Soil Mechanics at the University of Sydney—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 15).

Assistant Experimental Officer (graduate in a biological science (pure or applied), with an interest in chemistry or biochemistry) in the Nematology Department, to assist in work on (1) hatching factors of cyst-forming nematodes and manage the bio-assay, (2) chemical control of plant parasitic nematodes using soil sterilants and chemotherapeutants—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (March 16).

Lecturer (graduate in science or medicine) in Physiology—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (March 16).

PROFESSOR OF THEORETICAL PLASMA PHYSICS—The Registrar, University Registry, Oxford (March 23).

SECOND CHAIR OF BIOCHEMISTRY at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 31).

MASTER TO TEACH CHEMISTRY AND SOME BIOLOGY—The Master, Wellington College, Crowthorne, Berkshire.

MASTER TO TEACH PHYSICS to Open Scholarship level—The Headmaster, School House, Rugby.

REVOLUTION IN RETAILING

FOR 'a nation of shopkeepers' the British have shown little interest in improving the quality and efficiency of their retailing services to consumers. During the past decade, however, there has been a noticeable change, and many of the growing number of little boxes which line so many urban centres are themselves beginning to give way to various types of bigger stores and supermarkets. Although such changes have profound effects on the national economy, they have hitherto attracted little notice from economists and others; lack of exact information has made it difficult to make even a general assessment of their significance.

It is encouraging, therefore, to see a book which has been produced under the ægis of the Twentieth Century Fund and represents a valuable study of distribution trends and prospects in Europe*. The authors are specialists in the field of retailing and distribution, and, although the difficulty of collecting statistical information has been immense, the material brought together and the tentative conclusions should lead to much closer investigation and control of developments in the distributive trades.

Not only is there a lack of reliable information, but also what does exist makes comparisons difficult. Butchers and bakers, for example, may be retailing establishments in some European countries but not in others, and one which includes butchers in its census of distribution may not include bakers. Further confusion arises where wholesaling and retailing activities are described together in one unit in one country while they are separated in others according to the main activity. A still greater difficulty in assessing the place of retailing in the economy of different countries is the relative absence of information on total retail sales and gross margins as well as the retail sales of individual concerns. This is largely bound up with the private nature of so many retail organizations and renders it difficult to make accurate comparison of performance and, hence, forecast trends. Nevertheless, the wind of change is blowing so strongly that a rapidly increasing number of retailers are beginning to make information available in order that they can measure their effectiveness against that of their competitors.

Figures produced by Jefferys and Knee, for example, show the overall contribution of the retailer to the European scene. In 1955, 11 per cent of the total European labour force of 132 millions was engaged in one of the distributive trades. Of the 14,500,000 engaged in distribution, 3,400,000 were concerned with wholesaling and the rest in retailing. These 11,100,000 persons were employed in 4,000,000 establishments. Not unexpectedly, the number of people employed in commodity distribution increases (13·5 per cent were so employed in the United States in 1955) as the number of those employed in commodity production decreases and, in Europe over the past forty years, the number in wholesaling and retailing has increased by about 2 per cent. Among the more important reasons why the proportion of total manpower engaged in commodity distribution has increased compared with the proportion engaged in commodity production is that the volume of goods and services distributed per man-hour in distribution has risen much less rapidly than the volume of goods produced per man-hour in commodity production. The application of scientific techniques and methods of distribution has been negligible compared with what has been done in the field of production. It is surely remarkable that, in the National Productivity Year, those retailers in Britain who wish to apply method-study to their stores and shops can find no organized course concerned with training their employees in work-study specifically applied to retailing. Nor has any of Britain's leading stores carried out any detailed investigations to improve its display, layout and methods of working even remotely comparable with the admirable work carried out by the Dillon family in the United States.

A further feature which reflects the importance of the retailer in the national life is that retail trade is increasingly becoming a source of employment for girls and women. About half the total number of people employed in retailing in Europe are female, and, equally significantly, many of them are married women who work part-time. The contribution of retail organizations to the national economy should be assessed not only by the extra purchasing power which these married women workers represent but also by the contribution it makes to their individual lives.

Although the number of people engaged in retailing has measurably increased over the past half-century, information produced by Jefferys and Knee support common observation that the number of establishments concerned with retailing has increased very little. The trend has been towards a larger average size of retail unit. In Europe between 1930 and 1955 the number of retail establishments increased by about 10 per cent. The number of persons employed during this period increased from 2·3 per retail establishment to 2·7. Of more than passing interest is the fact that, in the United States in 1954 the average number of persons engaged per retail establishment was more than double that in Europe, 5·7 persons. This may explain why, in the United States, the sales per full-time person in 1955 were, at 20,000 dollars, approximately two and a half times the average for Europe and more than twice that for the United Kingdom. On this basis, if sales per person in Europe approached the American level, the total manpower required would be about 5 million full-time persons instead of the present 10 million; and, again not without significance, there appears to be direct correlation between sales per person engaged in retailing and the level of real consumption per head in the particular country*.

Although the vast majority of individual retail establishments in Europe are small one-man businesses, the tendency is for them to decline and the larger units to grow. Jefferys and Knee extended their inquiries to see how the different types of large-scale retail organizations were increasing their efficiency and their effectiveness. Although the co-operative movement in Europe has, generally, continued to increase its share of total retail trade, its advance has, of late, been considerably slowed down and, mainly because of their method of government and direction, the Co-operative Society will probably go on losing ground to other large-scale retailers. Independent multiple-shop organizations, on the other hand, have developed rapidly since 1914 and particularly in the food trades. In the United Kingdom the number of multiple-shop branches had risen to 36,000 by 1939 against 22,000 in 1914 with a steady increase in the number employed per branch. Equally, the variety-chain-store organizations have continued to increase their number of stores throughout Europe as well as the number of persons employed. While the multiple shop retailers have followed the traditional divisions between trades—grocer, butcher, men's tailor, etc.—the variety-chain-stores have completely reversed this policy and sell a wide range of goods from food to clothes, ironmongery and, now, radio sets. This has been achieved despite intensive pressure from small and multiple retailers and even against restrictive action by Government and local authorities. The growth of the variety-chain-stores has caused the well-established and traditional department stores to examine their merchandising and retailing policies as well as their location. Traffic congestion, parking difficulties, increasing rents and rates are all adding to their difficulties, and these will be further increased by the growth of mail-order firms which sell direct to the consumer and which have shown spectacular growth since the Second World War. About 3 per cent of total retail sales in the United Kingdom are now made through mail-order companies, and, largely because of the increase of urban purchasers and the sale of branded products, this proportion is increasing.

---

* *Retailing in Europe: Present Structure and Future Trends*. By Dr. James B. Jefferys and Derek Knee. Pp. xiv+177. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, 1962.) 25s.

* *Distribution in Great Britain and North America*. By M. Hall, J. Knapp and C. Winsten. (Oxford Univ. Press, 1961.)

Despite the growth of the larger retailers, however, the bulk of retailing activity is still carried out in small concerns. While their innate conservatism and desire 'to keep their business to themselves' makes change unwelcome, the threat of extinction is causing many small retailers to group together for cheaper bulk-buying and to make use of management services for mutual improvement. This co-operation, either through self-governing voluntary groups or through one of the growing number of organizations which have been set up for this purpose, has, hitherto, been largely confined to the food trades, but is now spreading to others. Its extension could well mean the preservation of many of the small-scale retailers. They have the advantage of close knowledge of their customers and of their customers' wishes, and, if they employ staff, can ensure that such staff is fully utilized. These are advantages, however, which are unlikely to stay with them long unless they develop training arrangements like those of the bigger organizations. The latter are beginning to pay not only closer attention to the selection of suitable branch managers and staffs but also are beginning to devote much greater care to determining the needs of their cusomers and what kind of service will best meet those needs.

Jefferys and Knee have not only performed a valuable service by gathering information. They have also used it to make forecasts which should be of value to all progressive retailers. So, too, has W. G. McClelland, research fellow in management studies at Oxford and still a director of a large grocery multiple group. In a recent broadcast on the Third Programme of the British Broadcasting Corporation, McClelland welcomed the spread of self-service stores and supermarkets in the food trades and hoped that these developments would spread rapidly in the non-food trades. Small margins and a high volume of sales could enable non-food supermarkets to trade as profitably as their food equivalents; they could perform an equally valuable service to the community by keeping down the cost of living. The abolition of re-sale price maintenance could also enable efficient non-food retailers to strengthen their own positions and make a marked contribution to pegging the cost of living. Price maintenance has virtually disappeared in the grocery trade because manufacturers have seen that they could not compete against other low-cost producers; unless non-food manufacturers are prepared to follow the same precept they will invite sharper competition from manufacturers in similar fields who will arrange to sell products like refrigerators direct to customers. If the latter tendency grows, the non-food retailer will find himself not only without margins but also without products to sell.

For most conclusions drawn by Jefferys and Knee there will be general approval. An overall increase of sales of up to 58 per cent by 1970 should be accounted for by a larger increase of sales in clothing, furniture, household appliances and other goods than in foodstuffs. More manpower will be required and the sales per person will increase. The number of establishments will almost certainly decrease in the next decade and the average size of them will increase; this will be even truer of foodstuff establishments than of others. The estimated increase in size of establishments will lead to a considerable new fixed capital investment in retailing, and, according to Jeffery and Knee, in Europe as a whole this may well amount to a total of 16 billion dollars. The entrepreneurs in retailing may well be forced to reconsider their traditional ways of financing capital expenditure.

But the greatest changes will have to come from the small retailers. In the next decade the multiple-shop organizations, and especially the variety-chain-store firms, will increase their share of the total trade, and small independent retailers will only survive by collaboration in merchandising and in the management of their enterprises. Before this occurs there must be radical change in the attitude of the majority of small retailers; butchers, bakers and grocers must quickly learn to become managers. The standard of retailing needs to be built up until it is accepted as a service demanding special techniques which require to be studied and developed. A number of leading retail organizations in Britain have already used the services of management consultants with considerable success in a number of ways. Instead of controlling stock by hunch, for example, operational research has been used to control the number of lines a warehouse may hold and to determine at what levels branch staffs may re-order; training courses have been devised to instruct branch managers how to keep stock-levels at an optimum. Electronic calculating machines are being regularly used to improve the information available to central buyers, while linear programming is now accepted as a means of reforming the means of distribution from factory or warehouse to shop or store. Already twenty computers are in use in the larger retailing organizations in Europe, and, as the means for hiring computing service becomes more widely known among smaller retailers, the use of statistical information will become much more common. Inter-firm comparisons will be extended to provide comparative information not only about sales per person, but also sales per man-hour and sales per linear part of the counter, if the latter continue to exist.

Before these fundamental changes come about much more attention will have to be paid to means of producing trained and competent manpower. Fundamentally, the challenge facing retail organizations is one of management, and this is daily becoming more and more apparent to many of those who control retail companies. In the next decade, two main problems will confront retail directors and these will only be surmounted by good management. The first is the supply of goods. The increasing role of the manufacturer in the branding, packing and advertising of consumer goods necessarily means much more pre-selling to the consumer and will drastically change the role of the retailer. This has already occurred with tobacconists, and is now taking place with grocers. The trend is likely to continue over a wide range of non-food goods. Instead, therefore, of grocers and ironmongers who are expert in their particular commodities, the immediate future should provide managers of grocery and hardware shops who are sufficiently informed to resist over-selling by manufacturers and overstocking by themselves.

The second problem will leave the retailer even more vulnerable. This is one of costs and margins and only those managers of retail establishments who can bring a mathematical approach to buying and distribution, a systematic approach to display and layout in their stores and shops, and a budgetary form of control to their financial accounting, can expect to attain high turnover with low margins. Moreover, unless shops and stores are organized and staffs are fully trained to provide genuine consumer satisfaction, they are still unlikely to succeed. Opening hours will have to be adjusted to make shopping possible and enjoyable, and this may mean changes in existing law. A five-day week for staff and longer opening hours are both immediately possible, and here the appropriate trade unions should see that the interests of the consumer are put first. Of education and training for the retail trades in Britain little need be said other than that what is being done is even less satisfactory than that for apprentices in industry.

England has one old-established College for the Distributive Trades, and Scotland a very new one. Adequate training for staff is provided by one leading grocery firm in England and one in Scotland. Those in control of the bigger supermarkets talk but do not act—they are mainly concerned to provide 'shelf-fillers'. Education for management in the retail trades is bedevilled by the number of proliferating bodies like the Institute of Grocers which have set up their own courses in management and so divert students from the admirable and nationally recognized arrangements first promulgated by the City and Guilds of London Institute a few years ago. In contrast to Britain's belated recognition of the need for education and training in the retail trades, there is the work of the School of Retailing, a constituent college of New York University, which was founded some forty-three years ago, and is now internationally recognized for its graduate and postgraduate work[*]. The relationship of education and training to productivity in retail organizations has been discussed by Prof. Harold F. Clark, of Columbia University, and Prof. Harold S. Sloan, of Fairleigh Dickinson University[†]. They also show that it is the trained managers who provide education and training facilities for their staffs in order that they can faithfully serve the customer. The future of retailing will depend on the quality of its management, and the experience of industry should now be used in the distributive trades to select and train individuals possessing the kind of educational background on which good management depends. Such trained managers could make a powerful contribution to the nation's productivity.

WILLIAM HARVEY'S LECTURES ON ANATOMY

Lectures on the Whole of Anatomy

By William Harvey. An annotated translation of "Prelectiones Anatomiae Universalis", by Prof. C. D. O'Malley, F. N. L. Poynter and Prof. K. F. Russell. Pp. 239. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1961.) 64*s*.

HARVEY'S great work *De Mortu Cordis* was first published in 1628; but in the Latin manuscript of his Lumleian Lectures on anatomy delivered at the Royal College of Physicians during 1616–26 we are able to read of his earliest presentation of his views on the circulation of the blood. Indeed, in his dedication of *De Mortu Cordis* to the President of the Royal College of Physicians and to other learned physicians he writes, "on several earlier occasions in my anatomical lectures I revealed my new concept of the heart's movement and function and of the blood's passage round the body. Having now, however, for more than nine years confirmed it in your presence . . . I have yielded to the repeated desire of all and the pressing request of some, and in this small book have published it for all to see". This shows quite clearly the importance of his lecture notes, and this translation presents them in a form convenient and easy for all to read. Harvey's manuscript is in the British Museum, having been presented by Sir Hans Sloane. In 1886 the Royal College of Physicians and Royal College of Surgeons published a facsimile reproduction together with a transcription of the lecture notes; but the authors frequently refer to errors in this publication. From the reproduction of several pages of the manuscript it is clear that accurate translation and presentation of the notes must be very difficult indeed.

Apart from the interest of this first account of the circulation it is revealing to find that the College of Physicians entered the anatomical field so early (actually in 1565) and performed a function in organizing lectures that might rather be expected from the Company of Barber Surgeons, had that body been properly organized.

Harvey deals with the whole of the body, except the skeleton, but his notes contain more than pure anatomy. His interest in comparative anatomy is shown by his reference to some eighty animals. We also realize that he was a busy practising clinician and a pathologist. There are many references to the diseases of his patients, with names. Although he is presenting anatomy it is notable that his thoughts are predominantly concerned with function; he is revealed as a physiologist. Thus he states: "Since the purpose of anatomy is to know or to recognize the parts and to know them through their causes, and these in all animals, for the sake of which and therefore for this reason, (1) action, (2) use". This preoccupation with function, of course, finds its zenith in his presentation of the structure and function of the heart.

In contrast to his 'modern' grasp of so many things in the body, it is interesting to see how much he still retained of the older, empirical teachings.

The authors are to be congratulated on performing a classic task in presenting this book to the wide audience that must eagerly receive it.

One unhappy feature mars this book. This is the use as a frontispiece of a coloured reproduction of the Rolls Park portrait of William Harvey. This was unknown until it was discovered by Sir Geoffrey Keynes and described in his Vicary Lecture in 1948. The home of the Harvey family was unoccupied, derelict and severely damaged. Sir Geoffrey Keynes was able to arrange for the safe removal of the portrait and those of Harvey's brothers. They found a home in the Royal College of Physicians for some ten years and were then removed by the owner. The portrait of Harvey was fraudulently exported to the United States, where it was sold. Those responsible were heavily fined in a magistrates' court in January 1962.

Even though the portrait is of special interest in that it shows William Harvey as he was during the period he was compiling his lecture notes, it would have been more tactful not to have flaunted it so blatantly with attributions to its present American domicile and ownership in a book touching so very closely on the Royal College in which Harvey delivered his lectures and which has so recently suffered the ignominious loss of the portrait.

RUSSELL BROCK

ANTOINE FRANÇOIS DE FOURCROY

Fourcroy

Chemist and Revolutionary 1755–1809. By W. A. Smeaton. Pp. xxi + 288 + 7 plates. (Cambridge: W. Heffer and Sons, Ltd., 1962.) 40*s*.; 6.00 dollars.

THIS book is the kind of foundation on which the history of chemistry will eventually be built. There are many volumes of laborious detail in which the wood cannot be seen for trees, and many full of enticing generalizations which serious research can easily disprove; but there are not many like this one which combines thorough scholarship with a grasp of how the particular subject fits into the general picture. It is common to find the history of chemistry presented in isolation, without reference to the industry, politics, society or educational system around it. Yet chemists are certainly not cut off from the world, and this book has the great merit of showing the life of a distinguished chemist as a whole, with all his varied activities and their influence on his scientific work.

Fourcroy is, indeed, a particularly attractive subject—active both in chemical research at the crisis of the chemical revolution and in politics in the France of Robespierre and Napoleon. His election to the Convention seems to have been against his will, but he served on it and on the Committee of Public Instruction during the Terror, and then on the Committee of Public Safety, returning after an interval to serve on the Council of State under Bonaparte. As the director-general of public instruction who planned the Imperial University to control all education he might well have become its first Grand Master, but was rejected probably because the Emperor needed the Church's co-operation, and Fourcroy was a freethinker. (So was the Emperor, unofficially.)

Fourcroy has often been held responsible for Lavoisier's execution, or at least for not having done all he could to save him. Dr. Smeaton argues, however, that the evidence on which Lavoisier was condemned was the same as that against all the Farmers-General of Taxes, and shows that Fourcroy actually risked his life in speaking for Lavoisier at a meeting of the Committee of Public Safety, to which he had then no right of entry. There is no proof that the incriminating letters found among Lavoisier's papers, which have been published by Prof. McKie, were ever reported to the authorities.

Unfortunately, little is known of Fourcroy's private life and character, and the author will no doubt be criticized for not having 'brought his subject to life'. However, it is not a scholar's part to produce imaginative reconstructions without evidence. What he does bring to life most vividly is the world of chemical teaching and research in which Fourcroy was a leader. To understand the processes of formation of scientific theory, it is necessary to understand not only the few contemporary ideas which have survived but also all the concepts and attitudes, since forgotten, which seemed important at the time and were the context in which advances were made. It is in this that the author is particularly successful.

Fourcroy was a distinguished teacher and writer of text-books, and did valuable work, generally in collaboration with Vauquelin, on plant and animal chemistry, the application of chemistry to medicine, and on inorganic salts. He produced what may have been the earliest systematic scheme of inorganic analysis, and, like most French chemists of the time, was often called on to apply his knowledge for practical uses. This book, which has good indexes, notes and copious bibliography, will certainly become the standard work on its subject.

A. M. DUNCAN

GEOPHYSICAL SCIENCES

Applied Geophysics U.S.S.R.

Edited by Dr. Nicholas Rast. Pp. 429. (London and New York: Pergamon Press, 1962.) 100*s*. net.

Fundamental Problems in Turbulence and Their Relation to Geophysics

Proceedings of a Symposium held at the Faculty of Sciences and at the Institut de Mécanique Statistique de la Turbulence of the University of Aix-Marseille, September 4–9, 1961, Marseilles, France. Edited by Francoise N. Frenkiel. (International Union of Geodesy and Geophysics and International Union of Theoretical and Applied Mechanics. Reprinted from the *Journal of Geophysical Research*, Vol. 67, No. 8.) Pp. iv + 234. (Washington, D.C.: American Geophysical Union, 1962.) 5 dollars.

Earth, Sea, and Air

A Survey of the Geophysical Sciences (Addison-Wesley Series in the Earth Sciences.) By Prof. Jerome Spar. Pp. vii + 152. (Reading, Massachusetts and London: Addison-Wesley Publishing Co., Inc., 1962.) Paperback 14*s*.; Hardbound 23*s*.

WE still know too little about geophysical studies in the U.S.S.R., and Dr. Rast's translation of a selection of Soviet papers on applied geophysics is to be welcomed. There are four papers on seismic methods, two on gravity, five on electrical methods and six on bore-hole logging methods. Undoubtedly, the most useful articles for Western readers concern the methods of electrical prospecting, on which the literature in Western countries is sparse.

The papers presented at a symposium held in Marseilles during September 4–9, on "Fundamental Problems in Turbulence and Their Relation to Geophysics", and originally published in the *Journal of Geophysical Research*, have now been published together in book form under the editorship of F. N. Frenkiel. The value of this publication need scarcely be emphasized.

Earth, Sea, and Air is a survey of geophysics intended for a course in a liberal arts college in the United States. Prof. Spar feels that the arts man needs some knowledge of science if he is to be effective in the teaching or administrative work in which he will later be engaged. This notion is, of course, still quite foreign to the English university or to the grammar or public school sixth-form on the modern or classical side. The book is quite a good one, emphasizing well the exciting human quest which any scientific field, if treated historically, represents. It would be an interesting experiment to use such a book as the basis of a course in an arts department of an English university.

Slightly irritating Americanisms crop up; for example, on p. 41 we read of the founder of geology William (Strata) Smith. It is also rather out of date and treats as an article of faith that the Earth was once molten, but then almost every geologist believes this, in spite of strong geophysical and geochemical evidence to the contrary. This, however, is poetic justice, as geologists are fond of quoting, for the discomfiture of the geophysicist, Kelvin's celebrated 'proof' that the age of the Earth was only some tens of millions of years. While rejecting this, they seem notwithstanding to have swallowed whole Kelvin's idea of a cooling Earth. Only in recent times does this idea seem to have been effectively challenged.

S. K. Runcorn

NON-LINEAR OSCILLATIONS

Nonlinear Oscillations

By Dr. Nicholas Minorsky. Pp. xviii + 714. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1962.) 107s.

THIS encyclopaedic volume, of more than seven hundred pages, is the most extensive treatment so far published in book form on the theory of non-linear oscillations. It will undoubtedly become the standard reference work on the subject and no applied mathematician can afford to be without it. The book, containing thirty-one chapters, is divided into four parts and only a brief outline of the contents can be given.

In Part 1 (eight chapters) topological methods are discussed, and the theory is based largely on that of Poincaré. The theory of stability is developed, especially in relation to the ideas of Liapounov. Part 2 (nine chapters) deals with quantitative methods and is largely concerned with the classical theory of approximations. The asymptotic methods of Krylov–Bogoliubov–Mitropolsky, both for autonomous and non-autonomous systems, is presented in detail. The highlight of Part 2, however, comes in Chapter 16, which is concerned with the stroboscopic method. This method was developed by the author himself who, in 1953, was awarded *Le Prix Montyou* by the French Academy of Sciences for this work. Part 3 (eight chapters) is given to the study of the oscillations of nearly linear systems, and it is based almost entirely on the stroboscopic method. There are chapters on synchronization, non-linear resonance, parametric excitation and oscillations caused by retarded actions. The next chapter introduces the concept of a parameter space and discusses, in this space, the topology of Lienard's equation:

$$\ddot{x} + f(x)\dot{x} + g(x) = 0$$

where $f(x)$ is a polynomial. Part 4 (six chapters) is concerned with relaxation oscillations, a subject where a wide departure from the near-linearity of Part 3 frequently holds. Because of this departure entirely different methods from those of analytic approximations are necessary. The discontinuous theory of relaxation oscillations is presented and it is applied both to electrical and to mechanical problems. Asymptotic methods are then discussed, including that of Cartwright–Littlewood and that of Dorodnitzin. The book concludes with a chapter on piecewise linear idealization.

A feature of the present work is the detailed exposition of the outstanding Russian contributions to the subject over recent decades. There are many references to the original papers and every research student in this field will need to use this book. The applications of the theory are chiefly in mechanics and electricity, fields where an immense amount of experimental evidence has been brought to bear on the theory. It has happened that the mathematical models that have been constructed in these fields have been particularly robust. This has not so far been the case with model making in the fields of biology and econometrics, where many non-linear phenomena also occur. However, the applications of the theory to biological fluctuations and to econometric recurrent processes are discussed and the limitations of the models are pointed out.

L. S. Goddard

ENGINEERING ASPECTS OF SUPERSONIC AIRCRAFT

Supersonic Engineering

A Symposium held at the Royal College of Advanced Technology, Salford. Edited by J. T. Henshaw. Pp. viii + 264. (London: William Heinemann, 1962.) 63s.

IN this book Heinemann, with the assistance of Mr. J. T. Henshaw, who has edited the contributions, have bound within one volume a series of lectures delivered at a conference which was held in May 1961 at the Royal College of Advanced Technology, Salford. Having myself spent tedious hours trying to obtain scientific papers presented at similar conferences and made available only to those present, I am always pleased when I see that a publishing house has been bold enough to make a book from this kind of material.

The subject-matter of this book is far more specific than its title would suggest, for it deals almost exclusively with the engineering aspects of the supersonic transport aircraft and, so far as one can expect within its 264 pages, provides a comprehensive survey of as widely varying topics as the basic aerodynamics, the structure and materials likely to be used in its design, the noise problem, the systems engineering, the safety and airworthiness and the power plants and their aerodynamics. The book is introduced by a chapter which outlines the problems posed by the supersonic transport and there are sections dealing with the stability and control and with the economics of operation. To my knowledge it is the first work to be published which attempts to cover the complete subject in this way.

In preparing this book, no attempt has been made to produce an academic text-book, something clearly impossible within the few pages, but rather its objective has been to present a synopsis of the many problems facing the engineer and by so doing, to stimulate the interest of those, as the book says, "experienced graduates", who are at present in the aircraft industry. This it probably will do quite successfully for the book is very readable and is almost devoid of mathematical analysis. However, I would criticize it on the grounds that it probably has gone too far in its attempt to make the exceedingly complex problems appear simple if tackled with sufficient common sense. I also find that the lack of rigour in most of the contributions makes it very hard to decide when an author is stating a well-established fact or his own point of view, valuable though that may be. To this end, liberal use of references would have been most welcome, but unfortunately they are completely absent from more than half the contributions. This is even more regrettable when one considers that the aim of the volume was to stimulate the interest of engineers, which implies that they will follow up with a more detailed study in their own field if they know where the information can be found.

J. K. Harvey

HISTORY OF VISCOSE RAYON

The Beginning of Rayon

By Edwin J. Beer. Pp. 206 + 13 plates. (Paignton, Devon: Phoebe Beer, Shorton Manor, Shorton, 1962.) 20s.

VISCOSE rayon was the first man-made fibre to reach the mass market. The pioneering work, which made this possible, began 60–70 years ago and is associated with the names of Cross, Bevan, Stearn, Beer, Topham, Tetley and many others. With the exception of Beer, these pioneers have vanished from the stage, and such accounts of the beginnings of viscose rayon as have appeared are based on the recollections of the generation succeeding Beer and his co-workers, that is, they are based to a considerable extent on hearsay. The author, Mr. Beer, has made available in his book, his own recollections, reinforced by extracts from his diaries and old letters, over the period covering the last few years of the nineteenth century at Kew until a year or so after Courtaulds had set up a plant at Foleshill, then just outside Coventry, in 1905.

The author's laboratory notebooks were handed over to Courtaulds many years ago and have disappeared. I myself do not think that this is very important except in so far as it would lead to greater precision in allocating priorities to ideas and the people responsible for them. After reading the book, one is left with a feeling of respect for Mr. Stearn, "Mr. Stearn's chemist", that is, the author, and their colleagues at having succeeded in developing a technology for producing a fibre from viscose, a liquid material which varied in colour, viscosity and spinnability, according to the source and nature of the wood pulp, the purity of the chemicals available to them and the ambient temperature.

The book is, therefore, a valuable source on the early history of viscose rayon. The information presented is not interpreted, that is, the author makes quite clear when he is quoting from his diary and letters and when he is commenting on other sources of information or hearsay. However, judged from the point of view of the book's stated purpose, it is too long and discursive, containing many interpolations of the author's experiences, particularly in India, after leaving viscose. I consider that the ease of following the development of viscose rayon would have been considerably improved if the author had organized his material better. On the other hand, if he had, the reader might have missed much information about social conditions at the turn of the century and about the experiences of the author, who certainly is in many ways an exceptional man.

L. A. WISEMAN

PROGRESS IN BIOCHEMISTRY AND PHYSIOLOGY

Annual Review of Biochemistry

Vol. 31. Edited by J. M. Luck and Associate Editors: F. W. Allen and G. Mackinney. Pp. vii+731. (Palo Alto, California: Annual Reviews, Inc., 1962.) 8.5 dollars.

Advances in Comparative Physiology and Biochemistry

Vol. 1. Edited by O. Lowenstein. Pp. xii+392. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.) 86*s*.

VOLUME 31 of *Annual Review of Biochemistry* begins with an autobiographical chapter by Dr. Mansfield Clark, whose studies on hydrogen ions and oxidation-reduction have contributed so much to biochemistry. Most of the 21 reviews in this volume are on subjects usually covered each year, but there is at least one surprise: an article on germ-free animal research (O. Mickelsen). This deals with the subject from its beginnings, which seem to go back to experiments designed to test Pasteur's suggestion that an animal could not live in the germ-free state. The suggestion proved to be wrong, and to-day there are about a dozen centres, most of them in the United States, where colonies of animals are maintained in a germ-free condition, that is, free from all detectable organisms, whether pathogenic or not. Germ-free rats and mice have been shown to have practically normal life-spans, and chickens, monkeys and guinea pigs have also been successfully maintained in a germ-free state for long periods. The technique can be used to throw light on many problems; for example, the effect of a germ-free upbringing on wound healing or on sensitivity to subsequent infection, or the role of the intestinal flora in animal nutrition, particularly as regards vitamin requirements. Other reviews of general interest deal with polypeptide hormones (K. Hofmann), inborn errors of metabolism (J. Larner), and insect nutrition (H. L. House). There are three chapters on nucleic acids and two on different aspects of immunology.

Advances in Comparative Physiology and Biochemistry is a new serial publication. Volume 1 contains reviews on the following subjects: digestive enzymes (E. J. W. Barrington), the amine oxidases of mammalian blood plasma (H. Blaschko), temperature receptors (R. W. Murray), neuromuscular physiology (G. Hoyle), animal luminescence (J. A. C. Nicol), and respiratory mechanisms and their nervous control in fish (G. M. Hughes and G. Shelton). The reviews are illustrated with many figures. Most of the contributions in the present volume come from university departments of zoology in Great Britain. In planning future volumes, the editor will, no doubt, be looking to authors from other departments and other countries to write some of the reviews. This new publication has been planned to keep physiologists and biochemists abreast of present-day work in the comparative branches of their subjects. It has made a good beginning.

D. C. HARRISON

CANCER CHEMOTHERAPY

Biological Approaches to Cancer Chemotherapy

A Symposium held at Louvain, June 1960, under the auspices of Unesco and the World Health Organization. Edited by R. J. C. Harris. Pp. x+431. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1961.) 96*s*.

THE failure of the organizers of the Louvain Symposium to define the meaning of chemotherapy in relation to cancer enabled the contributors to this book to range over a wide variety of biological and biochemical topics related to cancer therapy. This has the advantage that the reader is stimulated by many theoretical approaches to the alleviation or cure of cancer.

Most of the thirty-one contributions are directed towards answering one or more of the following questions. What are the differences between normal and cancerous tissue and which cellular functions are most suitable for therapeutic attack? What considerations affect the design and transport of drugs having a specific effect on malignant cells and can any steps be taken to protect the organism against undesirable side actions? What methods, other than surgery and externally applied radiation, may be used in the treatment of the disease? Because relatively little progress has been made in the chemotherapy of most forms of cancer, the answers to these questions are necessarily speculative. Danielli, in the introductory paper, suggests that the differences in properties between normal and malignant tissue are such that a drug, to be effective, will have to act on two or more of these differences.

Several papers are concerned with aspects of cell or tissue life which are potentially useful as points of chemotherapeutic attack. Thus homeostatic (or feedback) mechanisms, steroid hormone–pyridine nucleotide interaction, the dependence of epithelial tissue (from 5-day-old chick embryos) on the underlying mesochyme in tissue culture, and lysosomes are subjects for discussion. De Duve speculates on the induced rupture of the lysosome as a method for destroying malignant cells.

It appears from the articles by Bergel and by Larionov that they and their colleagues are concentrating on the problem of how cytotoxic chemicals may be transported specifically to their site of action. Both are synthesizing drugs in which a nitrogen mustard moiety is attached to a peptide chain, and both claim successes against transplanted tumours in experimental animals. Other papers concern the metabolism of drugs in general, their introduction into normally impermeable cells by pinocytosis or ion transport, and the way in which drug resistance arises. Jacobson reviews the inactivation of clinically useful antifolic acid antagonists by leukæmic and other cells and suggests ways by which this inactivation may be circumvented.

Four potential methods of tumour control, which can only loosely be called chemotherapy, are also discussed. The manipulation of the hormonal environment in the control of tumours of the endocrine glands and their dependent tissues is practised widely in clinical medicine. Furth and Mühlbock detail some of their experimental work, the former using primary mammary tumours in the rat and the latter transplanted ovarian tumours in the mouse. Secondly, the existence of specific antigenic groupings in cancer cells is reviewed. It is accepted that chemically induced tumours of rodents contain antigens not demonstrable in the corresponding normal tissue, but the position with 'spontaneous' tumours is less certain. Thirdly, the induction of cancer by viruses and the possibility that viruses will be found which specifically destroy tumours is discussed. Finally, Kinosita and Maisin both review the inhibition of azo dye cancer in the rat liver.

It is noteworthy that one of the most pressing needs in the investigation of cancer chemotherapy, that is the lack of an adequate method for the biological testing of drugs, is discussed in only one paper. Garattini and Palma are more concerned with the determination of general toxicity than with the investigation of the reactions of a wide range of tumours.

There is a considerable variation in the scope and standard of papers in this Symposium. Some describe their subject in the most general terms, others report the results of experimental work. They all combine to produce a fascinating picture of the difficulties of the problem and of the methods used to overcome them.

The editing of these proceedings is not of the standard normally expected in a book of this quality. There are several typographical errors, a lack of consistency in the use of abbreviations for chemical and biochemical substances and sometimes a failure to record the meaning of these abbreviations. The lack of firm editing and careful grouping and linking of the contributions has resulted in a collection of papers rather than in a useful guide to present trends in cancer chemotherapy.

D. B. CLAYSON

ECOLOGY FOR STUDENTS

Introduction to the Study of Animal Populations

By H. G. Andrewartha. Pp. xvii+281. (London: Methuen and Co., Ltd., 1961.) 30s. net.

It is scarcely possible to cover the whole field of animal ecology in a text-book of moderate size and cost; authors are practically obliged to develop selected sectors of it, and omit others altogether. Their purpose must be to convey to the student the principles underlying the inter-relations, distribution and numbers of animals, and to give him at the same time an introduction to the methods by which knowledge can be advanced. To a considerable extent these objects can be achieved independently of the actual material and context chosen for illustration.

Dr. Andrewartha's book is based on the well-known and much larger work of Andrewartha and Birch, *The Distribution and Abundance of Animals* (1954). It is divided into a section on "Theory", which occupies about two-thirds of the book, and a "Practical Course", consisting of twenty interesting and varied experiments to be carried out in the laboratory. The main emphasis in the theoretical section is on the environment; and for the most part the context chosen is the kind of terrestrial environment that man has influenced in varying degrees for purposes of crop and animal husbandry. It is a world that comes closer than most to the doors of the average university department; its predominant inhabitants are insects, and its 'natural' populations are those that are not being directly subjected to human intervention or control, though they may be living in fields, orchards or cultivated soils.

Against this background the environment is broken down into four major components, namely, weather, food, other animals and a place in which to live. A chapter is devoted to each of these; they occupy respectively 43, 32, 13 and 8 pages. In this case, doubts are likely to arise as to whether the picture they convey does give the student real insight into the basic attributes of environments in general, as they affect the individual. If he tried later to apply the same principles to analysing quite different environments, let us say those of a whale, a termite or a tapeworm, Dr. Andrewartha's components might be found lacking in realism, and not always mutually distinguishable. For a carnivorous cetacean, Where is the line drawn between food and other animals; or, for an internal parasite, between weather, food and a place in which to live? The last component especially seems to provide an umbrella for miscellaneous factors not analysed at all, or not readily assignable to the other three. In one place (p. 16) the environment as a whole is said to comprise "everything that may influence [the animal's] chance to survive and multiply", a definition that gives the appearance of overlooking the great complementary influence that heredity and physiology are likely to have on survival and reproduction.

In the practical course each experiment is worked out in full; tables of actual measurements are given, and where appropriate the latter are subjected to a useful range of statistical tests; permissible conclusions are drawn and commented on. Use is made of populations of such common laboratory animals as *Paramecium*, *Tribolium*, *Calandra*, and mice; or of snails, wood-lice and insects collected out of doors and brought into the laboratory; with a little improvization the experiments could be adapted for use almost anywhere. They will give valuable experience in laboratory methods. Quantitative observation and experiment in the field, however desirable as a supplement, often present almost insuperable difficulties at this introductory level.

V. C. WYNNE-EDWARDS

PLANT CHEMOTAXONOMY

Chemotaxonomie der Pflanzen

Eine Übersicht über die Verbreitung und die Systematische Bedeutung der Pflanzenstoffe. Band 1: Thallophyten, Bryophyten, Pteridophyten und Gymnospermen. Von Prof. R. Hegnauer. (Lehrbücher und Monographien aus dem Gebiete der Exakten Wissenschaften. Chemische Reihe, Band 14.) Pp. 517. (Basel und Stuttgart: Birkhauser Verlag, 1962.) 96 D.M.

This book intends to supply information of mutual interest to workers studying the morphology of plants and those concerned with phytochemistry, who have kept apart because their methods and terminology are different.

The author, who uses the classifications of Gilbert M. Smith, and partly of A. Engler, points out that the presence of similar compounds in a variety of plants does not necessarily imply a close phylogenetic relationship because a substance may owe its origin to entirely different metabolic processes. For example, some fungi develop cyanic acid but they do not produce it by enzymatic liberation from glycosides, as do higher plants (p. 138).

The chapters dealing with the chemistry of each group are preceded by brief anatomical descriptions and followed by comments in which the findings are surveyed and correlated with those reported for other groups of plants. Frequently, addenda contain information published in recent papers, up to 1961.

The chemical parts are divided according to compounds like pigments, volatile oils, carbohydrates and fats, and are subdivided according to localization, for example, carbohydrates in membranes and in the extracellular space, or according to chemical principles, such as derivatives of phenol, resorcin, hydroquinone, pyrogallol. The great seasonal variation in the concentration of active substances is mentioned for *Taxus*, *Ephedra* and some other plants. Often, structural formulæ are given and metabolic pathways outlined. Occasionally, the presence of a compound and its derivatives in various groups of plants is tabulated, for example, for chrysophanol. Biological actions are noted, some not well known, like the anthelmintic effect of algae (p. 86 ff.), the antibiotic activity of purine derivatives (p. 143) and of certain kinds of moss (p. 189), and the fall in blood pressure caused by a chemically unidentified alkaloid from the root of *Ephedra* (p. 459).

Both morphological classification of plants and the grouping of phytochemical data meet with great problems. For example, Cronquist considers that the classification of the plant kingdom adopted in this work has outlived its usefulness and is now disappearing from the text-books. The relevant chemical literature, too, varies in its approach as the biogenesis of plant constituents is widely studied and the concept of chemical races developed. This book is a welcome source of information to those interested in botany, pharmacognosy, pharmacology and biochemistry.

L. WISLICKI

A SURVEY OF PALESTINE'S VEGETATION

Plant Life of Palestine

Israel and Jordan. By Prof. Michael Zohary. ("Chronica Botanica": New Series of Plant Science Books, No. 33.) Pp. xi+262. (New York: The Ronald Press Company, 1962.) 8 dollars.

TO write a balanced and succinct account of the vegetation of Palestine is probably one of the most difficult tasks that can confront an ecologist. Even in its pristine, undisturbed condition, a country with such diverse topographic, edaphic and climatic features must have exhibited complex vegetation patterns; but when one super-imposes roughly ten thousand years of varied and intermittent interference by man and his beasts, then Nature and artifice combine to produce a situation which almost defies analysis.

What the pristine vegetation of Palestine was really like will probably never be known with certainty, but this in no way derogates from the value of an observant naturalist's deductions. For this reason, everyone who is interested in the vegetation of the eastern Mediterranean and the Near East will welcome Prof. Zohary's book, which, it must be added, fully acknowledges all the difficulties, and outlines the present characteristics of Palestine plant-life, and its possible antecedents, with commendable impartiality and restraint. It is also very much to the author's credit that he has been able to view the subject from so many aspects, in the space of so few pages, without loss of clarity.

Topography, soils, climate, floristics, life-forms and all the more important plant-societies of Palestine are dealt with in considerable detail, and, for good measure, we are then offered valuable, and very instructive, chapters on ecological behaviour, and on the relationships of man with the vegetation, all this rounded off with an excellent list of references and index. One might wish, perhaps, that Prof. Zohary had relaxed a little, and freed himself a little more from the strait-jacket of Continental phytosociology. He is at his best when recording plain facts and personal observations—the unexpected dormancy of deciduous trees during the most favourable season for growth; the anomalous behaviour of the carob tree, or the failure of tall trees and bushes to invade protected areas of batha and garigue—and one hopes that his successful completion of this book will now encourage him to set about writing a more leisurely, contemplative one, with ample digressions on the quirks and oddities of plant behaviour in Palestine, and speculations on the history and relationships of Palestine plants and plant associations. Such scientific ruminations would be a valuable supplement to the factual austerities of the present volume, and, coming from one with such extensive field experience in the Palestine area, would be an important contribution to that remote but most alluring of goals—an all-embracing survey of Mediterranean vegetation and its history.

R. D. MEIKLE

MYTHOLOGY OF THE ORIENT

Oriental Mythology

The Masks of God, Vol. 2. By Joseph Campbell. Pp. x+561+23 illustrations. (London: Secker and Warburg, 1962.) 50s.

IF Volume 1 of *The Masks of God*, adversely reviewed in *Nature* (187, 7; 1960), was an unsatisfactory hotch-potch, with this second volume Dr. Campbell executes a *tour de force*. Concerned now with the mythologies of the great civilizations of India, China and Japan, Dr. Campbell has plenty of literary, historical and archæological evidence to guide him in identifying what he most happily calls the mythological 'signatures' of these civilizations. No longer basing his argument on supposition, pseudo-biology, and inadequate ethnographic reports, he moulds his analysis consistently on the firmer ground of 'social representation'. His main point is to show how, as much to-day as in the past, the East is dominated by monistic thought: the individual, a monad or parcel of monads, is but an illusory projection of the social or moral order on one hand, and the divine order on the other. Indeed, the individual only begins to be relevant when merged with the void, when nothing becomes nothing.

In Western eyes this last is more than a paradox: it is a contradiction without meaning. 'Quite so!' the Easterner might comment: and the gulf between different modes of understanding remains. In contrasting this Eastern 'signature' with the Western—where the notion of the individual bestrides the world—Dr. Campbell seems to attempt, rather uneasily, to bridge the gulf. Since both modes of thought had a common source—in Sumer, that first of all flights into the civilized condition—he seems to say, and since, through several millennia, the civilizations of the East have flowered because of fertilizing influences from the West, a *rapprochement* is possible. Perhaps. Certainly this volume in itself could be a step away from Kipling's dictum.

One says 'could be' rather than 'is' because, though the reader will find this book a mine of information, not only are syntheses such as this two-edged and inherently vulnerable to attacks from many quarters, but also this particular volume is both too long and too short. The former because the central statement is apt to be lost in a plethora of detail and a rather diffuse style, and the latter because specialists will quarrel at the use and interpretations of their particular contributions. Nevertheless, here is a book worth reading and worth keeping for dipping into. One looks forward to Volume 3, which is to consider Western mythologies, and then—may one hope for a brief and concise statement?

K. O. L. BURRIDGE

THE INTERNATIONAL RESEARCH AND DEVELOPMENT CO., LTD.

THE International Research and Development Co., Ltd. was formed in December 1962 as an independent organization undertaking a wide range of scientific and technical operations for industry and Government agencies in the United Kingdom and overseas. The directors are: Lord Fleck (chairman), Dr. H. M. Finniston (managing), G. M. Baker, Dr. A. T. Bowden and Sir Harold Mullens. The secretary is W. A. Ranson.

The company was first established in April 1959 as the Nuclear Research Centre of C. A. Parsons and Co., Ltd., at Heaton, Newcastle upon Tyne. At that time it was principally concerned with special aspects of the research and development required by one of the consortia authorized to build nuclear power stations in Britain. It soon became apparent, however, that the trained manpower, disciplines, facilities and techniques appropriate to nuclear investigations could be applied to a wider spectrum of established and advanced industrial activities. To assist industry to maintain itself in the van of technological progress, the Centre extended its services to include such interests as masers, magnetoplasmadynamics, superconductivity and solid-state physics.

International Research and Development Co., Ltd., places a staff of 500 at the disposal of organizations which require technical assistance in the fields of engineering, metallurgy, physics and chemistry. This staff includes 230 graduate scientists and technical personnel with professional qualifications.

The laboratories are on a six-acre site within two miles of the centre of Newcastle. The main block of laboratories and offices contain metallurgical, physics, computing and basic engineering facilities as well as administrative and supporting services (Fig. 1). In separate buildings are a materials fabrication laboratory, an engineering laboratory and a 140-ft. test tower. The floor space totals more than 130,000 sq. ft.

The laboratories were formally opened by the Right Hon. F. J. Erroll, President of the Board of Trade, on January 21.

The following are general descriptions of some of the activies and facilities of International Research and Development Co., Ltd.

Metallurgy

Metallurgical research is carried out in laboratories well equipped for mechanical creep and corrosion testing, metallography, electron microscopy, X-ray diffraction and materials fabrication. Rare and refractory metals and alloys with nuclear and non-nuclear applications, as well as the common metals, are the concern of the Metallurgy Group.

Physical metallurgy. An important part of the metallurgical effort has been concentrated on materials for fuel elements for the natural uranium/magnox gas-cooled type of nuclear reactor. Investigations of uranium have been directed to the understanding and prediction of its growth and swelling under irradiation, its response to heat treatment when alloyed, its creep behaviour when subjected to cyclic temperature variation and its behaviour when transformed to the higher temperature β-crystalline state. As the addition of small amounts of alloying elements may improve various properties of uranium, assessments are being made of different binary and ternary additions. This Group is equipped to prepare thermal equilibrium diagrams.

As the can containing the uranium in a reactor must maintain its integrity under arduous operating conditions, the mechanism of intergranular cavity formation in magnesium alloys under slow rates of strain has been examined. Other investigations have been concerned with the effects of heat treatment and alloy composition on grain size, creep strength and ductility in magnesium-base alloys.

For reactor systems other than the magnox type, various aspects of the metallurgy of beryllium, zirconium and appropriate stainless steels have been studied.

Outside the nuclear field, investigations have been made of brazed joints, of welds in ferrous and non-ferrous metals, of non-ferrous alloys with niobium additions and of superconducting materials such as niobium–zirconium, vanadium–gallium and niobium–rhodium.

Engineering metallurgy. The greater part of the engineering metallurgical work concerns the examination of materials for large-scale engineering applications.

The present trend in heavy engineering designs to increased size and to wider working ranges of temperature and pressure has added to the importance of the selection and assessment of materials, and in the Company many investigations are devoted to high- and low-temperature materials in a variety of atmospheres (steam, air, carbon dioxide, etc.).

General investigations are made of processing techniques, including assessments of new methods of mechanical and heat treatments, such as ausforming in modern steels. Operations investigated range from the specialized brazing of small components to the welding of large sections of heavy electrical plant and large diameter pipework for marine use. Among other investigations are those relating to frictional wear in large bearings and gas seals, erosion of turbine blades by impact with condensed-steam droplets, surface breakdown during electrical discharge and factors affecting iron loss and magnetic permeability of various materials.

The extensive test facilities include equipment for the examination of stress rupture, for the selective high-sensitivity measurement of creep up to 750° C and for measuring mechanical properties down to $-200°$ C. Among the methods used for investigation and non-destructive testing are eddy currents, hot stage microscopy, magnetic behaviour, ultrasonics and potentiostatic measurements.

Non-Metallic Materials

Among the more useful ceramic materials, which can be loosely defined as high melting-point inorganic compounds, are the metal oxides, carbides and nitrides. Ceramics are of interest in modern technology mainly because they can be used at high temperatures, but their hardness, low electrical conductivity and, in the case of nuclear ceramics, good stability under irradiation are also important properties.

The fabrication and properties of uranium dioxide, uranium carbide and uranium oxide/stainless steel cermets have been investigated in the Company's laboratories. These materials were prepared from powders by either sintering, melting, a mechanical hot-working technique such as swaging or rolling, or a combination of these processes. Properties such as thermal conductivity, thermal expansion and mechanical strength have been measured up to 1,000° C. In some high-temperature applications, for example, the magnetoplasmadynamic generator, the volatility of ceramics becomes appreciable. The volatilities of a large number of oxides have been measured at temperatures up to 2,300° C.

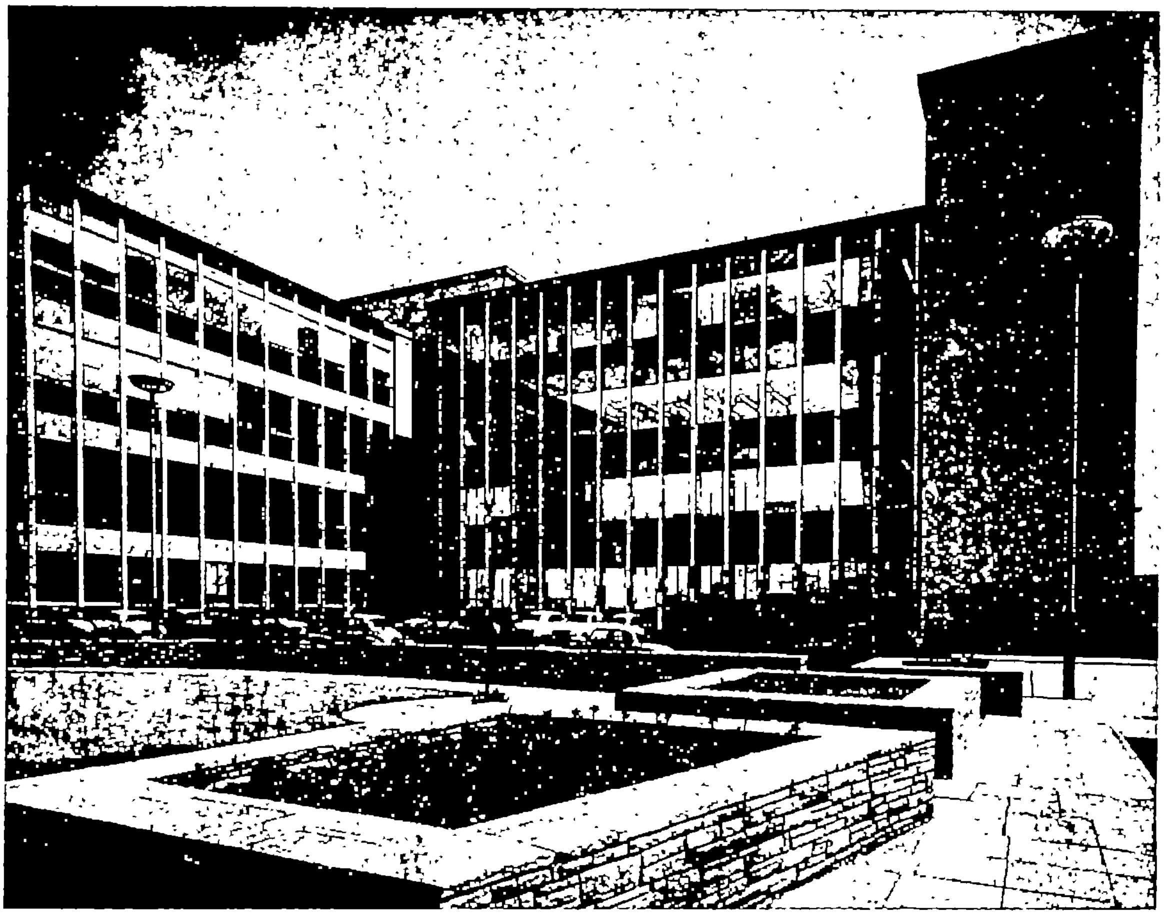

Fig. 1. The International Research and Development Co., Ltd., Newcastle upon Tyne

Other work includes the measurement of the electrical and thermal properties of magnesia powders for mineral-insulated cable, the growth of ceramic single crystals suitable for laser operation and the measurement of the thermionic emission of some materials stable at high temperatures.

Oxide semiconductors, especially materials with large positive and negative temperature coefficients of resistance, are being examined over certain temperature ranges. These materials are expected to have many technological applications in temperature measurement, control circuits and switching.

Chemistry

The corrosion behaviour of metals, alloys and non-metallic materials is especially important in engineering. An examination of the corrosion reaction between gases and solids, particularly those encountered in nuclear and conventional power plants (including gas turbines), is under way.

Mild, low-alloy and austenitic steels are being subjected to extremely long-term (up to 15,000 h) corrosion tests in carbon dioxide/monoxide mixtures in the ranges 150–300 lb./in.^{2} and 450°–750° C. Similar tests in steam at atmospheric pressure and up to 650° C are being made on low-alloy and high-chromium ferritic steels, austenitic stainless steels, nickel–chromium alloys and various hard metals towards the development of new and improved materials for advanced steam-power generating plant. Steam corrison experiments are also being carried out on newly developed zirconium alloys. Advanced techniques used in these experiments include interference microscopy for surface profile effect and radioactive tracers for diffusion measurements.

The corrosion of steels in flowing water of controlled *p*H and oxygen contents, with and without γ-irradiation, is also being examined.

Facilities are available for the detailed examination of the many types of reaction between solids, liquids and gases. A section is devoted to research and development on advanced chemical analytical techniques, including infra-red absorption spectroscopy, flame spectrophotometry, gas chromatography and the use of radioactive tracers. In addition, facilities exist for the routine chemical analysis of many industrial products.

The mechanisms and kinetics of the oxidation of graphite in air and the inhibiting effect of various compound additives on such oxidation are being studied. The aim of these experiments is to provide a volatile compound suitable for injection to extinguish a graphite fire under accident conditions. An investigation is also being made of the corrosion/erosion processes which occur at graphite anodes as used in the electrolysis of brine.

Investigations have been made of the thermal decomposition of carbon monoxide in carbon dioxide/monoxide mixtures, especially of the characterization of certain iron-bearing catalysts and the conditions under which they are effective. The carbon deposited in this catalytic decomposition of carbon monoxide at about 550° C is graphitized to a degree equivalent to that obtained with a thermal graphitization temperature of about 2,000° C. Simulation of carbon monoxide breakdown under irradiation has been achieved using an electron discharge, and the resultant carbon sub-oxides are being characterized using infra-red spectroscopic analysis.

Development work is being conducted on the production of graphitized carbon by the catalysed decomposition of carbon monoxide and on water purification by ion exchange and electrodialysis.

Engineering

Engineering covers a wide range, and varies from the construction of a large reactor test core to the investigation of sticking fuel element end fittings, and from the cooling of power transformers to the performance of gas-lubricated bearings.

Reactor projects. The building costs and safety requirements of nuclear reactors are such that before any reactor is built the satisfactory long-term behaviour of all components must be proved. This testing, sometimes of complete circuits, at other times of individual components, requires a large amount of specialized experimental plant.

Dragon reactor. The high-temperature gas-cooled reactor concept, on which the O.E.C.D. 20-MW *Dragon* project is based, involves radically new designs of core and fuel elements. The fuel elements are of highly enriched uranium dispersed in graphite and are clad in impermeable graphite. The test plant, designed and constructed in the Company, represents a section of the reactor core and consists of seven elements, each of seven hollow graphite rods. The elements are electrically heated and subjected to the conditions of gas flow, temperature, pressure and heat rating expected in the reactor; the total electrical heat input to the test core exceeds 3·5 MW. Extensive measurements of gas and surface temperatures, gas flow and pressure, vibrations and strains will give information on the thermal and mechanical behaviour of the reactor core. The continuous removal of oxidizing impurity gases from the helium is also being investigated. The information obtained should help to solve many other problems associated with the use of high-pressure helium in large vessels and helium in contact with graphite at high temperatures.

Steam-generating heavy-water-moderated reactor (*SGHW*). An alternative to the graphite-moderated gas-cooled reactor of the present British programme is the water-moderated steam-generating reactor with its many variants of moderator arrangement. The proposed fuel element for the heavy water (*SGHW*) reactor is a closely spaced multi-rod cluster. As the design is largely based on experience with single rods the experimental testing and determination of burn-out flux are of great importance. The Company has designed and built a test rig to simulate the operation of one complete fuel channel at reactor conditions of flow, pressure and temperature. The test section, containing an electrically heated multi-rod fuel element delivers a steam-water mixture into the main circulation loop. The heat input of more than 1 MW is supplied to all the rods except one, which is designed to allow a hot patch to be operated up to 'burn-out' heat fluxes.

Fuel element development. Engineering aspects of fuel element design fall into two sections: thermal and mechanical. In both cases important contributions have been made in the Company's laboratories, notably in the introduction and development to an advanced stage of the polyzonal spiral fuel element now being used in nuclear power stations in the United Kingdom.

The output of any reactor fuel element is in general subject to the two major limitations of maximum permissible cladding temperature and maximum permissible fuel temperature. Excluding metallurgical problems, the first of these limitations is largely governed by the efficiency of the heat transfer mechanism between cladding and coolant. Investigations have been made of the heat transfer characteristics of radial and longitudinal finning and, in particular, a form of spiral finning in which the cooling gas is continually being forced to leave the space between the fins and mix with the main coolant stream. New surface configurations are investigated in open-circuit air rigs or in high-pressure carbon dioxide closed loops to simulate design operating conditions of temperature, pressure and power rating. The results are processed by the Company's digital computer to yield the Stanton number, friction factor and Reynolds number which represent non-dimensionally the heat transfer, pressure drop and mass flow respectively.

Full facilities exist for the manufacture and mechanical testing of prototype fuel elements. Investigations in progress include the examination of the modes of failure of end assemblies under excessive compressive or tensile loadings, the relaxation of the can with respect to the uranium rod during thermal shock and cycling, the possibility of bowing of the element during its lifetime and the sticking of element end fittings during operation. The test furnaces vary in size from those required for a fuel end assembly to others capable of containing a full 30-ft. long stack of elements with the temperature varied along the length to simulate a reactor channel. To examine the rattling and vibration of fuel elements in coolant gas flow, single and stacked elements can be exposed to circulating cold carbon dioxide in a three-column vibration rig in the test tower. In this rig gross movements are observed through transparent windows between the mild steel duct sections, while fine movements are measured with capacity probes, accelerometers and strain gauges.

The continued action of reactor gases on hot elements may in time produce distortions which affect stability of heat transfer characteristics. To investigate this, stacks of fuel elements in vertical graphite channels are subjected to endurance tests, usually in carbon dioxide, under reactor gas-flow conditions. In an associated loop the loading, separation and discharge of strings of connected and thermocoupled elements are simulated under reactor operating conditions.

Gas-lubricated bearings. Although small gas bearings have been used for a number of years in various mechanisms such as wind-tunnel balances and electronic computers, little interest was taken in their application to heavily loaded shafts in large machinery until an incentive was provided by the development of gas-cooled reactor techniques, especially those using helium coolant.

The two major advantages of hydrodynamic gas bearings in gas circulators for reactor circuits are the elimination of oil lubrication with its attendant problem of oil leakage into the coolant and the elimination of gas seals to prevent the leakage of possibly radioactive coolant into the atmosphere. One great disadvantage is that gases have very low viscosities and during stopping and starting do not provide adequate lubrication. Thus for large bearings the selection of two compatible bearing materials, which have good wearing properties and are not subject to pick-up, is of importance. The low viscosities also require extremely fine clearances between the bearing surfaces to provide the requisite lifting forces. Test equipment has been built and operated in the Company for the study of all these problems.

Instrumentation. To meet the requirements of power stations, the Company has undertaken the design, development and supply of many instrumented systems of recording and control.

The Company has provided a large proportion of the instrumentation for nuclear reactors in the United Kingdom and overseas, having undertaken all phases from design to on-site maintenance. Typical installations include in-pile temperature, neutron-flux and gas-monitoring systems to take detailed measurements without interference with the normal charge and discharge of fuel elements. The associated data handling and overall automatic control equipment has also been built by the Company.

Instruments designed for a wide field of applications range from a simple fail-safe water detector to a capacitance-operated displacement indicator measuring to an accuracy of 0·001 in. in an environment of 1,000° C and 1,000 lb./in.^{2}.

Solid-state devices are being used in the equipment as much as possible to increase reliability and reduce maintenance. Control systems for d.-c. machine-tool motors of up to 10 horse-power have incorporated silicon-controlled rectifiers, which have also been used in alarm annunciator systems and in a.-c. power regulators. Regulators of up to 20-kW rating have been manufactured, and design studies completed for ratings up to 500 kW.

The many items of electronic equipment designed and built for specific purposes have included simulators for the study of reactor control problems and for the training of reactor operators.

Physics

The work of the Physics Group includes some of the more fundamental research and more novel investigations being made by the Company, including magnetoplasmadynamic conversion of heat directly into electricity and the superconductivity of materials at low temperatures.

Direct generation of electricity. Anticipating the eventual development of large-scale steam turbo-alternator plant to overall thermal efficiencies of about 45 per cent, it follows that any future performance improvement must be achieved through a radical change in technique. It appears impossible to better the performance of the steam plant at the temperature range over which it operates; consequently, interest must be directed towards utilizing higher temperature heat sources in conjunction with energy conversion systems which do not require highly stressed rotating parts.

The magnetoplasmadynamic generator, in which electrical energy is extracted from a plasma flowing through a transverse magnetic field, falls into this category and, of the presently known energy conversion techniques, appears to offer the most attractive possibilities for multi-megawatt power requirements. Therefore, the magnetoplasmadynamic generator has been selected for study as a long-term project and an experimental closed-cycle plant has been built by the Company. This has a mixture of helium and caesium as the working fluid and will operate at temperatures of 1,500°–2,200° C. As helium, or other chemically inert gas, would probably be used as the coolant in very high temperature nuclear reactors, such as might be developed from the O.E.C.D. *Dragon* project, this research is closely related to nuclear fission power.

A number of supporting experiments to evaluate plasma basic parameters are in progress, and diagnostic techniques include microwaves of 3 cm, 8 mm and shorter wave-lengths, spectroscopy and the use of Langmuir-type probes.

Experimental investigations are being made on the caesium-neutralized diode and also on a type of thermionic power generator in which space charge neutralization is produced by an auxiliary plasma discharge. Such thermionic generators are suitable for specialized applications in which powers from a few watts to a few kilowatts are required. Thermoelectric power generators for outputs up to a few hundred watts are being designed and constructed for applications in which their silence and reliability characteristics are particularly attractive.

Applied physics. The measurement of the physical properties of materials and a better knowledge of the solid state are important spheres of activity in applied physics. Work includes investigations of superconductivity, lasers and materials with large positive temperature coefficients of resistance, and measurements of thermoelectric properties, thermal conductivity and expansion, radiation emissivity, magnetostriction, hysteresis loss and electrical resistivity. Emphasis is placed on relations between the physical properties, examples being the correlation of thermal expansion with irradiation grain growth in uranium and the correlation of changes in Seebeck coefficients of metals and alloys with cold work. The application of physical principles to the development of modified eddy current techniques is under way, as are other non-destructive methods of testing for general use.

The existence of metals which show zero electrical resistance at temperatures near the absolute zero (usually in liquid helium which boils at about 4·2° K) has been known for many years. However, it is only recently that compounds and alloys have been discovered which have practical use in the construction of superconducting solenoids for producing high magnetic fields (greater than 50 kilogauss). Since Joule losses are eliminated and current desities can be extremely high, these promise to be more compact and economical than similar equipment using conventional techniques.

Many aspects of applications of superconductivity are being studied, including the design of refrigeration systems to produce the necessary low temperatures, feasibility studies of superconducting transformers, and the physical factors associated with the superconducting properties of selected materials produced by the Company. Prototype superconducting magnets and transformers have been constructed and tested.

Crystallography. Crystallographical research in the Company mainly concerns microstructural problems related to the performance of materials.

One major project is aimed at understanding the basic mechanism of the oxidation of graphite. Flakes of natural graphite have been examined in the electron microscope, both before and after oxidation, to determine the part that lattice or surface imperfections play as sites of active oxidation. The frequent concentration of oxidative attack in long narrow channels, changing direction in a crystallographic manner and with an impurity particle at the head of each channel, seems to indicate that catalytic oxidation is taking place. In this work an important facility is a specimen stage which permits the heating of graphite, or other materials, in a controlled atmosphere inside the electron microscope at temperatures up to 1,300° C, so enabling the oxidation process to be observed directly. The electron microscope is also used for the monitoring of crystallite size during the graphitization of thin films of amorphous carbon prepared by vacuum evaporation.

Another typical investigation has been the relating of microstructure to magnetic properties in evaporated films of iron–3·25 per cent silicon, the type of alloy used in transformer core sheet.

The X-ray laboratory includes diffractometer and microfocus units. Subjects examined have included the evaluation of lattice parameters for uranium carbides with different carbon contents, the determination of preferred orientation in uranium and beryllium, and the examination of various corrosion products and deposits in oils.

Irradiation. Experimental irradiation equipment has been developed and built by the Company for operation in research reactors of various organizations at home and abroad.

A typical project is the undertaking, in conjunction with the Nuclear Power Group and the Italian organizations Agip Nucleare and C.N.E.N., of a series of irradiation tests in the Euratom high-flux research reactor at Ispra. Specimens of enriched uranium and uranium alloys, manufactured by the Company, are irradiated to high burn-up in rigs, each of which consists essentially of a water-cooled assembly containing ten doubly canned stainless steel capsules in a helium atmosphere. Each capsule is capable of accommodating up to three specimens which are immersed in liquid sodium for improved heat transfer. Temperatures are carefully monitored and a 'thermal-history' rig outside the reactor identifies effects due to temperature alone. Theoretical studies include the evaluation of the uranium-235 enrichment necessary to achieve a given burn-up of fissile material in a fixed irradiation time, and the assessment of nuclear changes in the specimens as a function of irradiation dosage. Radiation shielding requirements and the radioactivity of rig components after irradiation are also calculated.

Health physics. All work with radioactive and toxic materials in the laboratories is constantly monitored by the Health Physics Section. This Section also advises on safety procedures for new techniques or materials and, as a public service, assists external organizations.

Theoretical Services

The Theoretical Group carries out mathematical investigations of problems which arise during practical research, and provides a service for the performance of routine calculations. It has a variety of analogue computers and a Ferranti *Pegasus* digital computer.

One of the major theoretical contributions has been an analysis of the creep of uranium, under thermal cycling and under irradiation, based on the assumption that deformation is locally homogeneous and that the difference in the expansion along the three crystal axes causes internal stresses which accelerate the creep rate. The theory has been applied to predict the rate of collapse of hollow fuel elements under external pressure, the rate of bowing of stacked fuel elements, and the swelling of uranium caused by the formation of bubbles of gaseous fission products.

There is an exceptionally flexible analogue computing service, using computers designed and built in the Company. These are used to simulate many operations and can be readily programmed to study overall automatic control equipment and the dynamic behaviour of engineering plant and systems, such as boilers and turbines.

The computing services are frequently used in design studies. These have included investigations of vibrations in large bearings and stresses in bodies of unusual shape, and the design of transformers, dry cooling towers and magnetoplasmadynamic power generators.

High-Voltage Laboratory

At present most of the high-voltage work at the Company concerns corona investigations. Both fundamental and practical studies are being made of corona discharge effects in solid insulation and liquid-immersed insulation assemblies. Electrical measurement aspects of corona discharges are also examined to evolve diagnostic techniques to determine the nature and extent of possible discharges and discharge damage, not only in small samples but also in complete assemblies. An extensive investigation has been made of the breakdown mechanism in high vacuum.

A typical investigation is that of the parameters affecting gas evolution in an electrically stressed oil gap, leading to the eventual breakdown of the oil. Other projects include investigations of conduction currents and the assessment of practical aspects of insulation processing.

To facilitate low-level discharge measurements the main Corona Laboratories have been screened, reducing the external radiofrequency disturbances from 40,000 μV to 6 μV at 1 Mc/s, and a corona-free high-voltage busbar system has been developed to avoid direct interference from the test equipment.

Equipment is available for experimental techniques involving direct recording of corona pulses by ultra-fast oscilloscopes and for pulse amplitude/frequency analysis using pulse counters. High-voltage bridges, dispersion meters and equipment for the calibration of all instruments is also available. Voltage sources include a 300-kV insulated tank transformer, noise free up to 150 kV, a 150-kV stabilized d.-c. supply and several smaller high-voltage sets.

Production Facilities

The specialized engineering facilities and the experience gained in the preparation of test and experimental equipment enable the Company to manufacture prototype and early production models of many components and instrumentation units for outside organizations.

Among the items the Company produces for nuclear purposes are irradiation rigs and instrumentation, nuclear fuels (including high-density uranium carbides), reactor simulators, experimental test rigs and many other reactor components. Products with an engineering bias include silicon-controlled rectifier units to control furnaces and motors, machines to measure the creep of materials in vacuum, water-cooled heaters of ratings up to 25 kW/ft.-length and vacuum tantalum furnaces operating at up to 2,200° C. More specialized products, usually designed for particular requirements, include arc jets. devices based on lasers, semiconductor devices, rare metal alloys (including superconducting materials) and equipment for plasma physics and cryogenics.

Client Relationship

All contracts are initiated by 'Project proposals', which establish the work required, suggested approach, staff assignment, estimated time and cost, and reporting arrangements. Unless an especially detailed preliminary study is required, this proposal is submitted to the client without financial obligation.

All sponsored work is confidential and senior staff have Government security clearance appropriate to their work. Any patent arising from a project is the property of the client.

NATURE OF STRONG RADIO SOURCES

By Prof. F. HOYLE, F.R.S., and Prof. WILLIAM A. FOWLER
California Institute of Technology, Pasadena, California

IN a recent paper[1] we have considered the possibility that masses of gas, $10^5 M_\odot$ to $10^8 M_\odot$, may accumulate at the centres of galaxies, and may behave as stars. The existence of such objects is supported theoretically by the energy requirements of strong radio galaxies, $\sim 10^{60}$ ergs or more[2,3], which seem to demand large aggregations which either draw on nuclear energy or on the very considerable gravitational energy that can arise in a massive body of stellar dimensions. The reason why gravitation can play a decisive part in the evolution of a very massive body is that the gravitational energy depends on $|\Omega| = GM^2/R$, where G is the gravitational constant, M the mass, and R a characteristic dimension. Since gravitational energy depends on the square of the mass, it can be of decisive importance for bodies in the range $10^5 M_\odot$–$10^8 M_\odot$, whereas it is in general unimportant in ordinary stars.

The view that such objects can exist is supported observationally by the Seyfert galaxies[4], which possess nuclei having dimensions of ~ 100 parsec containing gas in violent dynamical motion with velocities from $\sim 1{,}000$ km sec^{-1} to $\sim 5{,}000$ km sec^{-1}, the total dynamical energy of the gas being of order 10^{54} ergs. The energy in emission lines amounts to $\sim 10^{43}$ ergs sec^{-1}, corresponding to an astronomical magnitude of about -19. In ref. 1 our consideration of the hydrogen-burning phase for a star of mass $\sim 10^{8}\ M_\odot$ showed that the magnitude is in the region of -18. Moreover, the total energy output from the whole hydrogen-burning phase is $\sim 10^{57}$ ergs, which is of the order observed in the Seyfert galaxies.

We may add that although Seyfert galaxies appear at first sight to be uncommon objects, comprising perhaps 1 per cent of all major galaxies, their very short lifetimes, as galaxies with nuclei in eruption, imply that their number taken over a cosmological lifetime of $\sim 10^{10}$ years is high. To explain the observed frequency of Seyfert galaxies it is necessary that the average major galaxy (mass $> \sim 5 \times 10^{10}\ M_\odot$) shall undergo an outburst 10–100 times during its lifetime.

Two or three of the Seyfert galaxies are radio sources of intensities intermediate between normal galaxies and the strong sources. Our suggestion is not therefore that the observed activity explains the strong sources, but rather that the observed activity in Seyfert galaxies is a weak example of the process that gives rise to the strong sources—explicitly that masses of $\sim 10^{8}\ M_\odot$ are involved in the strong sources rather than 10^{5}–$10^{6}\ M_\odot$.

In our former paper[1] we considered evolution beyond helium burning, up to temperatures of $T_9 = 1$ or 2 (T_9 is in units of 10^9 K). We were concerned with comparing the loss of energy due to neutrino emission and the energy released by the burning of oxygen-16. Our aim was to show that the latter was greater than the former, and that an explosion could ensue from catastrophic oxygen burning, in analogy to what we have found[2] for stars with masses of $\sim 30\ M_\odot$. Our conclusion was that such explosions could occur, and we termed them super-supernovae. However, it has appeared on further investigation that this conclusion, in the form in which we stated it, was erroneous. The energy required for the creation of electron-positron pairs, which we had found at $M \simeq 30\ M_\odot$ to be less than the yield of energy from burning oxygen, turns out to play a dominant part at very large masses. It entirely overwhelms any form of nuclear energy generation, which therefore cannot lead to an explosive outburst of a really massive star. This is not to say that very massive stars cannot undergo violent disruption, but that the cause of disruption does not lie in a sudden nuclear energy generation at $T_9 \simeq 2$, as it probably does in ordinary supernovae.

During burning of hydrogen and helium the star is entirely convective (it being assumed that convection is not inhibited by a magnetic field). During these phases the ratio β of gas pressure to total pressure is $\ll 1$, and the density is proportional to $M^{-1/2}T^{3}$, both for a particular element of material as the star evolves, and also from one element to another at any moment. The radius R of the star is proportional to $M^{1/2}$ and to the reciprocal of the central temperature T_c; in fact:

$$R \simeq \frac{5{\cdot}8 \times 10^{9}}{(T_9)_c}\left(\frac{M}{M_\odot}\right)^{1/2} \text{ cm} \tag{1}$$

where $(T_9)_c$ is in units of 10^9 deg K. During burning of hydrogen $(T_9)_c \simeq 0{\cdot}07$, so that $R \simeq 8 \times 10^{10}\ (M/M_\odot)^{1/2}$ cm. The radius is about seven times smaller than this during burning of helium when $(T_9)_c \simeq 0{\cdot}5$.

After burning of helium to oxygen-16, which lasts for $\sim 10^{4}$ years or less, the central temperature rises. As $(T_9)_c$ approaches unity, neutrino losses shorten the evolution time to about a day. This, however, is the main physical effect of the neutrino losses, since pair creation then dominates energy considerations. With pair creation dominant we have the following formulæ, deduced on the basis that the star is still in approximate hydrostatic equilibrium as a polytrope of index $n = 3$:

$$\beta \simeq \frac{180}{\pi^4}\bar{K}_2\left(1 + \frac{180}{\pi^4}\bar{K}_2\right)^{-1} \tag{2}$$

$$\mu \simeq \left(\frac{180}{\pi^2}\right)^{1/2}\left(\frac{M_\odot}{M}\right)^{1/2}\left(1 + \frac{180}{\pi^4}\bar{K}_2\right)^{3/4}\left(\frac{180}{\pi^4}\bar{K}_2\right)^{-1} \tag{3}$$

$$\mu\beta \simeq \left(\frac{180}{\pi^2}\right)^{1/2}\left(\frac{M_\odot}{M}\right)^{1/2}\left(1 + \frac{180}{\pi^4}\bar{K}_2\right)^{-1/4} \tag{4}$$

$$\rho \simeq 1{\cdot}30 \times 10^{[illegible]}\left(1 + \frac{180}{\pi^4}\bar{K}_2\right)^{3/4}\left(\frac{M_\odot}{M}\right)^{1/2} T_9^{3} \text{ g cm}^{-3} \tag{5}$$

and equation (1) becomes:

$$R \simeq \frac{5{\cdot}8 \times 10^{9}}{(T_9)_c}\left(\frac{M}{M_\odot}\right)^{1/2}\left(1 + \frac{180}{\pi^4}\bar{K}_2\right)_c^{-1/4} \tag{1'}$$

Here ρ = density, β = ratio of gas pressure to total pressure, μ = mean molecular weight, $\theta = m_e c^2/kT$ and $\bar{K}_2(\theta) = \frac{1}{2}\theta^2 K_2(\theta)$, K_2 being the modified Hankel function of order two. Note that $\bar{K}_2(\theta)$ is normalized to unity as $\theta \rightarrow 0$, $T \rightarrow \infty$. At low temperatures $\bar{K}_2(\theta)$ approaches zero. In equation (1′), c designates centre. The foregoing expressions have been derived on the assumption that the electron–proton pairs are much more numerous than the electrons associated with nuclei but are still strictly non-degenerate. More accurate expressions for pairs dominant but not necessarily non-degenerate can be derived on the assumption that the chemical potential is zero for electrons and positrons in which case $\bar{K}_2(\theta)$ is replaced by various series expansions involving $\bar{K}_2(n\theta)$, $n = 1, 2, 3, \ldots$. At $T_9 \sim 1$ the foregoing expressions are sufficiently accurate for $M/M_\odot \gtrsim 5{,}000$ and at $T_9 \sim 2$ for $M/M_\odot \gtrsim 100$. The expression for β is independent of the assumption that the star is a polytrope of index $n = 3$. The numerical coefficients in the remaining expressions are not too sensitive to this assumption.

As T_9 approaches 2 the energy necessary for pair creation must be supplied by gravitation—it cannot be supplied by oxygen burning, as it is in stars with $M \simeq 30\ M_\odot$. This leads to a departure from hydrostatic equilibrium and the above formula relating ρ and T is no longer valid, the density rises without the temperature keeping step.

In this connexion we have derived the following curious result. For a normal star all equilibrium states possess negative total energy, that is, less energy than a dispersed state at infinity. But in the case of very massive stars, with T_9 high enough for pairs to play a critical part, the equilibrium state has positive total energy. We find the excess of energy, Q, compared with the dispersed state, is:

$$Q = \tfrac{1}{2}\,|\Omega|\, < \beta \,d\ln\bar{K}_2/d\ln T > \tag{6}$$

where again $|\Omega|$ is the absolute magnitude of the total gravitational energy of the star. The average must be taken throughout the star. But, since β and $d\ln\bar{K}_2/d\ln T$ are everywhere positive, the average is positive. In deriving this result we included the rest mass of the pairs. If this had not been included we should have obtained a negative value, as in the normal case. However, since pairs annihilate on dispersal our procedure would seem to be correct. At $M = 10^{8}\ M_\odot$ the rest mass of the pairs is comparable with that of the original nuclei when high temperatures are reached.

It is emphasized that hydrostatic equilibrium was assumed in obtaining the above result. An actual star need not be in hydrostatic equilibrium—indeed, the obtaining of a positive value demands that an actual star cannot be in equilibrium once pairs dominate over the electrons that were originally present. For the total energy cannot become positive, except possibly in the case of an explosive release of nuclear energy—and for very massive stars this is not the case. Hence an actual star implodes.

Lack of mechanical equilibrium implies that dynamical velocities are generated. For the masses under consideration, these velocities are not greatly below the speed of light. Thus, the velocities are of the order of, but less than, $(GM/R)^{1/2}$. Using the equation (1′) for R:

$$\frac{GM}{R} \simeq 2\cdot3 \times 10^{15}\left(\frac{M}{M_{\odot}}\right)^{1/2}\left[T_{s}\left(1+\frac{180}{\pi^{4}}\overline{K}_{s}\right)^{1/4}\right]_{c} \tag{7}$$

For $M/M_{\odot} = 10^{8}$, $(T_{s})_{c} = 2$, $\theta \simeq 3$, $\overline{K}_{s} \simeq 0\cdot28$, $(GM/R)^{1/2} \simeq 7 \times 10^{9}$ cm sec^{-1}, while for $M/M_{\odot} = 10^{9}$ the velocity of light is approached closely.

Two possibilities now arise. First, an idealized case of spherically symmetric implosion to the relativity limit $2|\Omega| \rightarrow Mc^{2}$. As this limit is approached general relativity must be used, and the effect of radiation on the gravitational field must be considered.

A more likely practical situation is one in which the star is rotating or does not possess strict symmetry and in which portions of the star break away from a central mass. The simplest case is one in which two pieces break away, moving in opposite directions, leaving a central mass that ultimately condenses to the relativity limit. Such a central mass must always be present, since energy considerations demand that the energy of the dynamically ejected portions be compensated by the gravitational binding of the remaining mass.

We see that masses perhaps of order 10^{7} $M_{\odot}$ can in this way be ejected at speeds comparable to c. The dynamical energy is less than, but comparable to c^{2}, say $\sim 10^{20}$ ergs g^{-1}. For $M = 10^{7}$ $M_{\odot}$ this implies an outburst of $\sim 10^{60}$ ergs. This we regard as the energy of outburst of a strong radio source. Our point of view is that the energies demanded by the strong sources are so enormous as to make it clear that the relativity limit must be involved. Normal dynamical motions within a galaxy give kinetic energies of no more than 10^{16} ergs g^{-1}, and this falls far short of the radio source requirement on any reasonable basis for the total mass involved. Even nuclear energy, yielding 6×10^{18} ergs g^{-1} in the case of hydrogen burning[6], requires an outburst involving 10^{8} $M_{\odot}$. While this mass is not impossibly high, hydrogen burning is not an explosive process, as has formerly been pointed out[7]. The light elements, carbon and oxygen, are the best materials for providing a sudden outburst, but these materials yield only 5×10^{17} ergs g^{-1}, and the necessary mass is then increased to $\sim 10^{9}$ $M_{\odot}$. The situation is made worse by the circumstance that upwards of 10^{60} ergs is very likely required for the most powerful radio sources. On any reasonable basis as to the efficiency of production of radio waves, the energy required lies at maximum in the range 10^{61}–10^{62} ergs, and this seems too much to attribute to the burning of the light elements. Our present opinion is that only through the contraction of a mass of 10^{7}–10^{8} $M_{\odot}$ to the relativity limit can the energies of the strongest sources be obtained.

Finally, the materials ejected have an important bearing on nucleosynthesis, particularly in their relation to what we have called the r-process[6]. There is strong evidence that the r-process nuclei were built from seed nuclei immersed in a sea of neutrons: to build the heaviest nuclei at least 200 neutrons per seed nucleus are needed. The temperature must have been about 10^{9} deg. K, as was shown by Burbidge, Burbidge, Fowler and Hoyle[6]. At this temperature, light nuclei, magnesium in particular, are strong neutron absorbers, and hence there cannot have been large numbers of light nuclei present (as there can be in the case of the s-process, which operates at lower temperature). This led us to propose[7] that the r-process arises from a mixture of neutrons and α-particles, a mixture given by a phase change break-up of iron-group nuclei, the phase change occurring at $T_{9} \simeq 5$. Such material on being ejected from a star cools due to adiabatic expansion, and as it does so the tendency is to rebuild heavy nuclei. However, the first step of the rebuilding process 3 helium-4 → carbon-12 is slow. We pointed out that for sufficiently low density only a very small fraction of the helium is able to build to carbon-12, and this small fraction we took as our seed nuclei. But we were not really able to keep the density low enough for the case $M \simeq 30$ $M_{\odot}$, which we then considered. We wish now to point out that at much larger masses the density is significantly lower (see equation 5) and the process works without difficulty.

A further satisfactory feature is that a difficulty concerning the absolute amount of r-process material is also resolved. So long as we took supernovæ occurring at a frequency of 1 per 300 years as the seat of origin of the r-process, the amount was grossly too large, at least by two orders of magnitude[8]. We now estimate that the amount of r-process material produced per outburst is $\sim 10^{2}$ $M_{\odot}$, approximately independent of M. With about 100 such occurrences in the lifetime of the Galaxy, the total production $\sim 10^{4}$ $M_{\odot}$, in good agreement with the observed absolute abundances.

Our previous estimates of the age of the Galaxy are changed by these considerations. On the basis of the observed abundances of thorium-232, uranium-235 and uranium-238 in solar system material and the calculated production rates in r-process events, we showed[8] that nucleosynthesis occurred over an interval 7 to 8 × 10^{9} years in duration prior to the formation of the Solar System 4 to 5 × 10^{9} years ago. This sets a low limit on the age of the Galaxy equal to 12 × 10^{9} years with an uncertainty of the order of 2–3 × 10^{9} years. We placed the r-process in stars with masses just above $1\cdot5$ $M_{\odot}$ for which the evolution time is $\sim 3 \times 10^{9}$ years and thus arrived at a galactic age $\sim 15 \times 10^{9}$ years. In a later paper Fowler[9] placed the r-process in stars of somewhat lower mass and arrived at an age $\sim 20 \times 10^{9}$ years. For the reasons advanced in this work we now assign the r-process primarily to very massive stars with very short lifetimes which lie in the centre of the Galaxy and hence believe that the best present estimate for the age of the Galaxy, or more specifically the galactic nucleus, is:

$$t_{GN} = 12^{+3}_{-2} \times 10^{9} \text{ years}$$

Small stars which formed early in the history of the Galaxy and which still exist because of long evolutionary lifetimes will contain heavy elements previously produced in the rapidly evolving very massive stars. The abundance distribution among the heavy elements and their isotopes in these old stars will differ considerably from that in young stars. Elements and isotopes produced in the r-process will be relatively over-abundant compared with those produced in the s-process[10,11]. The e-process elements near iron will be peculiar in that a short time scale e-process leads to abnormal ratios of chromium, manganese, iron, cobalt and nickel and especially among the isotopes of these elements. Comparisons of old-star spectra and young-star spectra should prove to be most significant in this respect.

This work was supported in part by the Joint Program of the Office of Naval Research and the U.S. Atomic Energy Commission, and in part by the National Aeronatics and Space Administration.

EVIDENCE FROM ISLANDS ON THE SPREADING OF OCEAN FLOORS

By Prof. J. TUZO WILSON, O.B.E.

Institute of Earth Sciences, University of Toronto, Toronto, 5

THE question whether the continents have been fixed in approximately the same relative position since their creation, or whether they have moved has been debated for fifty years. Perhaps the reason that this has never been settled is that much more is known about the continents than about the ocean floors, where the decisive evidence probably lies. If the Earth has been rigid, the history of the ocean basins should parallel that of the continents and large parts of the ocean floors should be old; but, if continents have moved, those parts of the floors exposed by the motion should not be older than the time of drifting. Explorations of the ocean floors may settle this matter, but in the meantime information has been sought from the literature published about ocean islands. This article deals with the evidence so obtained of possible horizontal motions of islands. Vertical motions have been discussed elsewhere[1]. Only those islands have been considered which lie in the main ocean basins, beyond continental shelves, island arcs and the andesite line[2]. This excludes such islands as New Zealand, Fiji and the West Indies. Consideration has been given to the possibility that there may or may not have been continental drift, but that if it has occurred it could have done so in an infinite number of ways. Special attention has been directed to the hypothesis that, if continents have moved, the motion may have been due to the action of convection currents rising under mid-ocean ridges and descending under the system of young mountains and islands arcs.

Table 1 lists islands for which fossiliferous limestones provide ages and a few islands dated by other means. The oldest dates reported for each island are given, but they are, of course, only minimum ages for the islands. J. L. Kulp's time-scale has been used[3]. Madagascar, Seychelles and Falkland Islands, which are well known to be atypical, will be omitted from this discussion.

Fig. 1 is a frequency diagram of the results. It makes a remarkable contrast with a similar diagram for continents which would be close to the dotted line shown on the diagram[42–44].

One immediate reaction to this apparent youth of the islands is to suggest that the ocean basins are nevertheless permanent and old, but that the study of islands is a poor method of sampling the floors. Another possibility is that continental drift has occurred as suggested by A. Wegener and A. L. Du Toit; that F. A. Vening Meinesz, A. Holmes, D. T. Griggs, R. S. Dietz, H. H. Hess, S. K. Runcorn and others have been correct in their advocacy of convection currents; and that the youth of the islands reflects the youth of the ocean floors.

To help make a choice between these alternatives, the distance of each island to the nearest point on a mid-ocean ridge was measured. The results for the Atlantic and Indian Oceans are given in Table 1 and plotted in Fig. 2.

Fig. 2 shows that the distance of islands from the ridge increases with the age of the islands. Although the correlation is not perfect it seems adequate to suggest as one possible explanation that many ocean islands have originated over the mid-ocean ridges and that the older ones have been steadily carried away from the ridge. In the Atlantic Ocean it is noticeable that six active or very recently active volcanic islands lie along the ridge. They are Jan Mayen, Iceland, the Azores, Ascension, Tristan da Cunha and Bouvet. On the other hand, islands with Cretaceous rocks, the Bahamas, Fernando de Noronha and Cape Verde, lie close to continents, while islands of Miocene to Eocene age, like the Faeroes, Bermuda, Saint Helena and Madeira, lie at intermediate positions. All these are inactive.

One interpretation of the cause of this observation is that convection currents are rising in the mantle under the mid-ocean ridge, that greater heat there tends to produce volcanoes, but that horizontal motion carries the volcanic islands away from their source in the ridge so that they become extinct and progressively older with distance from the ridge.

The distances for the Faeroes and Iceland are short, but this may be due to the fact that, if the Atlantic Ocean spread, it must have done so by the least amount in the north. Another contributing factor was perhaps the opening of Baffin Bay, which it is intended to discuss elsewhere. Another exceptional island is Christmas Island (Indian Ocean), which has moved far considering the age of its oldest exposed rocks, but, of course, its real age may be greater, and Andrews[45] has suggested that this may be the case.

Table 1. THE OLDEST DATES, DISTANCES TO THE MID-OCEAN RIDGE, AND APPARENT MAXIMUM RATES OF MOTION FOR SOME OCEAN ISLANDS

Island(s)	Oldest ages Period	m.y.	Distance to ridge (km)	Apparent maximum rate of motion (cm/yr)	Refs.
	Atlantic Ocean				
Jan Mayen	Pliocene	10	0	0	4
Iceland	Eocene	50	150	0·8	5
Faeroes	Eocene	50	600	1·2	6
Azores	Miocene	20	300	1·5	7
Madeira Is.	Miocene (Cret. ?)	20 (90 ?)	1,500	7·5 (1·7)	8
Canary Is.	Oligocene	32	1,900	6·0	9
C. Verde Is.	L. Cretaceous	120	2,200	1·8	10
F. de Noronha	L. Cretaceous	120	2,000	1·7	11
Bermuda Is.	Eoc. or Olig.	36	2,200	6·1	12
Bahamas	L. Cretaceous	120	3,000	2·5	13
Ascension	Pleistocene (?)	1	150	1·5	14
Saint Helena	Miocene (?)	20	700	3·5	15
Tristan da Cunha	—	18	0	0	16, 17
Bouvet	Pleistocene	1	0	0	18, 19
Falkland Is.	Pre-Devonian	1,100 (?)	3,100	—	20
	Indian Ocean				
Kerguelen	Miocene	20	1,200	6·0	21
Heard	Paleocene	60	1,500	2·5	22, 23
Saint Paul	Recent	1	0	0	24
Madagascar	Precambrian	2,700	1,800	—	25
Seychelles	Precambrian	600	700	—	26
Providence	Eocene–Oligocene	36	1,600	4·4	27
Christmas	Eocene	50	3,700	7·4	28
	Pacific Ocean				
Sala-y-Gomez	Pleistocene	1			20
Nasca Seamount	Miocene	20			29
Erben Seamount	Miocene	20			30
Hess Seamount	Middle Cretaceous	90			31
Cape Johnson Seamount	Middle Cretaceous	90			31
Daito	Upper Oligocene	30			32
Truk	Miocene	20			33
Sylvania Seamount	Eocene–Paleocene	60			34
Jaluit	Middle Tertiary	32			35
Eniwetok	Upper Eocene	40			36
Bikini	Lower Miocene	25			37
Ocean	Upper Tertiary	15			38
Mangaia (Cook Is.)	Miocene–Oligocene	25			39
Atiu (Cook Is.)	Pliocene	10			40
Makatea (Tuamotu Is.)	Eocene	50			41

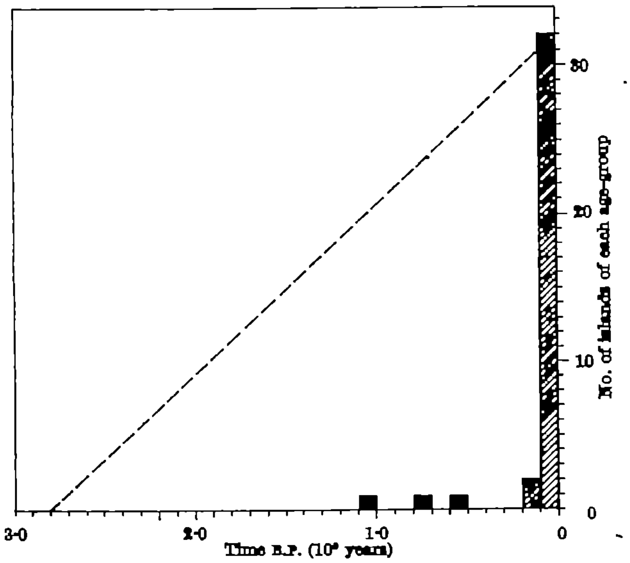

Fig. 1. Frequency diagram for ages of islands in main ocean basins. The dotted line is the corresponding curve for continents

Our method of dating islands is not precise, nor is it to be supposed that if drift occurred that all islands would have travelled at the same rate. Since the discovery of older rocks on islands would reduce their apparent rates of motion, the rates calculated and shown in Table 1 are maximum values. The average value found for the maximum possible rate of drift is 3·5 cm per year. It is interesting that this is of the same order of magnitude as that usually given for the rate of continental drift. S. K. Runcorn[46], after discussing various estimates of the possible rate of motion, concludes that 3 cm a year is the most probable value. Having regard to these uncertainties, the analysis suggests that, the farther an ocean island is from a mid-ocean ridge, the older it is likely to be, which supports the view that the floors of oceans may have grown by spreading from the mid-ocean ridges.

No such simple pattern is apparent in the Pacific islands. The explanation may lie in some combination of the following factors: (*a*) the continents are advancing over the borders of the Pacific Ocean; (*b*) H. H. Hess[47] has suggested a recent change in the pattern of mid-ocean ridges in the Pacific; (*c*) the data for the Pacific are poor, there being less dates per unit area than elsewhere, and most of those which are available were obtained by drilling or dredging; (*d*) another complexity is discussed elsewhere which suggests that some Pacific islands did not start at the mid-ocean ridge[48].

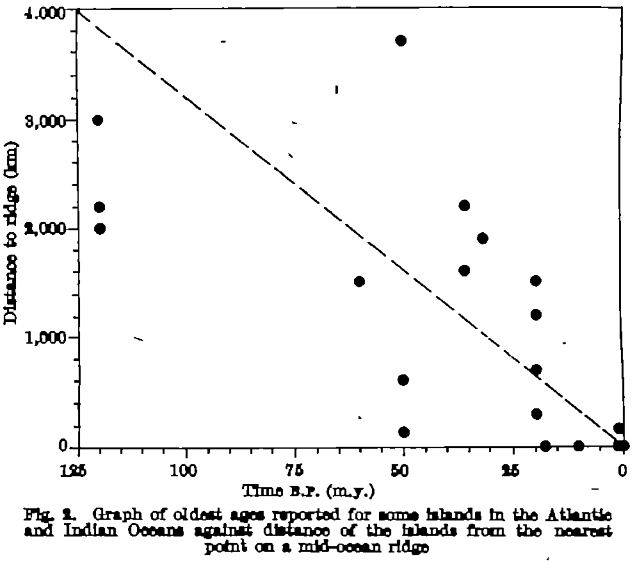

Fig. 2. Graph of oldest ages reported for some islands in the Atlantic and Indian Oceans against distance of the islands from the nearest point on a mid-ocean ridge

Examination of bathymetric charts shows that islands occur most commonly on the mid-ocean ridge at points where the ridge both changes direction and intersects a branch ridge. Iceland on the Wyville–Thomson Ridge, the Azores on the Azores Rise, Gough Island on both the Walvis Ridge and on the Rio Grande Rise and Easter Island at the point of intersection of several ridges are examples of islands so situated.

If one regards the ocean basins as permanent, one can take the view that all the ridges have formed over fractures and that places where fractures intersect are likely to be particularly favourable for extrusion. This could explain the growth of volcanoes and islands at those places. This theory has the disadvantage that it does not explain why the branch ridges are aseismic or why they are quite different in character and appearance from the mid-ocean ridge. Some branch ridges, like the Azores and the Nazca Ridge which passes through Easter and Sala-y-Gomez Islands, seem to be chains of volcanoes and seamounts quite unlike the mid-ocean ridges.

If, on the other hand, convection is occurring, it is reasonable to believe that bends in the mid-ocean ridge are associated with deflexions in the current system and that at such places reduced pressure or deeper fracturing may cause extrusion of more lava than elsewhere on the ridge. This could determine the location of volcanic islands on the ridge.

Convection also introduces horizontal motion. This would slowly move volcanoes away from their sources on the mid-ocean ridge, so that those volcanoes would cease to be active. The sources would remain fixed over the vertical currents and would produce fresh volcanoes. Thus, in time, each source on the mid-ocean ridge would produce a chain of progressively older extinct volcanoes, or perhaps two such chains, one on either side of the mid-ocean ridge (Fig. 3). Here is a possible explanation for ridges like the Walvis and Rio Grande. This proposal could be tested because the oldest seamounts on the branches should lie farthest from the mid-ocean ridge. All such branches might be flow lines. This hypothesis could explain the general parallelism of all the rises on either side of the Atlantic. The well-known herringbone pattern of the ridges could be an expression of the fact that Africa and North America did not move directly apart, but that each had a northward component of motion as well. For Africa at least palæomagnetic evidence has already suggested this[49].

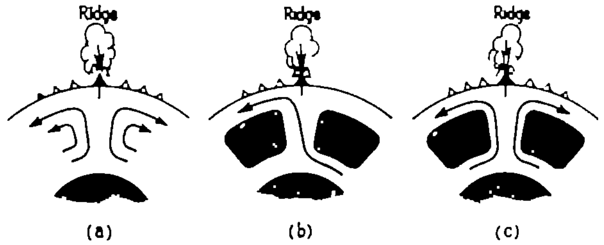

Fig. 3. Some possible patterns of convection, showing how chains of extinct volcanoes might be formed. The shaded areas represent stable cores of cells

The pattern of the Pacific is much less clear, but some suggestions can be made for the eastern part of the Pacific basin. The line of seamounts which extends east and then north-east from Easter Island may be its flow line. Part of it is called the Nazca Ridge. H. W. Menard[50] has shown it as a fracture zone but R. L. Fisher[51] has called it a line of seamounts. The Cocos Ridge off Colombia is nearly parallel with the Nazca Ridge and may be part of another flow-line. On the other hand, the West Chile Rise which joins Easter Island to the great fault through the Strait of Magellan may be a fault scarp.

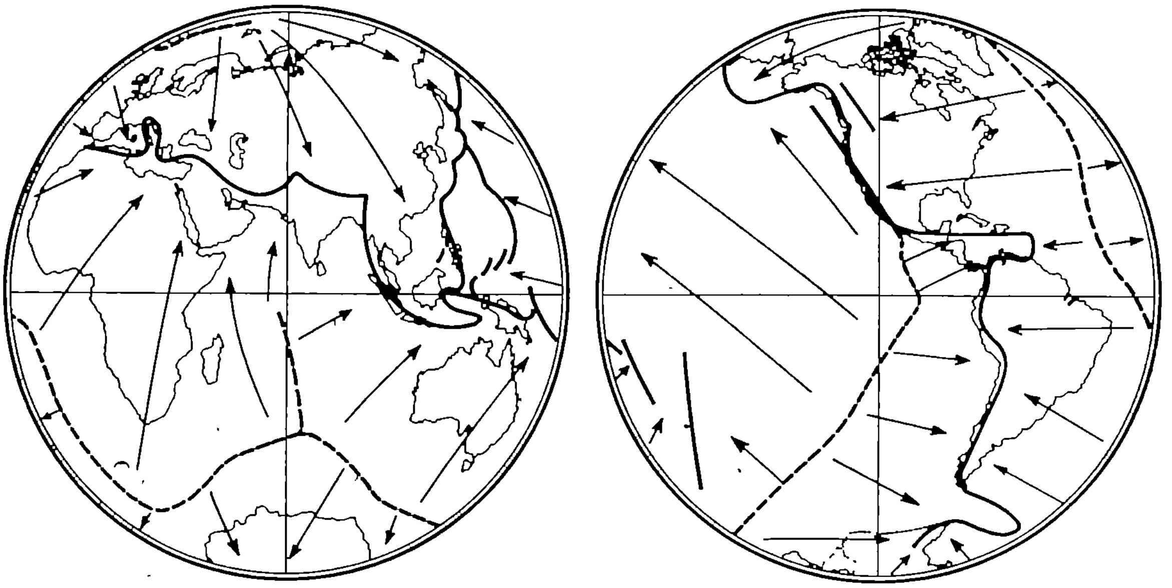

Fig. 4. Sketch of assumed convective flow from the mid-ocean ridge to the continental mountain system. The convection cell is a folded, irregular, cylinder with both ends west of North America

Thus the pattern of distribution of mid-ocean islands of different ages is considered to favour the hypothesis of spreading apart of some ocean floors and the pattern of aseismic ridges may be flow-lines indicating directions of recent movement. It is considered that at the contacts of mid-ocean and aseismic ridges with continents there are often areas of flood basalts, as in the Parana basin, Mexico, Ethiopia, Greenland and Scotland. This is probably not coincidental and may provide a means of dating the start of continental separation in various localities.

On the assumption that convection currents rise under mid-ocean ridges and sink under continental mountains, a map attempting to portray the probable pattern of horizontal flow has already been published[51]. If the aseismic ridges are flow-lines, more control is available and a more precise map (Fig. 4) based on this assumption has been prepared[48]. The chief change is in the north-eastern part of the Pacific Ocean. The new pattern of convection is not a torus, but one long cylindrical cell twisted about the Earth. Both ends of this cell lie off the west coast of North America. One end pinches out off Mexico where the East Pacific Rise reaches the Cordillera, the other end is broad and sheared off against the Cordillera of United States and Canada. The San Andreas fault and other structural features striking north-west may be consequences of this shearing.

If this view is adopted it seems likely that the Austral, Society, Tuamotu, and Hawaiian Island chains also lie along stream lines and that the progression in age of the islands along each chain is due to this cause. The Hawaiian Islands and some of the other chains are exceptional in that their source does not lie on the mid-ocean ridge. A fuller discussion of this[48] suggests that chains of islands could still be formed if the source of lava lay within the stable cores of convection cells of the type shown in Fig. 3c.

The recent discovery[52] of Miocene rocks on Oahu supports, but does not prove, the view that the Hawaiian Islands have been formed successively over a common source beneath the present position of the Island of Hawaii, and that they have been successively borne away toward the west. The dates given by Menard *et al.* indicate that the rate of movement is not greater than 10 cm a year.

OBITUARIES

Dr. J. L. Pawsey, F.R.S.

Dr. Joseph Lade Pawsey, Australia's pioneer in radio astronomy, died in Sydney on November 30, aged fifty-four. Dr. Pawsey was assistant chief of the Division of Radiophysics of the Commonwealth Scientific and Industrial Research Organization, which he had joined early in 1940 and where he directed the Division's radio astronomy work during the seventeen years preceding his death. During 1962 he was to have taken up a new appointment in the United States as director of the National Radio Astronomy Observatory at Green Bank, West Virginia. It was during a preliminary visit to the United States early in 1962 in preparation for this appointment that he became seriously ill, and it was only due to the medical skill and devotion given him through the efforts of his American colleagues that he lived long enough to return home to his family and indeed to accomplish a final work—the editing of a large collection of radio astronomical works shortly to be published. He is survived by his wife, two sons and a daughter.

Dr. Pawsey's interest in radio astronomy began while working on radar developments during the Second World War when confidential reports became available of the discovery of radio-frequency radiation from the Sun. After the War he began exploring these emissions and soon discovered that metre waves from the Sun consisted of two components—a basic thermal component from the Sun's million-degree corona, and a much more intense variable component which he accurately located in the vicinity of sunspots. From the impetus of these observations he began to form around him a group of physicists and engineers which was to play a leading part in the evolution of the new science of radio astronomy. Dr. Pawsey devoted most of his time to encouraging and stimulating this group, guiding them with inexhaustible patience and skill into a series of crucial experiments which helped to reveal the nature of the radio universe. The first unambiguous demonstration of the existence of radio stars, their first identifications with visible objects (nebulæ and galaxies as we now know), the mapping of the sky over a great range of frequencies, including the 21-cm emission of hydrogen, the detailed exploration of the complex emissions from the Sun, quiet and disturbed, and the interpretation of solar bursts in terms of matter expelled from solar explosions—these are a few of the contributions made by his group during his years of directorship. His interest in the astronomical results was matched by his interest in the development of the techniques required for obtaining them (he had, during the five years before the War, been intimately connected with the development of the original television system at Alexandra Palace), and again his group became known for novelty of approach to instrumental problems—various types of interferometers, the solar radio spectrograph, the grating aerial array, the Mills Cross and the multi-channel hydrogen spectrograph were all developed under his leadership. In the stimulus he gave his group for methods of obtaining higher and higher angular resolution, his interest lay more in the application of the principles of interferometry than in the conventional 'big-dish' approach; but when the decision was made to build a 210-ft. radio telescope for the Laboratory, he threw his energies into organizing the preparation of first-class receiving equipment needed to ensure its success.

Dr. Pawsey will be particularly remembered by his group for his ability to simplify complex problems and situations by pointing to the heart of the matter, for his willingness to discuss any aspect of a problem at all times at any level, and for his decisive and positive criticism of any manuscript or project put before him. He will also be remembered by his many friends across the world for his absolute integrity and honesty throughout his work and personal life.

Dr. Pawsey was made a Foundation Fellow of the Australian Academy of Science in 1954, and was elected Fellow of the Royal Society in the same year. He was awarded the Lyle Medal of the Australian Academy in 1954, and the Hughes Medal of the Royal Society in 1960. International recognition of his work was signified by his election as president of the Radio Astronomy Commission of the International Astronomical Union between 1952 and 1958.

His publications, though extensive, give no indication of his real contributions unless one reads the acknowledgments at the conclusion of scores of papers written by other authors. His most comprehensive work, in collaboration with Prof. R. N. Bracewell, is the classical text-book on *Radio Astronomy*.

Dr. Pawsey was a graduate of the University of Melbourne, where, in 1931, he won an 1851 Exhibition Scholarship to take his Ph.D. at the Cavendish Laboratory under Lord Rutherford. One may sense something of Rutherford's influence both in his love of the simple direct experiment and in his achievement of establishing the kind of group in which every member acquires the confidence and individuality to play his part in international research.

J. P. Wild

Prof. John J. Bittner

Experimental mammary tumour pathology suffered a great loss by the death in Minneapolis, on December 14, 1961, of Prof. John J. Bittner.

Born on February 25, 1904, in Meadville, Pa., he was educated at St. Stephen's College (now Bard), Annandale-on-Hudson, New York, where he earned his A.B. degree in 1925. He received his M.S. in 1929, and Ph.D. in 1930, at the University of Michigan.

Bittner was assistant in cancer research (1927–30) in the University of Michigan; research associate (1930–40) and assistant director (1940–42) at Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine; George Chase Christian professor of cancer research and director of cancer biology (1942–61) and professor of experimental pathology (1957–61) in the Medical School of the University of Minnesota; consulting associate scientist of the Sloan-Kettering Institute (1956–61).

Until about thirty years ago, it was generally agreed that mammary cancer in mice developed as the result of hormonal stimulation acting on susceptible tissues having the hereditary factor. In 1933 the situation of the causative factors of mammary tumours in mice began to change because the staff of Roscoe B. Jackson Memorial Laboratory announced the discovery of a non-chromosomal influence of maternal origin, which played a decisive part in the development of spontaneous mammary tumours in mice.

In 1936, Bittner wrote in a famous preliminary report: "Should further study demonstrate that the incidence of mammary gland tumours in mice may be affected by nursing, an explanation may be offered for the so-called extrachromosomal influence as a cause in the development of this type of neoplasm".

Bittner's major discovery (1939) was to identify this extrachromosomal influence with nursing, that is, with the milk factor.

So it was shown that spontaneous mammary cancer in mice usually resulted from the interaction of three causative factors: hormonal stimulation, inherited susceptibility, and the milk-borne mammary tumour agent.

Bittner also contributed to the discovery of an inherited hormonal influence. In 1944, when reciprocal matings were made between animals of the cancer-susceptible *A* (low incidence in virgins) and *C3H* (high incidence in virgins) strains, it was demonstrated that the hormonal pattern associated with the genesis of mammary cancer in virgin females was transmitted to the F_1 females, maintained as virgins, which had high incidences of mammary cancer. Bittner (1945) termed the hormonal mechanism responsible for the induction of mammary cancer in virgins "the inherited hormonal influence".

"The inherited hormonal influence . . . is probably the result of the action of multiple genes. The same genes probably do not produce the inherited susceptibility and the inherited hormonal influence."

Apart from these contributions, which opened entirely new fields, he wrote many other papers—245 in all—which made valuable contributions to the knowledge of mouse mammary tumours.

As may be expected, Bittner was the recipient of many honours and he was much sought after as a lecturer: among these were the Alvaranga Prize, College of Physicians of Philadelphia (1941); Comfort Crookshank Award and Lecture, London (1951); Bertner Award and Lecture, University of Texas (1957); honorary D.Sc. from Bard College (St. Stephen's) (1950).

In 1957 Bittner visited Perugia to participate in the Second International Symposium on Mammary Cancer. It was a great satisfaction to him to be the recipient (together with Alexander Haddow and Leonell C. Strong) of an honorary degree in medicine and surgery, from the University of Perugia, on July 29 of that year.

On February 23, 1961, when Dr. O. Meredith Wilson was inaugurated president of the University of Minnesota, Bittner was in a position of honour. In fact, he participated on behalf of one of the two oldest institutions represented, leading the academic group by wearing the gown of the Perugia University Medical School, incidentally with a colleague dressed in an Oxford (England) robe. On Thursday, February 16, 1961, *The Minneapolis Star* published a three-column article illustrated with coloured photographs of Bittner and other doctors in their academic gowns as they would appear at the inauguration.

Bittner returned to Perugia in June 1961 to participate in the Ciba Foundation Symposium on Tumour Viruses of Murine Origin (June 21–23) and the International Conference on the Morphological Precursors of Cancer (June 26–30), and to attend the centenary celebrations of the chair of morbid anatomy in the University of Perugia, as the representative of the University of Minnesota.

I would like also to recall the exceptional brightness and intelligence of his eyes and his inimitable charm. He was fond of his house and garden and was an enthusiastic photographer.

He is survived by his wife, formerly Mary Esther Mahaffy, two daughters, Mary Margaret (Mrs. Merlyn C. Bowker) and Elizabeth Ann (Mrs. Edwin H. Loague), two sisters, Katherine (Mrs. Leonell C. Strong) and Josephine (Mrs. George E. Turnbull) and a brother, Mr. Guy C. Bittner, to all of whom their many friends extend their deepest sympathy.

LUCIO SEVERI

His family, his numerous professional associates and friends, others who liked him personally, and many more who were stimulated by his writings learned with sorrow that Prof. John J. Bittner had died on December 14, 1961. Some of Bittner's fundamental contributions to cancer research and his background have already been summarized by Dr. Leonell C. Strong in the April 1962 issue of *Cancer Research*. Added emphasis of deserved international scope is placed on Bittner's contributions to cancer research by Prof. Lucio Severi in the preceding obituary.

To-day's investigators in cancer biology must realize indeed that the foundations of their discipline were laid by a few gifted researchers, such as Bittner, making a series of basic discoveries with keen intuition and painstaking observation. Bittner's important findings do not depend on the extensive instrumentation now so much used in oncology. His achievements demonstrate the pioneering application of uncomplicated experimental technique to clearly formulated problems, even in a field as complex as is the inquiry into the nature of cancer. The impact of Bittner's findings cannot be positively correlated with the cost of his instrumentation or with his laboratory space in square feet.

Bittner's long series of studies on the development of mammary tumours in mice has probably stimulated cancer research on a world-wide scale as much as any other single series of observations. His long-continued and scarcely fashionable insistence, particularly during the past decade, on a mammary tumour 'agent' rather than a 'virus' reflected his sound caution when faced with tempting premature extrapolation. While documenting painstakingly, throughout a lifetime, the part played by what we now call the Bittner agent, he also devoted careful observation to the factors interacting with his agent.

In a virus-conscious era of oncology, it is scarcely surprising that the question whether the Bittner agent is indeed a virus or a cytoplasmic 'gene' or 'particle' is often posed. Such semantic controversy revolving around as yet inconclusive data must not detract, however, from Bittner's important disclosure of the part played by an infective agent in the genesis of a mammalian neoplasm.

We may remember, further, that the Bittner of Bittner-agent fame consistently concerned himself with the part played by endocrine and metabolic factors in mammalian carcinogenesis. Two points are particularly pertinent. First, he emphasized that mammary cancer in the mouse can develop in the absence of a demonstrable agent, and that the burden of proof for assuming that the presence of an infective agent constitutes a *sine qua non* for mammary carcinogenesis in the mouse rests with those who make this claim. Secondly, he devoted much research to the question as to whether the agent exerted its effect via the endocrine.

Basic contributions by Huseby and Bittner related in this connexion to endocrine mechanisms of breast cancer in the mouse. Many others, too many to name, are indebted to Bittner for the opportunity to co-operate with him, as I am.

Bittner's scholarship in the field of inquiry into the nature of cancer was indeed an invaluable asset not only to those privileged to work with him, but also to many others who came or wrote for his advice. He was open-minded to new approaches and willing to lend his unreserved support to explorations of unconventional fields. The resolution of several temporal parameters of physiology and pathology at different levels of mammalian organization would not have been possible without his guidance and help. In later years, Bittner's activities also included the support of the work of others by making available his inbred strains of mice. He kept up with the literature in a rapidly developing field which he had so greatly stimulated and remained active in the laboratory for seven years following a first coronary occlusion, which preceded the second, fatal one. He died on his way to work. He lives in the history of biology and medicine with those endeavouring to understand organisms and their diseases by dint of painstaking observation.

FRANZ HALBERG

NEWS and VIEWS

The Geological Society of London: Awards

The following awards for 1963 have been made by the Geological Society of London: *Wollaston Medal*, to Dr. F. A. Vening Meinesz, emeritus professor, University of Utrecht, for his pioneer researches in geophysics, notably in measurements of gravity at sea, and his studies of isostasy and thermal convection in the Earth; *Murchison Medal*, to Mr. N. L. Falcon of the British Petroleum Co., Ltd., for his application of geology to exploration for petroleum throughout the world; *Lyell Medal*, to Prof. T. N. George, University of Glasgow, for his researches on carboniferous stratigraphy and palæontology and work in the field of evolutionary palæontology; *Bigsby Medal*, to Prof. W. S. Pitcher, University of Liverpool, for his work on igneous and metamorphic rocks, particularly in north-west Ireland; *Wollaston Fund*, to Dr. G. M. Brown, University of Oxford, for his contributions to petrology and mineralogy; *Murchison Fund*, to Mr. E. H. Francis, Geological Survey of Great Britain (Scottish Office), for his contributions to stratigraphy and volcanism, especially in the Midland Valley of Scotland; *Lyell Fund*, a moiety to Dr. G. P. L. Walker, Imperial College of Science and Technology, for his researches on the volcanic rocks of Iceland and Northern Ireland; and another moiety to Dr. A. E. M. Nairn, Turner and Newall Fellow, King's College, Newcastle upon Tyne, for his researches in the field of palæomagnetism and palæoclimatology.

The Institute of Physics and the Physical Society: Appointments and Awards

The following appointments and awards for 1963 have been made by the Institute of Physics and the Physical Society: *Guthrie Lecturer*, Prof. L. F. Bates, Spencer professor of physics at the University of Nottingham. The Lecture will be delivered during the International Conference on Magnetism to be held in Nottingham during September 7–11, 1964; *The Thomas Young Medal and Prize*, jointly to Prof. C. H. Townes, of the Massachusetts Institute of Technology, and Prof. A. L. Schawlow, of Stanford University, California, for their work in originating the principle of the optical maser; *The Duddell Medal and Prize*, to Prof. B. N. Brockhouse, of McMaster University, Ontario, Canada, for his work on the lattice dynamics of crystals and the development of the three-axis crystal spectrometer used in this work; *The Charles Chree Medal and Prize*, to Dr. M. N. Hill, of the University of Cambridge, for his work in marine geophysics, particularly in connexion with the application of the seismic method in the deep ocean; *The Charles Vernon Boys Prize*, to Dr. K. D. Froome, of the National Physical Laboratory, for his contributions to experimental physics, particularly his determination of the velocity of light, his invention of a source of continuous short waves and his method for accurate measurement of length.

Mining and Mineral Technology at the Imperial College of Science and Technology:

Prof. J. C. Mitcheson, C.B.E.

James Cecil Mitcheson, who retires on September 30, has been professor of mining and head of the Department of Mining and Mineral Technology at the Imperial College of Science and Technology since 1952. This critical period has coincided with the contraction of many of the mining schools in the Western World, and it is in a large measure due to Mitcheson's leadership that the Royal School of Mines has strengthened its position, modernized its outlook and taken a full part in the expansion of the Imperial College. A man of absolute integrity, he combines firmness of purpose with kindness of nature in a manner which has earned the respect and affection of both his colleagues and his students. He came to the Royal School of Mines with an established reputation as an administrator and expert in the economics of coal mining and quickly won the confidence of the metalliferous mining industry. A past-president of the Institution of Mining Engineers, he is now vice-president of the Institution of Mining and Metallurgy. To his academic and professional duties have been added many public responsibilities, including that of chairman of the Safety in Mines Research Advisory Board and, since 1961, chairman of the Geological Survey Board. However, his principal interest has long been mining education in all its forms and, characteristically, his activities in this field have extended far beyond the Imperial College. For these and other public services—all generously and modestly given—he was awarded the C.B.E. in 1961. Mitcheson was Dean of the Royal School of Mines from 1959 until 1962, during which time the rebuilding of the School was planned and initiated. His experience, judgment and rare human qualities have had an important influence on the course of mining education in Britain.

Prof. R. A. L. Black

Prof. R. A. L. Black, who is to succeed Prof. J. C. Mitcheson, has spent most of his professional life in South Africa. He was, however, born and brought up in England, being educated at Stowe and the Royal School of Mines (Imperial College of Science and Technology). His university course was interrupted by the outbreak of war when he volunteered for the Air Branch of the Royal Navy, in which he served as a member of air crew and was awarded the Distinguished Service Cross. At the earliest moment after hostilities ended he returned to the Royal School of Mines and, graduating with honours in 1946, he immediately joined the staff of the Central Mining and Investment Corporation in Johannesburg. This large finance house controls a number of important mines, and Black was given a wide practical experience of underground mining operations before being called to head office. Here he was appointed assistant to the consulting engineer with responsibility for the development of a research programme covering rock mechanics and ground control. Following a short period of actual mine management, he was in 1956 appointed to his present position as Chamber of Mines professor in mining engineering in the University of the Witwatersrand, Johannesburg. Since his appointment, Black has reorganized the undergraduate courses, changing the emphasis away from the teaching of applied technology towards a better grounding in the sciences and basic engineering principles. At the same time he has developed a postgraduate school together with a research unit largely engaged in studying problems arising out of mining at great depth. His own especial fields of interest are in rock mechanics and explosives engineering. In addition to his academic activities Black has been dean of the University Residence, where Mrs. Black and he have most successfully provided a 'home' for some 160 students and 20 members of staff for the past four years.

The U.S. National Bureau of Standards

Dr. Ernest K. Smith has been appointed chief of the Upper Atmosphere and Space Physics Division and Robert W. Knecht chief of the Ionosphere Research and Propagation Division at the Boulder Laboratories of the

National Bureau of Standards, U.S. Department of Commerce. These divisions are part of the Central Radio Propagation Laboratory.

Dr. E. K. Smith

DR. SMITH succeeds C. Gordon Little, who was recently appointed chief of the Central Radio Propagation Laboratory. Since joining the Bureau's staff in 1951, Dr. Smith has investigated such ionospheric phenomena as sporadic-E, F-region anomalies and studies of the atmospheric refractive index for non-ionized gases.

Mr. R. W. Knecht

MR. KNECHT succeeds Dr. Smith as chief of the Ionosphere Research and Propagation Division. He joined the National Bureau of Standards in June 1949 immediately on graduation in physics from Union College in Schenectady, New York. After an initial assignment in Washington, he was transferred to Alaska, spending eight months at Barrow Radio Propagation Field Station and, afterwards, two years at Anchorage as physicist-in-charge of the North Pacific Radio Warning Service. Since his return from Alaska in 1954, Mr. Knecht has worked primarily in the fields of ionospheric physics and solar-terrestrial relationships. He was formerly chief of the Sun–Earth Relationships Section. After exploring the possibilities of a satellite-borne top-side sounding experiment for investigating the ionosphere, Knecht promoted the development of *Topsi*, the U.S. fixed-frequency top-side sounding satellite scheduled for launching in the first half of 1963.

Scientific and Technical Personnel in the Federal Government

ACCORDING to *Scientific and Technical Personnel in the Federal Government, 1959 and 1960*, the professional scientific and technical staff in the Federal Government increased by 26 per cent to 156,000 between 1954 and 1960 (*NSF* 62–26. Pp. vi+79. Washington, D.C.: Government Printing Office, 1962). The Department of Defence employed 37 per cent of these, 56,100 in 1959 and 57,400 in 1960, more than two-thirds being engineers. The Veterans Administration employed about 29,000 in 1960, mostly in health occupations. The total included about 27,500 women in 1959, mostly in health professions where about 58 per cent were women, compared with 3,900 or almost 8 per cent in science and less than 1 per cent in engineering. The number engaged in research and development was relatively stable during 1958–60, and in 1960 about 44,000 were in research and development, about half in the Department of Defence. Of the 53,000 scientific personnel in 1960, 18,000 were in the physical sciences and nearly 22,000 in biological sciences. Non-professional scientific and technical staff in the Government increased by 11 per cent over the period 1958–60 from 75,200 to almost 83,500, more than 35,800 in 1960 being in engineering and 11,500 in mechanics. Almost 36,000, or 43 per cent of the total, were in the Department of Defence and only 14,200, or 17 per cent, in research and development.

Problems in the Communication of Scientific and Technical Information

IN September 1962 the Department of English and Liberal Studies of the Welsh College of Advanced Technology began an investigation into the problems involved in the communication of scientific and technical information. A circular letter was sent to a group of fifty-four research centres and companies, inquiring what forms of writing they required and what difficulties and weaknesses, if any, they encountered. All the thirty-one companies which replied expressed their concern with the present standards in technical writing, and nineteen suggested a visit to discuss the subject, while seven submitted detailed opinions or documentary evidence. All the companies welcomed the Department's positive measures to train undergraduates in written and spoken communication and were willing to co-operate in the investigation. Some were interested in suggestions for short courses for their graduate personnel, either in the college or in the companies themselves. A circular letter inquiring about the prevalence of communication problems in science and engineering departments in universities and colleges of advanced technology is being sent out to all such colleges and to selected universities, and the writing of reports has been discussed with the professors of chemical, civil and electrical engineering in the University of Nottingham, where much interest in standards of writing was shown. Staff in scientific departments at the Universities of Leeds, Liverpool and Reading has also been approached, and it is proposed to make inquiries of a number of national research centres and institutes and of more companies. Experiments have already been made with testing methods in recent college courses and examinations, and consideration of the philosophical problems involved in the processes of written communication will commence shortly.

Mental Health Book Review Index

THE *Mental Health Book Review Index* contains a list of books relating in some way to mental health, and the title of each book is followed by references to reviews of the book which have appeared in the appropriate journals. Volume 7 deals in this way with some 300 new books and there are also included new reviews of books which have been referred to in previous volumes (Pp. xiii+66. Flushing, N.Y.: Miss Lois Afflerback, Paul Klapper Library, Queens College, 1962. Annual subscription, 3 dollars). The field of mental health is widely interpreted and covers not only psychology and psychiatry and sociological aspects, but also a good many books of general cultural interest. For example, the present volume includes Sir Charles Snow's Rede Lecture on *The Two Cultures and the Scientific Revolution*, J. P. Sartre's *Being and Nothingness* and Teilhard de Chardin's *The Phenomenon of Man*. In these days when it is increasingly difficult for workers even to know what is published in their own field, not to mention in allied disciplines, this publication serves a very valuable purpose. The *Index* is sponsored, among others, by the World Federation for Mental Health.

Animals

THE aim of the new magazine, *Animals*, published by Knowledge Publications, Ltd., at 2*s*. weekly, commencing January 8, is expressed by the editor-in-chief, Armand Denis: ". . . to interest you in every aspect of the animal world". The main appeal is visual, well over half the space being given to pictures, four-fifths of which are superb colour photographs. Sir Julian Huxley and Sir Solly Zuckerman are patrons, and there seem to be links with the World Wildlife Fund, although what these may be is not made precisely clear. The editorial board includes the Duke of Bedford, Gerald Durrell, Bernard Grzimek, Nicholas Guppy, Gavin Maxwell, Alan Moorehead, Peter Scott and Niko Tinbergen. The editor is John Chancellor, and the consulting editor Michael Tweedie. The text is less informative than should be expected for the price, an outstanding instance being an 800-word article on the giant panda, which seems mainly concerned with how little we know of this species while failing to give as much as is known. (Perhaps somebody will one day explain why the giant panda was not named as one of the world's rarest animals until it was adopted as the symbol of the World Wildlife Fund (British Branch).) There is also a tendency for error and misstatement, not always trivial and sometimes needless, to creep in, and to maintain our interest in the animal world it may be necessary to bring the textual matter more closely into accord with the high standard of the art work.

Estimation of Calcium in Biological Material

The adaptation of the flame-photometer to the estimation of calcium in biological material has proved difficult because of serious interference from other ions commonly present. Sodium and phosphate ions are specially troublesome, sodium enhancing and phosphates inhibiting the intensity of the calcium flame. Other ions also interfere in varying degrees of severity. The intrinsic simplicity of flame-photometry, however, has made worth while the development of several techniques for isolating calcium ions free from interfering material. G. E. Trout, of the University of the Witwatersrand, Johannesburg, has recently described an improved technique whereby the calcium is purified by means of ion-exchange chromatography on fine-mesh resins (*South Afric. J. Med. Sci.*, 27, Nos. 1 and 2; July 1962) It is particularly suitable for the estimation of calcium in tissue ashes. The method has been extensively tested with a synthetic mixture of sodium, magnesium, potassium and calcium salts.

Control of Ticks on Livestock

In 1958 an expert panel on tick-borne diseases of livestock was established by the Food and Agriculture Organization, the first meeting of this body being held in November of that year. The recent publication, *The Control of Ticks on Livestock*, is the first to be provided by the panel (*FAO Agricultural Studies No. 54*. Prepared by S. F. Barnett. Pp. vii + 115. Rome: Food and Agriculture Organization of the United Nations; London: H.M.S.O., 1961. 5*s*.; 1 dollar). The whole subject of tick control is reviewed very thoroughly, and this booklet can claim to cover the whole of the subject from the angle of the field veterinary officer. It contains a select reference list of titles dating from 1941. The nine chapters deal with reasons for controlling ticks; control of parasites off the host; control of parasites on the host; timing of ixodicidal applications; ixodicides; deterioration and depletion of ixodicidal washes and estimation of their concentration; resistance of ticks to ixodicides; toxicity of ixodicides; and a summary. Eight very important pages were left unprinted in the copy received for review; this may also apply to two other pages at the end of the book. It is to be hoped that this has not happened with other copies.

Courses supported by the U.S. National Science Foundation

Under the title *Science Course Improvement Projects* the National Science Foundation has issued a booklet listing and describing the courses designed to improve the teaching of science and mathematics as well as engineering supported by the National Science Foundation (NSF 62–38. 1: *Courses, Written Materials, Films, Studies supported by the National Science Foundation*. Pp. 64. Washington, D.C.: National Science Foundation, 1962). In all, some 132 courses and studies are listed. The projects are arranged in four main groups, concerned first with elementary schools, secondly with secondary schools, thirdly with technical institutes, and fourthly with college and university projects. Under these headings, they are arranged according to disciplines. The information covers courses, written material, films and investigations.

The Simon Population Trust

The Simon Population Trust was formed following a bequest of £15,000 from the late Lord Simon of Wythenshawe. The objects of the Trust, designedly formulated in broad terms, are: (1) to promote a better understanding of the problems of world population and resources; (2) to encourage such research, education or other actions in any part of the world as may contribute to the adjustment of population to resources. The need had long been felt for an objective and independent body, non-partisan and of broad sympathies, which could give encouragement and adequate financial support to promising initiatives from any quarter, and which could enable new growing points to develop until a comprehensive and well-balanced provision existed for meeting this important need of modern civilization. By the terms of the Trust, the Trustees are enabled to give support to a wide range of projects. However, as yet they are not in a financial position to subsidize basic researches such as have yielded the oral methods of contraception which are now on trial. The objectives which the Trustees think are at present worthy of support include the following: birth control in place of abortion; use of midwives; improvement of methods acceptable to Roman Catholics; local manufacture of contraceptives; reversible sterilization in males; travelling fellowships. Further information is obtainable from the Simon Population Trust, 69 Eccleston Square, London, S.W.1.

Announcements

Prof. W. M. Fairbank, of Stanford University, has been awarded the 1963 Oliver E. Buckley Solid-State Physics Prize of the American Physical Society, for his work on the properties of helium-3, and especially for his part in the discovery of flux quantization in superconductors.

The Office of Documentation has issued a booklet surveying the scientific information activities of the National Academy of Sciences–National Research Council (Publication 1031. Pp. vi + 49. Washington, D.C.: National Academy of Sciences–National Research Council, 1962). These are described under the divisional subject heads and, besides listing the various Committees concerned and information services, the booklet lists the various publications available.

The fifteenth international symposium on "Crop Protection" will be held at the State Agricultural College. Gent, on May 7. Further information can be obtained from Prof. J. van den Brande, State Agricultural College, Coupure Links, 233, Gent.

The Plant Phenolics Group is organizing a symposium on "Methods in Polyphenol Chemistry" at the Dyson Perrins Laboratory, Oxford, during April 2–4. Further information can be obtained from the honorary secretary. A. H. Williams, Research Station, Long Ashton, Bristol.

An international symposium on "Physical Processes in Radiation Biology" will be held at Michigan State University during May 5–8. Further information can be obtained from Mr. Bruce Alderman, Room 24, Kellogg Center, Michigan State University, East Lansing, Michigan.

The spring meeting of the British Society of Rheology will be held at the College of Aeronautics, Cranfield. during April 17–19. The subject of the meeting will be "Ductility in Metals and its Relation to Fabrication Processes". Non-members of the Society are invited to participate in the meeting. Further information can be obtained from Mr. R. Pearce, Department of Materials, Cranfield, Bletchley, Bucks.

The British Radio Spectroscopy Group is organizing a conference on "Ions, Masers and Irradiation" at the Physics Department, University of Keele, during April 8–10. The topics covered will include the experimental and theoretical investigations of both bound and free ions; the relation of such investigations to optical, infra-red and microwave masers; the use of microwave spectroscopy to detect effects produced by irradiation at radio, microwave or optical frequencies. Further information and registration forms are available from Dr. D. C. Lainé, Physics Department, University of Keele, Staffs.

GEOLOGICAL ASPECTS OF COMMONWEALTH ECONOMY

THE eleventh Inter-University Geological Congress was held in the Department of Geology, University College, Cardiff, during January 3–5. The subject of the congress was "Geological Aspects of Commonwealth Economy" and more than 120 delegates from at least 20 universities and colleges attended.

The first speaker was J. H. Bean, of the Geological Survey of the Federation of Malaya, who described the iron deposits of Malaya. He pointed out that iron ore has been worked on a commercial scale in Malaya since 1921, but since the Second World War the industry has been greatly expanded and now makes a significant contribution to the national economy. About eighteen different iron ore deposits are being worked at the moment, nearly all being located in the proximity of the coast. The iron deposits are found in a wide variety of host rocks—quartzite, schist, quartz porphyry, limestone, andesite, agglomerate, shale, etc.—but one feature common to most of them is that they are associated with granite. The primary iron ore mineral is usually magnetite (Fe_3O_4), less frequently hæmatite (Fe_2O_3), and in one deposit it is siderite ($FeCO_3$). Mr. Bean described several of the important deposits and then went on to consider the genesis of the iron minerals. He thought the fact that iron ore deposits almost invariably lie close to granite masses indicates a genetic relationship. In several areas magnetite and hæmatite are associated with different phases of mineralization. Thus, in the Kedah Peak area, on the north-west coast of Malaya, magnetite is associated with the pegmatites while the hæmatite appears to be of a later hydrothermal origin. In the Ipoh deposit, 100 miles farther south, magnetite is associated with high-temperature silicate minerals, such as garnet and epidote, while the hæmatite is devoid of such minerals, presumably indicating formation at a lower temperature. Probably, the mineralogy of any particular deposit depends on the time of concentration of the mineralizing solutions in relation to the magmatic cycle, with magnetite forming from early solutions and hæmatite from later ones. Finally, Mr. Bean pointed out how the lithology and structure of country rocks control the location and form of ore bodies. Thus, tabular ore bodies are formed in well-bedded shales, but where the rock is of a structureless nature the ore body is irregular. Again, in folded areas ore is usually located along the limbs of folds but rarely along the crests.

The second paper was given by D. Ostle, of the Atomic Energy Division of the Geological Survey of Great Britain. Mr. Ostle discussed prospecting for atomic energy minerals. He pointed out that in recent years most attention has been directed at uranium, thorium and beryllium-bearing minerals, and that some work has been done on the geological environments in which helium can be expected to occur in economic concentrations, since this element is of potential value in gas-cooled reactors. Mr. Ostle discussed in detail methods of radiometric prospecting, particularly stressing the role of the aeroplane in this respect. Aeroradiometric surveys can log radioactivity from a height of 500 ft. above ground-level and, properly used, this technique is an invaluable time saver. Where an area is covered by drift normal radiometric survey techniques are useless, and one means of overcoming this problem is by determining the amount of radon in ground air. Mr. Ostle described other geochemical techniques of prospecting for atomic energy minerals, including systematic sampling and analysis, by fluorimetric and colorimetric means, of uranium in natural ground waters. He also remarked on the selection of geologically favourable areas where these prospecting techniques can be most profitably applied. Thus, it has been found that in igneous rocks, uranium and thorium are largely concentrated in rocks of acidic composition. No deposits of any significance have ever been found in basic igneous rocks.

In the afternoon session, Prof. J. G. C. Anderson, of University College, Cardiff, dealt with the role of geology in hydro-electric development. He began by saying that although civil engineering excavations have greatly assisted geologists, it was not until comparatively recently that widespread use was made of geological information in the design and structure of major engineering works. Yet the engineering geologist has probably just as important a part to play as the mining and the oil geologist. The use of geology in saving money and ensuring safety in the carrying out of major works can be just as important as in locating mineral and energy resources. In the past 25 years this has become more widely recognized. and in the United States an Association of Engineering Geologists has been founded. Prof. Anderson continued by saying that geological knowledge has three main applications in the construction of major hydro-electric developments. The first is in choosing dam and power station sites where the necessary structure can be built with minimum cost and maximum long-term safety. Where the geology of a dam site is not taken into account the result may be the collapse of the dam. The disaster at Dolgarrog can be cited as an example where only a very superficial examination of the geology of the dam site was made, leading to serious weaknesses in the foundations and abutment. The second application of geology to hydro-electric development is in choosing tunnel routes which afford the optimum geological conditions and avoid structures likely to cause special difficulty and even danger. Prof. Anderson cited many examples, including the Loch Sloy and Rheidol hydro-electric schemes, where a geological investigation had indicated alternative tunnel routes of greater potential efficiency and safety, at no extra cost, other than that originally planned. He concluded his address by pointing out that the third application of geology to hydro-electric development lies in the location of suitable constructional materials as close to the major works as possible.

In the evening, Dr. P. G. Harris, of the University of Leeds, dealt with recent volcanic eruption on Tristan da Cunha. Dr. Harris, a member of the expedition sent by the Royal Society to the island, outlined the volcanic history of the island, and with the aid of slides traced the evolution and effects of the recent parasitic volcano. A short film of the volcanic eruption was also shown.

The congress continued the next morning, January 4, with a paper by Dr. W. Idris Jones, director-general of research at the National Coal Board, on fuel gases in the coal measures. Dr. Jones said that the presence of methane in coal-bearing strata has been a constant hazard to coal-mining throughout its history. A complete understanding of how methane is stored and emitted by coal and its surrounding strata is still lacking, and research is now being directed to increase fundamental knowledge of the coal/methane relationship. In recent years, techniques have been developed that make it possible to drain gas from seams or worked-out areas, and pipe it to the surface as fuel. Dr. Jones claimed that Britain led the world in this technique, and said that possibly, in the near future, methane drainage would become part of standard mining practice. He thought the amount of gas which was being wasted nowadays presented a great challenge. Up to 150,000 million cubic feet is lost into the atmosphere every year. Ultimately, coal-mines may provide about 10 per cent of Britain's present gas requirements. Dr. Jones also reported on fuel gases which can be derived from coal seams by gasification *in situ*, the gas produced being led to the surface through boreholes. This involves carbonizing the coal by transmitting heat through it under close control, a technique which has been very successfully used in the U.S.S.R. Dr. Jones concluded by pointing out that both techniques require a knowledge of the geometry and physical properties of the strata in order to exploit natural conditions and obtain maximum yield of gas.

A comparison of oil accumulation conditions in Trinidad and the Canadian Prairies was jointly given by P. Fitzgerald-Moore and Dr. J. Weeda of the Shell International Petroleum Co. Dealing first with the Canadian oil fields, Mr. Fitzgerald-Moore pointed out that oil had accumulated mainly in Upper Palæozoic and Mesozoic sediments. The oil basin lies between a mobile belt and a shield. The general geological history is of geosynclinal warping of the crust, followed by mountain building and foredeep sedimentation, which has migrated shieldwards in time. Oil was found in epicontinental deposits bordering the miogeosyncline, and in quartz sandstones of the early foredeep phase which border, and are derived from, the shield. This latter oil becomes heavier towards the shield and forms an important tar belt. Mr. Fitzgerald-Moore stated that other accumulations of oil have been found in transgressive sands of the foredeep, derived from the craton, and regressive sands of the foredeep, from a Cordilleran source. He also described the tectonic structure of the area, in particular, some remarkable flat-lying thrusts in Palæozoic strata. Mr. Fitzgerald-Moore pointed out that the deeper structures of the Cordillera are unknown but he thought there had possibly been a *décollement* between the crystalline basement and the overlying Palæozoic rocks.

Dr. J. Weeda turned to the Trinidad oil field but first placed it within the framework of the Orinoco Basin. This is essentially Tertiary in age and has followed the same general geological history as the Canadian Basin, although the latter involves far less crustal downwarping. Dr. Weeda said that oil was found in the transgressive and regressive sands in the Orinoco Basin, but in this case the transgressive sands derive from the Cordillera, and the regressive sands from the craton. There was also an extensive tar belt bordering the shield, he added, but only insignificant oil accumulations occurred in the epicontinental deposits. Dr. Weeda concluded by describing the tectonic structure of the Trinidad oil field. This is extremely complex and has been described as "the graveyard of geologists' reputations". The shelf area is broken by numerous powerful faults and the incompetent Tertiary sediments of the mobile belt exhibit flowage and diapiric structures.

The first lecture in the afternoon session was given by L. C. Noakes, the British Commonwealth Geological Liaison Officer, on underground water in Australia. Three-quarters of the Australian continent, said Mr. Noakes, has been described as an 'arid zone'. Although the zone supports only 2 per cent of the population, it provides 40 per cent of Australia's mineral wealth, and 30 per cent and 25 per cent of the beef cattle and sheep population respectively. Underground water supplies have played an extremely important part in the exploitation of mineral resources and the development of pastoral farming. Mr. Noakes commented that the geology of the arid zone divides it into well-marked areas of differing water potential. A quarter of the zone overlies compact, crystalline Pre-Cambrian rocks of low ground-water potential. In this area water accumulates mainly at the interface between weathered and unweathered rock, and in joints and fault zones. A sixth of the zone is underlain by the more permeable Upper Pre-Cambrian rocks, which thus possess a higher ground-water potential. More than half the area overlies major sedimentary basins, such as the great Artesian Basin, which have a high water potential. An appreciable proportion of the underground water in these areas, Mr. Noakes suggested, may be 'fossil water', derived from pluvial periods hundreds of thousands of years ago, and retained in the rocks ever since. Finally, there are small areas where crystalline Pre-Cambrian rocks are overlain by recent unconsolidated sediments, which act as aquifers. The speaker pointed out that water problems in Australia may be common to a number of States, and this has resulted in the recent founding of the permanent Inter-state Underground Water Conference. Finally, Mr. Noakes emphasized one of the most important and interesting problems in hydrogeology, namely, the establishment of a 'water balance' in artesian water supplies. This ensures, first, that these supplies are not depleted by excessive usage, and secondly, that they are used to their maximum capacity compatible with natural replenishment.

Mr. J. W. Pallister, commissioner of the Geological Survey of Tanganyika, delivered the final lecture of the congress on "The Geological Survey and Economic Development in East Africa". He said that the social and economic development of the East African territories can be divided into four phases, and in each the official Geological Surveys have played an important and distinctive part. The first phase broadly occupies the early 1920's, when the Surveys were established, to the onset of the Second World War. During this period the Surveys were mainly assisting and stimulating the small mining industries which were largely interested in exporting such minerals as gold, tin, mica, copper, lead and diamonds. Mr. Pallister emphasized that the Surveys were busy with many *ad hoc* investigations, and there was little opportunity for systematic geological mapping. During the Second World War—the second period of economic development—there was a demand for special strategic materials such as wolfram, graphite, kyanite and niobium minerals. Local industries, cut off from normal sources of supply, also developed local raw materials. The third period, which occupies the post-War years up to independence, saw an increased interest in the natural resources of Africa by both the British Government and the local population. During these years the Surveys embarked on long-term systematic mapping. After some years of prospecting, the partial withdrawal of interest by large outside mining concerns compelled the Surveys to undertake the prospecting and assessing of potential mineral deposits beyond the point when private interests would normally take over. This also coincided with a tendency for the local population to take an increasing part in the prospecting and exploiting of smaller deposits. With independence, Mr. Pallister pointed out, the new countries are eager to develop their natural resources. This development is dependent on outside Governmental or international agencies for funds, and the basic geological information required by these kinds of organizations has stimulated systematic mapping of the geology. Mr. Pallister concluded by saying that the Geological Surveys have always played an important part in developing water supplies. Not only have new water supplies been developed in areas where existing sources are inadequate, but also in areas where sources, although sufficient in quantity, are badly contaminated and seriously affect the health of the local people.

On the last day of the congress, field excursions were arranged to two local coal-mines—the Cwm and Nantgarw Collieries—and also to the Llanharry Iron Ore Mine. Other field trips which were arranged had to be cancelled because of poor weather. M. J. Wilson

PALÆOMAGNETIC STUDIES IN THE U.S.S.R.

IN the U.S.S.R. intensive palæomagnetic studies began in 1953. Since that year three palæomagnetic conferences have been held and a special Palæomagnetic Commission formed at the Institute of Physics of the Earth. A special task entrusted to this Commission is the collection of palæomagnetic data for further studies and generalizations. One of the first comprehensive and detailed works on palæomagnetism in the U.S.S.R. was the memoir by Khramov[1] on the palæomagnetic correlation of sedimentary formations in Western Turkmenia, ranging in age from the Lower Jurassic to the Quaternary. Besides its main object this study opened up other problems, such as geochronology on a wider scale, the rate of sedimentary accumulation and the problem of the continental drift. In the introduction and in the first chapter Khramov gives a brief history of palæomagnetic research and a detailed description of the methods used. The last-mentioned subject has provided material for a special book written by Khramov and collaborators[2]. Another important publication is that by Kalashnikov[3], who begins by providing the general setting of the problem (pp. 1242–1257) and by giving a succinct review of the achievements in this field outside the U.S.S.R. This study, Kalashnikov claims, demonstrates beyond any doubt that there exists a definite functional relation between the orientation of magnetic vectors of rocks and their age. Many problems, however, such as the cause of reverse polarity and of the part played by the continental drift, remain still unsolved.

In the second part of this work (pp. 1257–1279) the author gives a most valuable summary of the results of palæomagnetic studies in the U.S.S.R. during the past decade. This summary consists of the tabulation of data relating to 111 collection localities, involving more than 5,000 oriented and measured specimens of rocks ranging in age from the Cambrian to the Quaternary. Against each locality item are given the values of declination and inclination of the magnetic vector and the calculated values of the co-ordinates of the North Pole. These data are then represented on eleven polar projections of the northern hemisphere, one for each geological period. The average values of the positions of the North Pole during each period are used to provide a background for the construction of the polar migration curve. The greater scatter of points relating to the polar position during the Lower Palæozoic era necessitates the separation of the migration curve into two widely separated sectors, one based on the data of the European part of the U.S.S.R. and the other of the Asiatic part. The main migration curve with its European sector extension is in general alignment with the migration curve constructed on the basis of data from West European and British localities, but, as the summary diagram shows, differs widely from the migration curves based on American and Chinese data. This suggests the influence of continental drift. Such a world-wide marshalling of palæomagnetic data and comparison of the polar migration curves is a great achievement. At the same time Kalashnikov points out that to be fully acceptable these results must agree with the results of palæoclimatology and palæogeochemistry. He does not discuss the data of palæogeochemistry, but with regard to the data of palæoclimatology he claims that so far as the U.S.S.R. is concerned such a correlation has been achieved, as shown by the material published by Forsh and Khramov[4], Rukhin[5] and Strakhov[6]. Among problems still remaining unsolved are the problem of the continental drift, of the possibility that the Earth is increasing in size in time, of the velocity of polar migration and its variation in time (the average velocity of polar migration as calculated by Kalashnikov for the span of 500 m.y. is about 2 cm per annum). TROPICAL HÆMATOLOGY

AN international colloquium on "Tropical Hæmatology" was held at the Prince Leopold Institute of Tropical Medicine, Antwerp, during November 30–December 2.

The inaugural academic session was presided over by the Governor of the Province of Antwerp, president of the Administrative Council of the Institute, who welcomed the participants among whom were many foreign hæmatologists.

In his opening lecture, Prof. P. G. Janssens, director of the Institute, dealt with the perspectives offered by the proposed installation at Antwerp of university faculties; on the other hand, he emphasized the responsibilities of official bodies in the particular problems raised by the medical aid given by Belgium to the developing countries.

The Academic Lecture was given by Prof. J. Van Riel, of the Institute of Tropical Medicine, the subject being "The Great Steps of Progress in Public Health".

The first working session, presided over by Prof. J. Schneider (Paris), was concerned with tropical hypereosinophilias. This was discussed by Dr. A. M. Smit (Amsterdam), Dr. M. Fernex (Basle), and Profs. W. Mohr (Hamburg), A. F. Essellier (Zurich) and P. G. Janssens (Antwerp). From the discussion it appeared that though many of the hypereosinophilias contracted in the tropics can be explained by helminth infestations, many cases remain enigmas. Infestations by parasites of which natural hosts are animals are responsible, at least in part, for the appearance of the syndrome. It was also emphasized that the eosinophilia of helminthiasis is a reflexion of the tissue mastocytosis found in these cases, in which allergy seems to play only a minor part (so-called 'resorption eosinophilia').

The second working session, with Prof. Mohr (Hamburg) in the chair, discussed blood groups and blood transfusion. Prof. J. Schneider (Paris) dealt with tropical diseases transmitted by blood transfusion; of these, malaria is the most frequent, the other tropical diseases being seldom or only very rarely transmitted by this procedure. Prof. J. Jadin (Antwerp) dealt with blood groups in Congolese. The pygmoids possess genetic ABO frequencies very different from the negroids. Certain negroid tribes seemed to have cross-bred with the pygmoids, especially in Kivu and in the north of Equateur Province.

The third working session, under the presidency of Prof. Lambin (Louvain), was devoted to the serum proteins of hæmatological importance. Profs. G. Charmot (Marseilles) and R. Vargues (Tours) dealt with African macroglobulinæmias. They showed that, in Africa, macroglobulinæmia secondary to first stage trypanosomiasis, tuberculoid leprosy and to malaria is not uncommon. All their cases of macroglobulinæmia were confirmed by ultracentrifugation. Drs. G. Van Ros and M. Van Sande (Antwerp) and R. Druet (Usumbura) then discussed the serum haptoglobin and transferrin groups in White and Negro peoples as demonstrated by electrophoresis on starch gel. The frequencies of the genes determining these groups has been established as well as the existence of certain uncommon types in Negro peoples. It was also stressed that anhaptoglobinæmia was common in carriers of the sickle-cell trait. Finally, Drs. Van Sande and Van Ros also dealt with the value of agar-gel electrophoresis in hæmatology, especially in the determination of the types of haptoglobin and transferrin, and in the detection of abnormal hæmoglobins.

The fourth session, with Prof. J. H. P. Jonxis (Groningen) in the chair, was concerned with the investigation of fœtal hæmoglobin. Prof. A. B. Raper (Bristol) mentioned the factors delaying the passage of fœtal erythropoiesis to that found in adults. Prof. J. Sonnet and Dr. M. Michaux (Leopoldville) described in detail a case of persistence of fœtal erythropoiesis in an adult, and Dr. G. Helderweirt (Antwerp) demonstrated that the detection, by a personal method, of Rh + fœtal red cells in the blood circulation of pregnant and delivered Rh – women enables us the better to understand and supervise Rh immunization during pregnancy.

The fifth session, presided over by Prof. A. C. Allison (London), discussed tropical anæmias. Prof. T. A. J. Prankerd (London) described two methods of detecting folic acid deficiency. One of these determines the concentration of folic acid in the serum using *L. casei*, the other measures the excretion of formimino-glutamic acid in the urine after the administration of histidine. Dr. H. R. Marti (Basle) reported observations made on the symptomatology of thalassæmia in 200 patients showing either the alpha- or beta-forms. Dr. H. Knüttgen (Hamburg) gave a report on the phagocytic activity of the cells of the bone marrow in malaria. Finally, Dr. H. M. Gilles (Liverpool) dealt with the epidemiological and clinical aspects of the anæmia caused by hookworms.

The sixth and last session, under the presidency of Prof. A. Dubois (Antwerp), considered the abnormal hæmoglobins (Hb). Prof. J. H. P. Jonxis (Groningen) described the molecular structure of these Hb's, and Prof. P. Boivin and L. Hartmann (Paris) their antigenic specificity. Prof. A. C. Allison (London) dealt with the relationship between the hæmoglobinoses and deficiency in erythrocytic glucose-6-phosphate dehydrogenase. Finally, Profs. E. Silvestroni and I. Bianco (Rome) described the varieties of human Hb and of thalassæmia reported so far from Italy.

G. VAN ROS

QUASI-CONTINUOUS OUTPUT FROM A RUBY OPTICAL MASER

By M. S. LIPSETT and DR. L. MANDEL

Department of Physics, Imperial College of Science and Technology, London, S.W.7

SEVERAL workers[1,2] have observed that reducing the crystal temperature may suppress the relaxation oscillations (or spikes) in some ruby optical masers. As the fluorescence line-width narrows the energy is made available to fewer resonator modes, and the interval between successive spikes is progressively shortened until they merge and quasi-continuous output results.

We wish to report observations of a similar effect, but at room temperature and for quite different reasons. We have observed quasi-continuous output from a ruby optical maser oscillating with a very non-uniform distribution of energy along the length of the maser rod.

Our observations were made on a ruby rod 2·5 mm in diameter and 3·76(7) mm long, faced with spherical surfaces in what was to have been a near-confocal configuration. The radii of curvature of the reflecting surfaces were found to be 3·84 mm and 3·69 mm. The detailed optical properties of this crystal are not known. Such maser crystals are, of course, far from optically perfect[3-5]. The ruby was excited in the usual way by a linear flashtube in an elliptical cylinder reflector. Part of the emerging maser light beam was sampled by means of a beam splitter and directed to a fast-response photocell from which the temporal development was recorded. At the same time a magnified image of each face was photographed in turn (through a red filter to remove background light) with a single-lens reflex camera.

Fig. 1 illustrates the kind of temporal behaviour that was observed at room temperature, while Fig. 2 shows a corresponding set of photographs of the reflectors. It should be noted from Fig. 1 that, although the maser light fluctuates fairly strongly, its intensity does not approach zero for several hundred μsec. Similar behaviour was observed both for input energies near threshold and well above threshold. Near threshold, where a few well-defined spikes might have been expected, the output lasted for 50 μsec or less.

The photographs of Fig. 2 show the mode pattern at both ends of the maser rod. Maser light diverges from tiny areas on one surface to a broad area on the other surface and re-converges to conjugate points on the first surface. The maser modes are therefore cone shaped. Fig. 3 illustrates the situation.

Some features of these modes are somewhat puzzling. For example, the bright pairs of spots always occurred at the reflector of smaller radius of curvature, even for quite a variety of reflecting coatings. A possible reason for this preferred direction is that the reflector of greater radius of

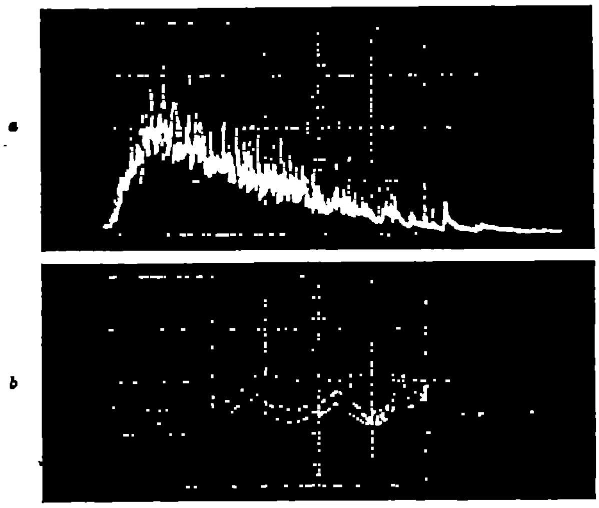

Fig. 1. Time development of the output from the maser. *a*, Vertical scale arbitrary, horizontal scale 50 μsec per division. The signal is due entirely to the maser radiation. The input to the flashlamp is 160 joules (15 per cent above threshold); the pulse of pumping light lasts about 1 m.sec. *b*, Portion of trace under the same conditions as *a* expanded to 1 μsec per division

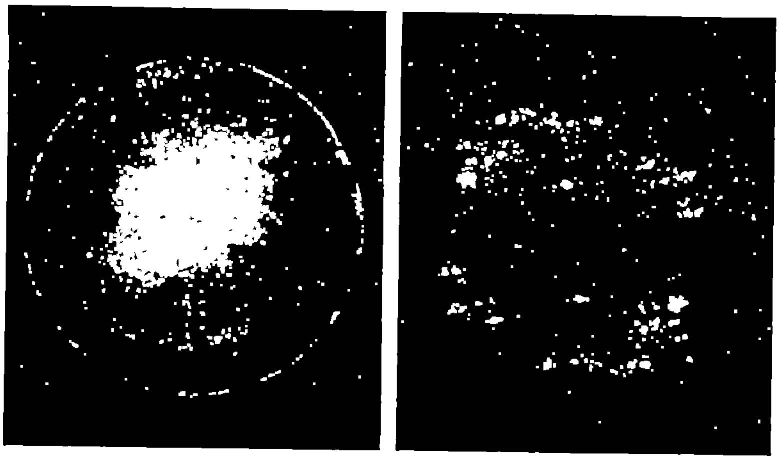

Fig. 2. Photographs of both ends of the maser for the same input conditions as in Fig. 1. Note the symmetry about any diameter

curvature more nearly matched the spacing of the surfaces[6]. Our measurements were not sufficiently accurate to confirm this possibility.

To understand why the output might be quasi-continuous for these conical modes let us consider how the rate of stimulated emission varies along the length of the resonator. We note from Fig. 2 that the energy density associated with the mode varies from one surface to the other by a factor of about 50. Since the probability of stimulated emission is proportional to the energy density, the rate of depletion of the metastable level—and therefore the relaxation cycle—varies appreciably along the crystal. In any elementary region of the crystal typical relaxation oscillations may be occurring, but the sum of all such contributions from the crystal leads to a fairly continuous output. Burch[7] has analysed the convergent wave-front kind of resonator and has predicted the possibility of quasi-continuous maser output for certain energy distributions (see also Pao[8]). These conditions appear to have been met in our observations.

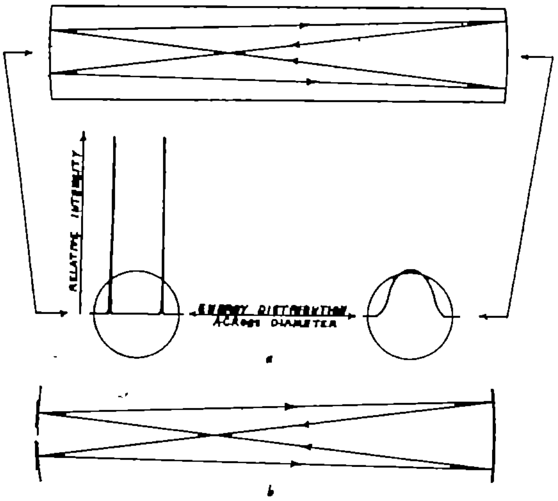

Fig. 3. Mode behaviour suggested by Fig. 2; b, equivalent conical resonator

The observed modes were much more asymmetric than one might have expected from the geometry of the ruby. However, the resonator dimensions were such that the reflector spacing was intermediate between the two radii of curvature. It has been shown by Boyd and Kogelnik[6] that this is one condition on the resonator leading to modes with high diffraction losses and, as will be seen from Fig. 2, the diffraction losses are indeed high at one face. An equivalent conical resonator[9] can be formed by a spherical reflector and a pair of plane reflectors arranged as shown in Fig. 3b. Evidently a spherical reflector can behave as a large number of such pairs of planes—at least to a first approximation of small areas—when the maser prefers to oscillate in highly asymmetric modes.

One can probably obtain similar behaviour by other reflector configurations. The most obvious choice is a maser rod faced at one end with a plane reflector and at the other with a spherical reflector having a radius of curvature equal to or slightly greater than the length of the crystal. Exact matching of the dimensions may lead to excessive energy densities at the plane reflector. Burch[7] has suggested an alternative scheme with one concave and one convex reflector. If the foregoing explanation of the quasi-continuous output is correct in principle, any configuration giving rise to modes with a non-uniform distribution of energy might be expected to reduce the tendency of maser crystals to exhibit spikes. This point should not be too difficult to investigate and might provide a clue to the design of ruby optical masers for producing continuous oscillations.

We are grateful for technical assistance from Mr. B. Bates and Mr. R. V. Shack. The work was supported financially by a grant from the Department of Scientific and Industrial Research.

LOW-GRADE METAMORPHIC ROCKS FROM THE PRINCE CHARLES MOUNTAINS, EAST ANTARCTICA

By D. S. TRAIL
Bureau of Mineral Resources, Geology and Geophysics, Canberra

WITH few exceptions the rocks so far described from the East Antarctic Shield are high-grade metamorphics, predominantly gneisses, granites and granulites, in the granulite or the almandine amphibolite facies of metamorphism as defined by Fyfe, Turner, and Verhoogen[1]. Small exposures of low-grade metamorphic rocks have been described from Western Dronning Maud Land (long. 0°) (ref. 2), from Mount Sandow (long. 101° E.) (ref. 3), and from Oates Land (long. 156° E.) near the boundary of the Shield[4].

In the southern ranges of the Prince Charles Mountains low-grade metamorphic rocks have recently been discovered by the Australian National Antarctic Research Expeditions. The rocks crop out within an area of 2,000

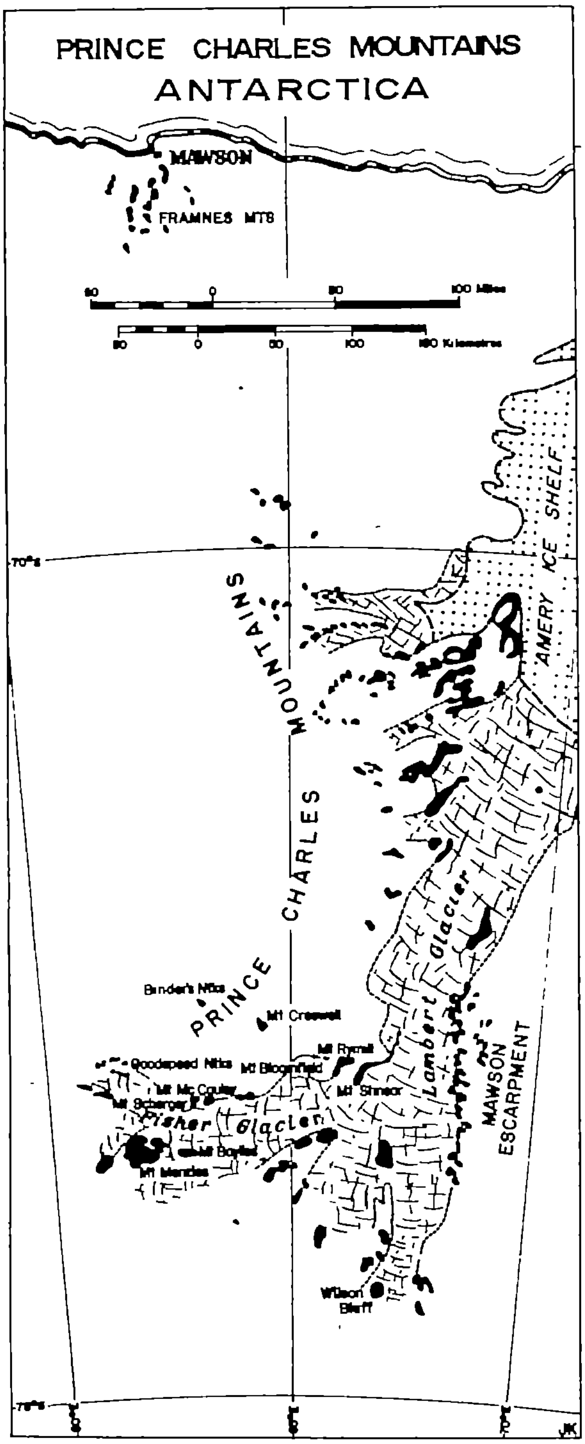

Fig. 1

sq. miles (5,000 km^2) around the Fisher Glacier. They may be continuous with similar rocks at Wilson Bluff, at the head of the Lambert Glacier.

High-grade metamorphic rocks form the outcrops along the coast of East Antarctica between 45° E. and 80° E., and the numerous nunataks within 100 miles of this coastline[2,3]. These rocks are gneisses, granulites, and foliated granites, with biotite, garnet and pyroxene as their principal ferromagnesian minerals. The northern ranges of the Prince Charles Mountains are formed by similar high-grade metamorphics; they also contain a low-lying area of Permian sediments[4].

Low-grade metamorphic rocks were first discovered in this sector in 1957 when M. Fisher, an Expeditions surveyor, was landed at Mount Stinear, in the southern ranges of the Prince Charles Mountains, where he collected slate and mica schist from moraine fringing the mountain. M. Mellor, an Expeditions glaciologist, collected metamorphosed sandstone from moraine in the Goodspeed Nunataks in 1958 [4]. Later in 1958, I. McLeod was landed at Wilson Bluff, near the southern termination of the Prince Charles Mountains, where he found outcrops of mica schist, quartzite and amphibole-bearing rocks, quite unlike the high-grade metamorphics typical of the East Antarctic Shield[4].

In 1960, R. Ruker reconnoitred the mountains along the north side of the Fisher Glacier[7]. The outlying nunataks—Binder's Nunataks, Mount Creswell and Mount Bloomfield—are composed of gneisses in the almandine amphibolite facies of Fyfe, Turner and Verhoogen[1]. The large mountains fringing the Fisher Glacier are dominantly made up of quartzites and mica schists in the greenschist facies. These low-grade metamorphic rocks are intruded by large bodies of massive biotite granite and by basic dykes. Moraine near these mountains contains fragments of dolomitic marble and large blocks of jaspilite and hæmatite.

D. Trail extended the investigation south of the Fisher Glacier in 1961. Mount Menzies, a massif 18 miles across, is composed of greenschist facies rocks, dominantly chloritoid quartzite with bands of micaceous quartzite and mica schist.

At Mount Bayliss, marble, quartzite and amphibolite, originally in the greenschist facies of metamorphism, are interbanded with granite and have been thermally metamorphosed. Later intense shearing has imposed a strong sub-horizontal foliation on both the granite and the metamorphosed rocks. Slate and phyllite are common in the moraine on both mountains.

The structure of Mount Bayliss suggests that a major thrust-plane may separate low-grade and high-grade metamorphic rocks. In the interpretation of seismic traverses between Mawson and the Goodspeed Nunataks, Goodspeed and Jesson[8] show a deep rock-surface depression between the gneiss at Binder's Nunataks and the quartzite at the Goodspeed Nunataks. This depression may be occupied by a major tectonic discordance.

The low-grade quartzites and schists are the metamorphosed equivalents of quartz-rich sands and silts which would be produced by the erosion of terrain composed of the dominantly acid, high-grade gneisses.

Evidence for two episodes of metamorphism has been obtained from the coast of Kemp Land between long. 60° E. and 55°. E (100–200 miles west of Mawson). Here, basic dykes, which sharply cut well-foliated gneisses, are themselves metamorphosed; some have developed garnet and have a faint, discordant foliation[9].

Starik *et al.*[10] have obtained values between 400 million and 1,500 million years for the absolute ages of various high-grade metamorphic rocks from the East Antarctic Shield. From determinations of both high-grade and low-grade metamorphic rocks, Starik *et al.*[10] and Sarah Deutsch *et al.*[11] have obtained an age between 400 million and 500 million years for the latest metamorphism in East Antarctica.

The low-grade metamorphic rocks have probably been involved only in the latest, Lower Palæozoic episode. They may be considerably younger than the high-grade metamorphics, many of which have been repeatedly metamorphosed in successive orogenies throughout the Proterozoic era.

In moraine at Mount Rymill, Ruker[7] discovered fragments of unmetamorphosed sandstone and shale with *Glossopteris* and other fossil plants, referred to the Permian by Mary White[12]. These unaltered rocks may be exposed *in situ* in mountains at the head of the Lambert Glacier.

I thank I. McLeod for guidance and R. Ruker for information. I also thank W. R. McCarthy, of the Australian Mineral Development Laboratories, for the petrographic determinations of rock type and metamorphic facies on which this work is based.

My colleagues and I are grateful to fellow members of the Australian National Antarctic Research Expeditions for their support and assistance to geologists in the field.

Publication of this communication is authorized by the Director, Bureau of Mineral Resources, Australia, and by the Director, Australian National Antarctic Research Expeditions.

STRUCTURE OF RIPPLE MARKS

By PROF. J. E. HEMINGWAY

Department of Geology, King's College, University of Durham, Newcastle upon Tyne

AND

A. M. CLARKE

Production Department, National Coal Board, Gateshead, 11

A VALUABLE new classification has recently been proposed by Allen[1] for asymmetric ripple marks, based essentially on their external form and scale. Allen has also offered an explanation of how straight and trough (*sic*) cross-stratification is generated. This is based on his own and other selected observations of straight and linguoid asymmetric ripples in shallow seas, estuaries and rivers. Allen's mechanism involves overstep by the advancing foresets of a ripple on to the upstream (stoss) slope of the succeeding downstream ripple, which itself is being synchronously eroded up to the moment of its burial. His figures (*A* and *B*) show that if this mechanism is correct, the erosion surfaces, which form the boundaries of the sets of cross-strata generated from a society of aggrading ripples, must always be oblique to the regional depositional dip of the deposit. Furthermore, if his suggestions relating the depth of water to the thickness of individual sets or units or cross-strata are to be accepted, the dip of the upper boundary of the set must always be greater than, or equal to, the dip of the stoss side of the ripple or dune.

In making his assumptions Allen appears to have disregarded two commonly observed phenomena: (*a*) the ubiquitous field observation, that in both large and small scale cross-stratification the lower boundary of the cross-stratified unit or set is generally parallel and not generally oblique to the regional depositional dip, as evidenced by preceding and succeeding plane-concordant stratified formations; (*b*) the phenomenon referred to as 'kolking' by Blasius[2] and 'pot-holing' by Simons *et al.*[3] and what, following Simons *et al.*[3], may be termed 'toe-blasting' of the front of an advancing dune or asymmetric ripple.

When the net effect of deposition and erosion in a fluvial or distributary dune system is positive (for example, the system is aggrading) any explanation of the resulting bedding structures must therefore take account of these two phenomena.

The results of preliminary examinations of both straight and festoon types of cross-stratification on the north-east coast, in the Jurassic at Whitby (N.G.R. *NZ* 898115) and elsewhere, and the Carboniferous at Seaton Sluice (*NZ* 3476) and Hawick (*NU* 2617) and in numerous other exposures in other systems, may be represented as follows:

(1) *Festoon cross-stratification* (Fig. 1). The morphological element responsible for festoon cross-stratification appears to consist of the lower segment of a nearly circular trough the axial line (that is, the line formed by the intersection of the axial plane with the surface of the trough) of which may be inclined at various angles in the plane of the regional dip. The erosional furrows appear to be

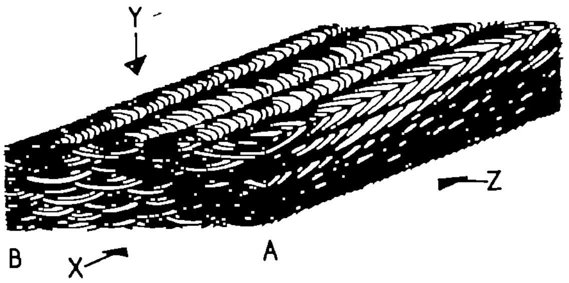

Fig. 1. Block diagram of festoon bedding, showing surface form of plane of truncation (Y) parallel to regional depositional dip

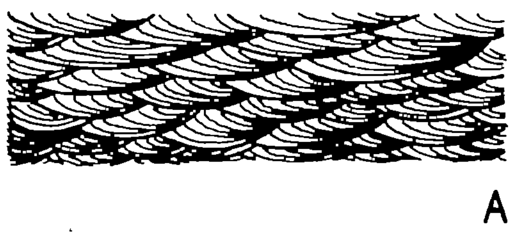

Fig. 2

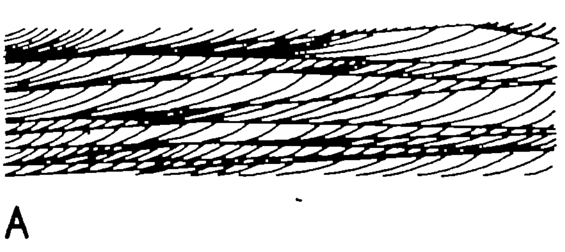

Fig. 3

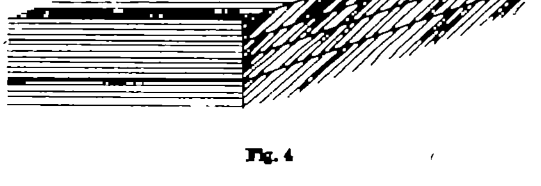

Fig. 4

formed by the trace of this inclined trough across an earlier surface parallel to the regional dip. Allen has already directed attention to the offset super-position of the furrows as a consequence of the surface pattern of a society of linguoid dunes.

The foreset deposits filling the furrow consist of a conformable series with the same shape and inclination as the trough element responsible for the furrow. Thus the foresets are seen to be conformable with the base of the furrow when viewed perpendicular to the main current direction in Fig. 1. The section parallel to the main current direction *Z* in Fig. 1 illustrates one of the causes of the apparent irregularity of thickness displayed in those exposures of festoon cross-stratification in which the unit boundaries are parallel. It also shows one of the causes of the apparent concavity of much of the cross-strata in such an exposure.

Oblique sections across sets of festoon trough cross-stratified units reveal a wide range of forms. The section at approximately 20° to *AB* (Fig. 2) is similar to a type of trough cross-stratification recently described by Allen[4] from the Senni Beds of the Lower Old Red Sandstone of the Black Mountains, and by Zhemchuznikov *et al.*[5] from the Carboniferous of the Donetz Basin and in contemporary alluvial sediments by Shantzer[6]. Zhemchuznikov *et al.*[5] ascribe this type to the upper part of the main channel in shoal and braided portions (Table 2).

Basin-like (*sic*) bedding similar to that seen in sections perpendicular to the main current direction festoon cross-stratification is attributed[5] to inshore marine conditions as expressed in sandstones and coarse siltstones (Table 3). Fig. 3 shows a vertical section at approximately 70° to *AB*: this also appears to have been considered as having a distinctive environmental significance by Zhemchuznikov *et al.*[5].

Botvinkina[7] has also given a detailed morphological classification of cross-stratification. This sets out as individual types many forms which are identical to those seen in the varyingly aligned transverse sections of festoon cross-stratification. Clearly an appreciation of the orientation of the plane of dissection of this structure in both natural sections and borehole cores is fundamental to their interpretation and effective classification.

The variety of festoon cross-stratification illustrated in Figs. 1–3 occurs when the dip of the axial line of the foresets is greater than the maximum dip on the sides of the furrows. Slightly different cross-sections may be constructed when the maximum dip on the sides of the furrows is greater than that of the axial line of the foresets. Other types differentiated by Botvinkina[7] belong to sections from this latter case.

(2) *Straight or rectilineal cross-stratification* (Fig. 4). The only required modification of Allen's explanation of how straight cross-stratification is generated is that it should be adapted to explain the parallelism of the individual sets with the regional depositional dip (Fig. 4).

It may be that differences in the depths of the advancing 'potholes' are the principal factor controlling the height of the large-scale festoon cross-stratified units. If this is the case then the systems elucidated by Simons *et al.*[3] are generally applicable, and consequently the differences in the depth of 'toe-blasting' may control the thickness of successive units of straight cross-stratification.

In conclusion, the mechanism proposed by Allen for the generation of cross-stratification is not acceptable for the exposures we have observed. However, cross-stratification with individual sets oblique to the regional depositional dip have been observed, but only on a small scale. The latter we believe are related to ripple drift, and we refer to this type as drifted cross-stratification or cross-drifting.

DECOMPOSITION OF TRITIUM-LABELLED ORGANIC COMPOUNDS

By Dr. E. ANTHONY EVANS and F. G. STANFORD

Radiochemical Centre, Amersham, Bucks.

THE very rapid progress which is being made in the application of tritium-labelled organic compounds for many physical and biological investigations[1] has prompted the publication of this article on the decomposition of tritium-labelled organic compounds. A more general account of the self-decomposition of compounds labelled with radioactive isotopes has recently been published[2], with special reference to sugars labelled with carbon-14.

The high specific activities which can be obtained with tritium compounds, the short range[3] (0·7 mg/cm^2) of the weak β-radiation (maximum energy[4] between 17·5 and 19·4 keV and mean energy[5] 5·52 keV) and the long half-life[6] (12·3 years) of tritium, enables compounds labelled with this isotope to have a very wide variety of uses ranging, for example, from luminous paint[7] to radiotherapy[8]. The half-life of tritium, although conveniently long for most experimental uses, represents a decomposition rate of approximately 5 per cent per annum in the storage of labelled compounds, due to the natural decay of tritium to helium, that is, primary (internal) decomposition[9].

Specific Activity and Types of Molecules

In any organic compound C_nH_mX (where X is any element or group of elements other than hydrogen), the replacement of one hydrogen atom per molecule with tritium results in the compound $C_nH_{m-1}TX$ (the letter T is used to represent a tritium atom) having a specific activity of 29·12 c./m.mole. When considering the decomposition of such labelled molecules one must recognize two types: (*a*) molecules which are labelled at one position only, that is, specifically labelled; (*b*) molecules which have multiple labelling, that is, in more than one position.

As hydrogen atoms directly attached to oxygen, nitrogen and sulphur atoms are labile, that is, exchangeable in hydroxylic solvents, only compounds with tritium atoms directly attached to carbon atoms are considered. Compounds in class '*a*' are often produced with the tritium isotopic abundance at one hydrogen position of very nearly 100 per cent and the concentration of tritium in the molecule sometimes as high as 50 per cent or more of the total hydrogen atoms. Compounds at such high specific activities are required, for example, for radiotherapeutic use[8] or for luminous compound work[7]. For most tracer applications of tritium-labelled organic compounds, isotopic abundances of less than 10 per cent are normally required and in the majority of cases the tritium abundance in a molecule varies from 0·1–1 per cent only. The activity associated with one molecule of a tritium compound containing one atom of tritium is approximately 5×10^{-20} c. and the energy available from tritium corresponds to 0·88 eV/atom/day. This energy is much less than most bond dissociation energies[9]; about 4 eV are normally required to rupture a bond.

Primary Decomposition

When the tritium atom of a mono-tritiated molecule disintegrates, helium is produced leaving a non-radioactive recoil fragment. Molecules containing more than one tritium atom would give rise to radioactive recoil fragments if the tritium atoms did not disintegrate at the same time, which is unlikely to occur and ultimately only non-radioactive decomposition products will arise by primary (internal) decomposition. Consider for example the labelled amino-acid glycine-2-T ($NH_2.CHT.COOH$); primary (internal) decomposition due to natural decay will not give rise to radioactive impurities. This is shown by the figures in Table 1, glycine-2-T remaining radiochemically pure even after 21 months.

The atomic and molecular consequences of radioactive decay for tritium and one or two tritiated hydrocarbons have been examined[10]. For the simple tritiated hydrocarbon methane (CH_3T) the predominant process is one in which neutral helium-3 separates leaving a positively charged methyl group, namely, CH_3^+, and less frequently hydrogen atoms are also split off leaving CH_2^+, CH^+ and C^+. Similar results have been obtained with tritiated ethane[11] giving rise to positively charged ethyl groups, $C_2H_5^+$. These results are in direct contrast to the behaviour of tritium[10]. In molecules of TH, the pure β-emission fails to dissociate, which remain as $(He_3H)^+$. It seems likely, therefore, that in tritiated molecules of greater complexity, primary (internal) decomposition will give rise to neutral helium-3 and positively charged groups which may further loose hydrogen atoms. For the more complex molecules no information is yet available regarding the nature of these non-radioactive decomposition products, but they could possibly be conveniently studied by using doubly labelled molecules, labelled, for example, with carbon-14 and tritium. The proportion of the breakdown fragments labelled with carbon-14 could then be detected. However, unless the specific activity with respect to both isotopes is very high, the recoil fragments would have to be carefully sorted from the singly labelled molecules remaining.

Table 1. DECOMPOSITION OF TRITIATED AMINO-ACIDS

Owing to the very short range of the β-particles it is reasonable to assume that all the energy of the radiation will be self-absorbed. In the solid state, therefore, decomposition due to primary (external) radiation, that is, radiation from other molecules, is likely to be a major contributing source. Interaction between radioactive and unlabelled molecules will be much smaller in solution and primary (external) decomposition will be minimized, most of the β-radiation being absorbed by the surrounding solvent, especially in aqueous solutions where the molecules may be solvated. The decomposition should be minimal at infinite dilution, but the gross effects of variation in concentration have yet to be studied in detail.

Secondary Radiation Effects

The decomposition or transformation due to the reaction of a labelled molecule with a reactive species, for example, free radicals or the excited decomposition fragments of primary decay, presents the most serious problem in the storage of tritium compounds. Such secondary radiation effects give rise to radiochemical impurities which can often present a serious disadvantage to the tracer compound user. This is especially true for experiments, for example, on the metabolism or some analytical use of tritium compounds, the results of which can only be deemed reliable if the tracer labelled compounds are of a high radiochemical purity. Fortunately for many uses the presence of a few per cent impurity is not necessarily an embarrassment, but it is obviously most desirable to know the exact radiochemical purity of the labelled compound before use.

Chemical Decomposition

All organic compounds are thermodynamically unstable, but chemical decomposition at room temperature, for many compounds. is usually very slow and can be slowed even further by storing the compound at low temperatures. In radiochemical investigations the presence of chemical non-radioactive impurities is not normally a handicap; but for work involving the absorption or reaction rates of a particular labelled compound. these chemical impurities may prove embarrassing. As chemical decomposition can give rise to radiochemical impurities, compounds are often stored at low temperatures to reduce this type of decomposition to a minimum.

Storage

The numerous tritium-labelled compounds described in this article have been kept as weighed crystalline solids, freeze-dried solids or dissolved in solvents at concentrations approximately 1–5 mc./ml. Ampoules contained air or were sealed *in vacuo*, although there is at present no evidence to suggest that the presence of a small volume of air affects the stability of compounds not normally affected by oxygen.

Methods of Analysis

Two methods of analysis were used for determining the radiochemical purity of the tritiated compounds.

(1) Dilution analysis (D.A.), which is carried out by diluting a small weight of the labelled compound with about 1,000 times its weight of carrier. The mixture is homogenized in a suitable solvent, the solvent evaporated, the sample dried and the specific activity measured. The compound is recrystallized several times until the specific activity is unchanged on two successive recrystallizations. When possible a suitable derivative is prepared and the specific activity of the pure derivative measured. If all the specific activities are identical the compound can be regarded as radiochemically pure. Care must be taken to ensure that all samples are dried to the same extent or inaccurate values will be obtained. This is especially true with compounds which contain water or solvent of crystallization. Derivatives must be selected carefully and reactions which involve the substitution of non-labile hydrogen atoms in the labelled compound should be avoided. Tritium measurements were carried out by combustion of samples to tritiated water by the Schöniger technique[12] and the activity measured in a β-liquid scintillation counter (Ekco Electronics No. 612). The overall accuracy of this method was ± 7 per cent.

(2) Liquids and gases were subjected to gas-liquid chromatographic (G.L.C.) analysis[13] and the radiochemical purity was assumed to be no better than the chemical purity (± 5 per cent). Other compounds were examined by paper chromatographic analysis (P.C.) in the solvent systems described in the Tables. The tritium activity on the developed chromatograms was determined with a 2π-gas flow (argon–10 per cent methane) proportional chromatogram scanner[14]. Identical results were obtained on scanning both sides of a paper chromatogram. The accuracy of this method was about ± 5 per cent and the limit of detectability approximately 1 μc.

Results

The Tables contain a selection of tritium-labelled organic compounds for different classes of compounds at a variety of specific activities. All the compounds studied were radiochemically pure when first prepared and their subsequent rate of decomposition under various storage conditions has been determined.

Conclusions

By an examination of the Tables it can be seen that the decomposition of tritium-labelled compounds can be minimized by storing the compounds dissolved in a suitable solvent. Chemical and secondary radiation decomposition are reduced by storing below room temperatures. For many compounds the storage in aqueous solution appears to be a most suitable method for reducing decomposition rates. In numerous cases there does not seem to be any great advantage in storing the compound at − 40° C than at 0° C. At low temperatures there is the additional problem of sublimation of the protecting solvent to other parts of the tube, if there is a temperature gradient, leaving the substance unprotected; frequent examination is then required.

Tritium compounds having specific activities less than 500 mc./m.mole, when stored under the best-known conditions suffer no serious decomposition for at least one year. For compounds with higher specific activities, the rate of decomposition will increase with increasing specific activity and will depend on the actual type of compound. Among the most stable classes of compounds are amino-acids, purines, pyrimidines and steroids. Nucleosides at high specific activity > 1 c./m.mole appear to be one of the more sensitive classes of compounds, the rate of decomposition when stored under the best conditions being 0·5 – 1 per cent per month. As more labelled compounds are prepared there will obviously be some members of a particular class or group which will be found more sensitive to radiation effects than others within that class. For example, the amino-acid methionine is slightly more sensitive to radiation effects than other amino-acids of the same specific activity and uridine-T is one of the more sensitive of the nucleosides.

There are a number of anomalies, for example thymidine-6-T at high specific activity (4 or 14 c./m.mole) appears to keep better at room temperature in aqueous solution than at –40° C. This may be due to a shorter life of reacting species (for example, free radicals) at room temperature than at – 40° C giving less time for secondary decomposition to occur[15], but at present the anomaly is unexplained.

It is hoped that this article will guide the many users of tritium-labelled compounds in selecting the best method of storage at present known. There is obviously much more information to be obtained regarding the mechanism of the decomposition and the nature of the products of primary nd secondary decomposition. Further work is in progress in our laboratories and a more detailed account of the decomposition of individual compounds will be reported on at a later date.

We thank Dr. John R. Catch and Mr. D. A. Lambie for their interest and the United Kingdom Atomic Energy Authority for permission to publish these results.

EFFECT OF IONIZING RADIATION ON ADENINE IN AERATED AND DE-AERATED AQUEOUS SOLUTIONS

By Miss J. J. CONLAY

Fondation Curie, Institut du Radium, Paris

THE radiation chemistry of the nucleic acids and their constituents has been investigated by various workers[1–4]. It is known that in these macromolecules the purine and pyrimidine bases are the elements most susceptible to radiation damage, and that the purines are less radiosensitive than the pyrimidines[1,2], which one would expect from the increased resonance of their structure. Pyrimidine attack is enhanced by a factor of approximately 2·5 in the presence of oxygen, and is a result of peroxidation at the 4 : 5 bond[1]. Peroxides are not found, however, when purines are irradiated in aerated solution[1,3]. This article is concerned with the estimation of the extent of radiation damage to adenine in aqueous solution, both in the presence and in the absence of oxygen, and the identification of the primary products formed.

10^{-3} M solutions of adenine in triple-distilled water were irradiated at room temperature, in the presence of oxygen, with 40 kV X-rays and under vacuum with cobalt-60 γ-rays. Total doses in the range 300,000 r. were given. The resulting solutions were subjected to ion exchange chromatography, using a 12-mm column of 'Dowex-50' and eluting with 2 N hydrochloric acid, a technique which has already been described[4]. Typical elution diagrams are shown in Figs. 1*a* and *b*.

In both cases the major product appears in section *B*, and these fractions were collected, lyophilized and the product subjected to descending paper chromatography in various solvents. Section *B* was thus shown to contain a single product of which the R_F in three solvents and absorption spectrum at different *p*H corresponded with those of 8-OH-adenine. This compound was synthesized for comparison by reacting 4,5,6-tri-NH$_2$-pyrimidine with phosgene in alkaline solution. When mixed with the synthetic compound, the irradiation product was inseparable by column or paper chromatogram.

On similar treatment, section *A* yielded traces of hypoxanthine, more in the absence than in the presence of oxygen. Other degradation products were certainly also present here, which have not been identified.

No products were detected in section *C* when the solutions had been irradiated under vacuum. In the presence of oxygen, however, this section was found to contain traces of isoguanine and a compound which shows no absorption above 220 mμ, but produces a spot on a paper chromatogram, with a strong fluorescence under ultra-violet light (2537 Å). No result was obtained by spraying the chromatogram with Fink's reagent[5] (0·5 N sodium hydroxide followed by a solution of *p*-dimethylaminobenzaldehyde) which reacts to form a coloured complex with pyrimidines saturated at the 4 : 5 bond. Michl's reagent[6] (an ethanolic solution of eosin saturated with mercuric chloride) which gives a red-violet coloration with purine derivatives, also gave a negative result with this product. Since it shows no ultra-violet absorption, the chromophoric group in the pyrimidine ring must have been changed, which, if it is a primary product, implies saturation of one of the double bonds in this ring. For stearic reasons, and considering the electronic structure of the molecule, it seems unlikely to be the 4 : 5 bond as in the case of the pyrimidines, but more probably the 1 : 6 or 2 : 3 bonds.

Nothing was detected in the fractions after the unreacted adenine, but on eluting the column afterwards with 0·25 N sodium hydroxide, 4,5,6-tri-NH$_2$-pyrimidine was found. This is presumed to arise from the formamido-pyrimidine already noted by Hems[1], which would readily lose the CHO group in 2 N hydrochloric acid. Contrary to Hems's results this compound appeared in the presence as well as in the absence of oxygen; but it may well have been that in this case the aerated solutions were not fully oxygen saturated throughout the irradiation time.

The results show the same primary reaction in both cases: attack by an OH• radical at C_8, which is the position of highest electron density when the molecule is approached by an electrophylic reagent[7,8]. The highest bond order is found in the 7 : 8 bond, thus reaction in the presence of H• and OH• radicals should occur primarily via substitution of OH at C_8 or saturation of the 7 : 8 bond. On the basis of these considerations and the experimental results obtained, the scheme as shown in Fig. 2 is suggested for the reaction in the absence of oxygen.

In the presence of oxygen, though the primary step is the same—the secondary products may differ. Reactions due to OH• radicals will be unchanged but the H• radicals should be largely converted to HO_2•. The formamido-pyrimidine should not, therefore, be formed. If hydroperoxides are formed as a result of HO_2• attack, they must immediately decompose, as they have not been detected. If the HO_2• radicals are not thus directly responsible for the augmented base attack in the presence of oxygen then this must be due to the removal of H• radicals preventing recombination with OH•, and thus leaving more OH• radicals free to attack the solute molecules.

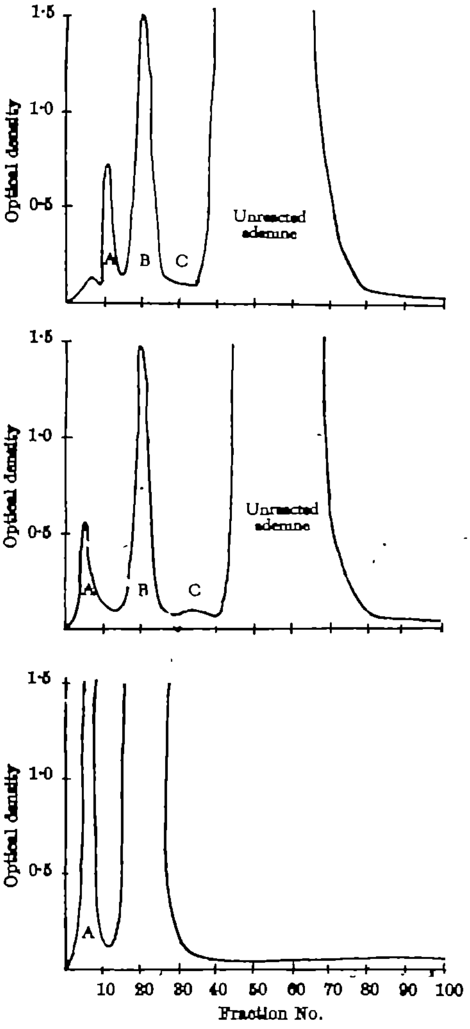

Fig. 1. Ion-exchange chromatography of irradiated adenine and 8-OH-adenine solutions. 12-mm column 'Dowex-50'. Elution with 2 N hydrochloric acid. Fraction volume 3·5 ml./10 min. optical density at 260 mμ. *a*, After irradiation of 100 ml. 10^{-4} M adenine solution, in the absence of oxygen, dose = 440,000 r.; *b*, after irradiation of 80 ml. 10^{-4} M adenine solution, in the presence of oxygen, dose = 300,000 r.; *c*, after irradiation of 40 ml. 10^{-4} M 8-OH-adenine solution in the presence of oxygen, dose = 300,000 r.

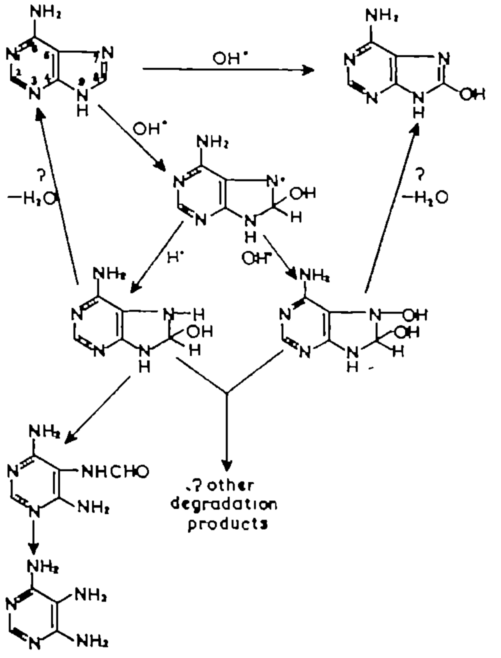

Fig. 2

It is notable that when adenine reacts with OH• radicals from Fenton's reagent, the 8-OH compound is also the product formed[9]. Other possible primary reactions include deamination at C_6, producing hypoxanthine, which is found to a slight extent, or substitution in position 2 giving isoguanine, which appears also to be present in trace quantities in section *C*, in aerated solutions. No trace of the N_1 oxide which is produced by oxidation with hydrogen peroxide[10] was found.

Table 1. R_F of Compounds on Paper Chromatograms

	n-Butanol : morpholine : diethylene glycol : water 4·5 : 1·5 : 1 : 2	*n*-Butanol : diethylene glycol : water (in atmosphere NH_3) 4 : 1 . 1	*n*-Butanol : methanol : formic acid 3 : 0·5 : 2·5 (paper impregnated with 30 per cent *cyclo*hexanol/acetone solution)
Adenine	0·55	0·61	The solvent was allowed to run off paper; therefore R_F's not calculated, only corresponding positions of products and blanks obtained
8-OH-adenine	0·48	0·32	
B	0·48	0·32	
Hypoxanthine	0·40	0·49	
A	0·39	0·40

C	280	250		
			*p*H	Neutral
4,5,6-tri-NH_2-pyrimidine	287	240	280	240

G(-adenine) was found to be approximately 0·85 for aerated solutions and 0·35 for de-aerated ones. The ratio is thus comparable with that for the pyrimidines but the values are lower in agreement with the data already known. (*G*(8-OH-adenine) was approximately 0·15 in oxygen and 0·05 under vacuum. (These measurements were made using values for the extinction coefficients as follows: adenine λ_{max} 263 mμ, Σ_{max} 13,100 l. mole^{-1}cm^{-1}; 8-OH-adenine λ_{max} 272 mμ Σ_{max} 10,900 l. mole^{-1}cm^{-1}.) The *G* values indicate that 8-OH-adenine is more sensitive to radiation than adenine itself, if it is the major primary product formed. This was confirmed when a solution of 8-OH-adenine (10^{-4} M) was irradiated in the presence of oxygen, and under the same conditions as adenine. The resulting solution subjected to column chromatography (Fig. 1c) showed that G(-8-OH-adenine) is approximately twice the value for G(-adenine), and that the product in section A from irradiated adenine solutions is a secondary product resulting from attack on the 8-OH-adenine. The final product in section A has not been identified; but in solution it is yellow in colour and shows an absorption maximum in acid solution ($pH \sim 1$) at 335 mμ and a minimum at 298 mμ. There may be more than one product present here. It is interesting to note, in this connexion, that the N_1 oxide of adenine has also been found to be destroyed more rapidly by ultra-violet light and ionizing radiation than adenine[10], which seems to be one of the most stable purine derivatives.

I thank Dr. R. Latarjet for his interest in this work, Dr. B. Ekert for advice and help, and the Medical Research Council (U.K.), from whom I have received a French exchange scholarship.

RECOVERY FROM RADIATION INJURY: A PROPOSED MECHANISM

By Dr. ROBERT F. KALLMAN

Department of Radiology, Stanford University School of Medicine, Palo Alto, California

EXPERIMENTAL evidence has emerged over recent years which better defines the course of recuperation following injury to certain kinds of cells caused by ionizing radiation. Biological systems varying widely in complexity have been examined under somewhat different conditions, and have yielded results which appear to agree qualitatively, if not quantitatively. It is the purpose of this article to point out the common thread running through these diverse findings, and to suggest a mechanism for their explanation.

Irradiating hamster cells *in vitro* and defining survival as the ability to form macrocolonies, Elkind[1] has compared the effect on survival of single, acute radiation exposures with doses given in two fractions. Varying lengths of time were allowed to intervene between the first, or conditioning, dose and the second, or test, dose. Essentially, the net effect of a given dose delivered in two fractions was never so great as when it was delivered singly. The effect on surviving cells of the first of two fractions disappeared completely by approximately 20 h, that is, recuperation was complete. Elkind has sub-divided this 20-h period into two phases: (1) recovery, meaning changes in survival response after an initial exposure, which changes occur during the period of division delay; (2) repair, meaning changes in per cent survival that involve repopulation by viable cells. A characteristic and well-defined fine structure was described for the recuperation kinetics during the first few hours following initial irradiation, that is, the recovery period. This consisted in the curve of surviving fraction after a constant second dose as a function of time between the two fractional doses rising to a maximum some time during the first 3–6 h, then falling to a minimum shortly before 10 h, and finally rising again progressively to complete recuperation at about 20 h. This progression of sensitivities may be described qualitatively in other ways, equivalent to Elkind's description. Thus one may substitute the term population resistance for surviving fraction in certain of Elkind's fractionated dose-survival graphs (for example, Fig. 7 in ref. 1). Alternatively, the term I, defined as residual injury, would be roughly equivalent to the reciprocal of surviving fraction (Fig. 1, curve 1). (The terms, residual injury I, and conditioning dose D_C, are used throughout this article as established and defined by G. Sacher in *Radiation Biology and Medicine* (edit. by Claus, W. D., 283, Addison-Wesley, 1958).) It will be seen that the level of residual injury falls to a minimum shortly after exposure to conditioning irradiation, then rises to a maximum, and then falls until it finally reaches the level characteristic of an unexposed population. Elkind has presented an attractive hypothesis to account for this kind of behaviour, largely on the basis of changes in extrapolation number inflicted by the conditioning irradiation: recovery, he concludes, consists in the return of a radiation-altered extrapolation number to its original value, that is to say, the reappearance of the shoulder of the survival curve of the sensitive cells.

The kind of recuperation kinetics, that is, the qualitative shape of the residual injury curve in two-fraction experiments already described, is similar to that observed in at least three other biological systems. As Elkind has pointed out, two-fraction acute lethality experiments in mammals have yielded similar curves. Mole[2] originally described an initial maximum in residual injury followed by a minimum before the approximately exponential fall in two-fraction injury curves (Fig. 1, curve 4). *CBA* mice were exposed to a conditioning dose of 400 r. and were tested with second doses at intervals of 6 h–20 days later. His findings have since been amply confirmed by Storer and Sanders (Fig. 1, curve 5) (unpublished data, cited by Elkind[1]) and by myself and Silini (Fig. 1, curve 3) (unpublished). It must be noted that acute death of an animal at the LD_{50} in whole-body irradiation experiments reflects radiation depopulation of vital tissues, notably the blood-forming system, to just below a critical number of sensitive cells. The likelihood that the shape of this injury decay curve is attributable to changes in the probability of survival per unit radiation dose of bone marrow cells after conditioning irradiation is well supported by the recent findings of Till and McCulloch[3]. Thus, bone marrow cells irradiated *in vivo*, allowed to recuperate in their normal environment before exposure to a second radiation dose, and tested by their ability to form visible clones in the spleens of irradiated recipient mice exhibited a pattern of recuperation similar to that described here: an initial minimum in residual injury occurred at 5 h with a subsequent maximum at 10–15 h (Fig. 1, curve 2).

In a series of experiments on spontaneous mammary tumours of mice, we[4,5] have found indications of the same kind of recuperation pattern, though on a greatly expanded time scale (Fig. 1, curve 6). When solid tumours, *in situ*, were given a conditioning dose of 1,120 rads, there was an apparently higher degree of residual injury at the fourth day than at the second day thereafter. In these experiments, the criterion of radiation effect was 50 per cent cure, that is, the dose estimated to cure 50 per cent of tumours as determined by interpolation between the cure rates for a graded series of doses.

From a comparison of the 'smooth' curves in Fig. 1, which have been plotted freely from the available data,

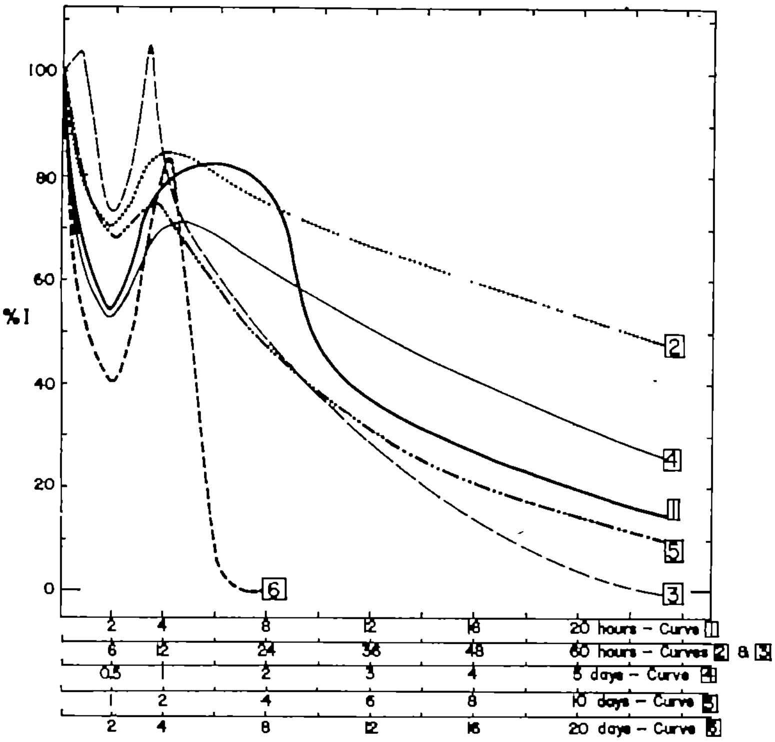

Fig. 1. Curves showing the change in effectiveness of a second dose of radiation as a function of time between first and second dose. All data have been converted to the same ordinate scale of percentage residual injury (%I). Each curve is plotted on its own arithmetic time index, as abscissa, with the different abscissal indexes arranged so that the initial minima fall at the same distance from the ordinate axis. All curves are freehand fits to experimental data. Conditioning doses, method of detecting residual effectiveness, biological system employed, and investigators were, respectively: curve 1, 433 rads, constant second dose, hamster cells *in vitro*, Elkind (ref. 1); curve 2, 400 rads, constant second dose, mouse bone marrow *in vivo*, Till and McCulloch (unpublished); curve 3, 800 r, variable second dose, *C57BL* mouse acute lethality, Kallman and Silini (unpublished); curve 4, 400 r, variable second dose, *CBA* mouse acute lethality, Hole (ref. 2); curve 5, 400 r., variable second dose, *CF*-1 mouse acute lethality, Storer and Sanders (cited by Elkind (ref. 1)); and curve 6, 1,120 rads, variable second dose, *C3H* mouse spontaneous mammary tumour cure, Kallman and Tapley (ref. 5)

the conclusion appears amply justified that, as a general phenomenon, conditioning irradiation evokes this pattern of early refractoriness succeeded by a rise in sensitivity prior to a final monotonic course of recuperation. The liberties taken in the choice of abscissal scales in Fig. 1 were deliberate—so that this conclusion might be the more apparent.

For the majority of mammalian cells that have been tested quantitatively after both *in vitro* and *in vivo* irradiation, D_0's have been reported in the range of 100–150 rads and extrapolation numbers from approximately 2 to 10. The majority of cell populations thus far studied must, until proved otherwise, be assumed to be essentially asynchronous with respect to the positions of the component cells in the generation cycle. That is to say, at any given instant an asynchronous cell population will contain cells in all stages of mitotic and interphase activity, the exact proportion of cells of any given stage being dependent on the duration of that stage. For example, if the stage of DNA synthesis lasts, say, 8 h and the cell cycle averages 20 h in duration, 40 per cent of the cells in a random population would be expected to be in DNA synthesis. The concept that cell radiosensitivity varies according to the position of a cell in its generation cycle has been bolstered by the findings of Terasima and Tolmach[6,7]. When HeLa cells were synchronized by selective means and homogeneous populations of such were irradiated during different parts of the cell cycle, it was found that, with respect to loss of reproductive integrity, radiosensitivity changed continuously and mitotic (M) cells were most sensitive (D_0 about 70 rads), early G_1 cells were minimally sensitive (D_0 baout 180 rads), cells grading from late G_1 to early S were very sensitive (D_0 about 100 rads), and G_2 cells were relatively insensitive (D_0 about 160 rads). (The notation used for distinguishing different periods in interphase is, as established in present-day usage, G_1 to denote the immediate post-mitotic, pre-DNA synthetic period, S to denote the period during which DNA is synthesized, and G_2 to denote the post-DNA synthetic, pre-mitotic period.) Quantitative estimates of the radiation sensitivities of these major stages relative to early G_1, the least-sensitive state, would therefore be: M = 2·57-fold, late G_1-early S = 1·80-fold, and G_2 = 1·13-fold. These differences in radiosensitivity were evidenced by changes in the slopes of the survival curves rather than in the extrapolation numbers which varied between 1·5 and 2·5, not correlated with phase. (In the most recent experiments the different survival curves were carried down to less than 0·01.) Undoubtedly, these findings are in themselves mean estimates of sensitivity in the various major stages identified; owing to technical difficulties in achieving and maintaining higher possible degrees of synchrony, not to mention the difficulties associated with the ability to resolve small differences in survival curve slopes or extrapolation numbers, small radiosensitivity differences between immediately adjacent stages cannot be detected with high precision or confidence.

Using a completely different technique based on pulse-labelling asynchronous populations of L cells and ascites tumour cells with tritiated thymidine, Dewey and Humphrey[8] have furnished qualitative and quantitative[9] confirmation of the preceding order of sensitivity. In contrast, however, Chinese hamster cells[10,11], subjected to the same kind of radiation treatment and analysis after pulse-labelling with thymidine, showed a different order of phase-dependent radiosensitivities. Moreover, for these cells, the phase-dependent order of sensitivities differed for ultra-violet as compared with cobalt-60 γ-radiation. Further work is necessary in order to resolve these differences between cell types as well as kind of radiation.

It is difficult conceptually to reconcile typical mammalian cell survival curves[1,12,13] which are characterized by an initial shoulder followed by a straight line down to low surviving fractions with any population that is not homogeneous. But it has been shown[7,14,15] theoretically that mixed populations may indeed exhibit net survival curves which cannot easily be distinguished from those expected for homogeneous populations; the first decade of a survival curve is the portion in which the shape will reflect mixtures of sensitivities from different sub-populations such as suggested here, and, unfortunately, it is this very region in which insufficient data are available.

Although earlier evidence indicated different periods in the cell cycle when division delay is manifested, it appears most likely that those cells the ultimate reproductive integrity of which is unimpaired by irradiation but which are delayed in their passage through the division cycle experience this delay some time during the G_2 period. As shown by Whitmore *et al.*[16], cells in stages other than G_2 will progress through the generation cycle at a rate close to the normal until they reach the point of the reversible blockage in G_2. They will then remain at that point until they have recovered from the injury responsible for division delay. The preceding is based on experiments with L cells; and it may be remarked, parenthetically, that there is now some evidence for acceleration of the passage of certain cells through the S stage during the period when they are actually being irradiated[17].

In addition to a dependence of surviving fraction on radiation dose and phase of the generation cycle, the duration of reversible division delay is also dose-dependent[16,18–21] and probably phase-dependent as well. Terasima and Tolmach[6,7] also reported phase-dependent differences in mitotic delay as a function of generation stage of irradiated cells. Thus, mitotic delay is minimal for cells irradiated in G_1 and increases as they pass through S and G_2. In confirmation of Whitmore *et al.*[16], it was also reported that the major portion of mitotic delay occurs in the G_2 period. Furthermore, the duration of division delay would appear to be correlated with the normal absolute length of the division cycle as well as with the amount of radiation absorbed, so that cells which normally experience longer generation times will not emerge from the dose-dependent division block as rapidly as will those with shorter division cycles[9].

It must be kept in mind that the populations of cells which have been used in the study of phase-dependent radiosensitivity, as well as dose-dependent division delay, are relatively homogeneous with respect to the duration of the generation cycle and, correspondingly, its several sub-divisions or phases. In marked contrast to this is the situation in a neoplastic cell population, particularly as found in a spontaneous animal tumour. We owe to Mendelsohn[22] the knowledge that cells of spontaneous mouse mammary tumours are indeed an extremely heterogeneous population with respect to generation time. Making cellular autoradiographic measurements of tumours taken from animals which were infused with tritiated thymidine for up to 10 days, Mendelsohn found that doubling times as long as this maximum infusion period of 10 days were not uncommon. Tumour doubling times were normally distributed with the majority falling between approximately 4 and 18 days. Presumably, these doubling times are reflexions of the generation times of the component tumour cells. Even though cells which do not incorporate the label over infusion periods of maximum duration might be regarded as non-dividing or incapable of division, it is unquestionable that some cells require approximately this great an interval (> 10 days) between periods of DNA synthesis. It is significant that, despite this marked heterogeneity in generation times, the durations of S, G_2 and M are relatively constant; it is the G_1 period that is capable of varying from cell to cell and ranges from hours to weeks in the growth fraction of these tumours[23].

Based on the foregoing evidence, the following hypothesis is suggested:

(1) That fraction of a cell population the future reproductive integrity of which is damaged, but not completely destroyed, by a first dose of radiation, that is, the 'surviving fraction', will nevertheless experience division delay of duration proportional to absorbed dose.

(2) The survival of cells exposed to a first dose will depend on the probability of survival per unit dose relative to each cell's generation stage; thus, immediately following initial irradiation, there will be fewer survivors in those states characterized by greater radiosensitivity or higher probability of death per unit dose, and the balance of cells in the population will be shifted toward a greater proportion in the relatively resistant states than at the beginning of irradiation.

(3) Recent evidence[7,15] supports the assumption that the duration of division delay depends not only on dose but also on state of the cell; the closer a cell is to the point of blockade in G_2, the longer the division delay per unit dose. (If the findings of Das and Alfert[17] are generally applicable to other types of cells and other radiation doses, the S compartment would be depleted faster than others.) One would then predict the following course of fluctuations in the proportions of cells in the major compartments in an exponentially growing asynchronous population: a possible initial depletion in the S compartment, with G_1 decreasing at least as rapidly, owing to the passage of its members into S; next, a progressive depletion in G_1 with S remaining essentially constant until G_1 is completely exhausted, at a time roughly that of the normal duration of G_1; and, finally, a progressive exhaustion in the S compartment at a rate consistent with the normal rate of passage through S.

Throughout the preceding succession of compartmental changes, G_2 would be expected to increase to approximately 100 per cent by virtue of the accumulation of all cells which were in earlier stages at the time of irradiation and which would be expected to be blocked during this generation stage. (The essential features of this proposed sequence of events are graphically illustrated in Fig. 2 of the paper by Painter and Robertson[24].)

(4) Assuming, on the other hand, that all cells experience division delay strictly in proportion to dose and with no dependence on generation state at the time of radiation exposure, surviving cells would progress through the division cycle until the point of blockage occurs sometime during G_2; this is contrary to the most recent evidence, but must be considered as well as the preceding, alternative, point.

(5) During the course of this compartmental shift, it is predicted that the overall radiosensitivities of the resultant mixed populations will change accordingly. As the proportion of cells increases in G_2, therefore, and particularly while it decreases in late G_1–S and M, the net or overall sensitivity of the mixed population would approach that of a pure population of G_2 cells. Since the available evidence indicates that G_2 is a relatively resistant phase, such a population would be expected to suffer less loss of reproductive integrity per unit dose than the original random population.

(6) As mentioned in (2) here, owing to the relatively greater radioresistance of early G_1 cells, conditioning doses large enough to kill all but a few cells would leave survivors predominantly in G_1. Thus, while the more sensitive late G_1–S compartment would be severely depleted promptly, this same compartment would tend to be renewed with time from the surviving G_1 pool. This kind of redistribution, leading to a temporary repopulation of late G_1–S prior to the G_2 blockade, would therefore tend to lower overall population radioresistance from its immediate post-conditioning state toward the unirradiated level.

(7) If a second radiation dose is administered at a time when more cells than normal are in G_2 and early G_1, that is, near the beginning of post-irradiation blockade, the net visible effect would be a higher probability of survival or a lower number of cells killed per unit dose than in the starting population. In other words, a state of refractoriness relative to the sensitivity of the unirradiated population would have been induced.

(8) It is attractive to assume that because cells are, in a sense, synchronized by radiation in so far as they are blocked at a common stage, G_2, they may also be then synchronized in their escape from the block. This is entirely consistent with the sequence of events outlined in (3) here: Cells irradiated close to the block point in G_2 experience longer delays than their younger counterparts and thus, in effect, 'wait' for these younger survivors to reach the same stage. Because of the tendency for the cells which reach the block latest to be delayed least, there should be a greater than normal proportion of cells entering the next mitotic division. There is good evidence[16,24–26] for a kind of compensatory overshoot in mitosis in the first post-irradiation division. If this were to follow, as a general rule, it would provide a partial explanation for the relatively rapid fall in radioresistance toward the end of the refractory state: the presence of a pulse of such mitotic cells would tend to increase the net population sensitivity and thus 'mask' the resistance of the as-yet-unrecovered blocked cells. This is supported by the recent report of Painter[25] that the mitotic overshoot in HeLa cells at 7–9 h post-irradiation is made up largely by cells which were in S during irradiation. It is likely,

however, that soon after the reversibly blocked cells emerge from G_2, they assume an asynchronous progression; and that in a relatively short time—no greater than the mean generation time, perhaps—each of the compartments of the generation cycle will contain roughly the same proportion of the total population as existed in the random population prior to initial irradiation.

It is suggested, therefore, that the finding typified by Elkind's 'recovery' is related to this shift in the proportions of cells in the different compartments which are characterized by different sensitivities. Indeed, the fact that radiosensitivity fluctuates in this way in the several systems already noted points to the universality of this phenomenon. The possibility must also be entertained that this state of relative population refractoriness may be produced by the accumulation of cells in a state other than the normal G_2—a non-normal state which simulates G_2 but differs in that it is a perturbed G_2 which is none the less characterized by a lower-than-average radiosensitivity.

(9) The foregoing considerations deal principally with the event occurring in hours to perhaps a very few days after initial, or conditioning, irradiation. The subsequent recuperative events, designated by Elkind as 'repair', may be postulated to be of a different nature and, as Elkind has suggested, concerned largely with repopulation by surviving cells which have resumed their normal course of generative activity.

If the proposed interpretation is valid, several observations take on a different aspect. Although the radiotherapeutic literature is, unfortunately, lacking in controlled quantitative data on clinical material, there are many radiotherapists[27-29] who find that fractionated treatments delivered less frequently than daily are at least as successful as a course of strict daily irradiation. While these and other regimes of radiotherapy may owe their success to different reasons (for example, altered tumour cell-stroma relationship, etc.), it may well be that daily irradiation of many tumours serves to shift an increasingly larger proportion of cells into these stages of lower radiosensitivity so that the later the fractional dose is administered in a given course of treatment, the less its tumoricidal efficiency per given number of tumour cells.

A particularly interesting extrapolation of the foregoing concerns the expected effects of dose protraction, or decreased radiation intensity, on asynchronously growing cell populations. Assuming the hypothesis to be valid, it would be expected that soon after continuous protracted irradiation is initiated, there would be some critical maximum overall time of exposure during which the maximum lethal effect could be produced. As dose rate decreases and overall exposure time increases, however, it would be expected that surviving cells would tend to accumulate at a relatively less sensitive point of reversible mitotic blockade. This would result in a net decrease in lethal effectiveness with dose rate, the population survival depending on the balance between the rate of escape or reversibility of some cells from the block with the rate of production of the same kind of block in other cells. As Thomson and Tourtellotte[30] initially demonstrated, the $LD_{50/30}$ of mice increases steeply as the dose rate falls from ~ 10 r./min to ~ 3–5 r./min—that is to say, as the irradiation time increases from ~ 1 h to ~ 3 h.

In addition, Brown *et al.*[31] and myself[32] have found that the significantly lowered lethal effectiveness of radiation delivered continuously over ~ 6 h (~ 2 r./min), as compared with single doses given in less than ~ ½ h, is quantitatively the same as the effectiveness of two or more high dose rate fractions given in the same overall 6-h time. These data, for which there are no published quantitatively comparable studies on mammalian cells *in vitro*, strongly suggest that the so-called 'dose rate effect' has a basis in the present proposal. The practical significance of the extrapolation of the proposed hypothesis to the dose rate effect is obvious and need not be discussed further at this point.

NATURE OF THE PHOTOREACTIVABLE ULTRA-VIOLET LESION IN DEOXYRIBONUCLEIC ACID

By JANE K. SETLOW and RICHARD B. SETLOW

Biology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

IT has been shown by Wulff and Rupert[1] that ultra-violet-induced thymine dimers in *Escherichia coli* deoxyribonucleic acid (DNA) can be split by treatment with a yeast extract in the presence of 'light' of longer wave-length. Such treatment can partially reactivate the biological activity of ultra-violet-inactivated transforming DNA[2]. These experiments strongly suggest, but do not prove, that some or all of the biological photoreactivation of DNA, as well as its chemical photoreactivation, arises from the elimination of thymine dimers by the yeast extract and visible light.

The answers to two questions are of interest: (1) Does the biological reactivation caused by the photoreactivating yeast extract involve thymine dimers, and, if so, (2) is the splitting of thymine dimers sufficient to account for all the increase in biological activity observed? The biological damages in transforming DNA that are caused by large doses of 2800 Å radiation are partially reversed by irradiation at 2390 Å. This reactivating effect has been quantitatively correlated with the splitting of a fraction of thymine dimers that results from a shift in the equilibrium of dimerized and undimerized thymine–thymine sequences[3]. We have attempted to answer these two questions by determining the biological effect of 2390 Å reactivation on photoreactivation with yeast extract. If the yeast extract increases biological activity by reversing thymine dimerization, DNA inactivated by 2800 Å irradiation and then treated with yeast extract should not show the reactivating effect of 2390 Å irradiation. The magnitudes of the maximum reactivation by 2390 Å irradiation and by the yeast extract after various doses of 2800 Å radiation should indicate how much of the biological effect of the yeast extract is caused by thymine dimer splitting.

Methods of ultra-violet irradiation, the transformation assay and the description of markers have been given previously[3,4]. The yeast extract was prepared according to the method of Rupert[5]. (We thank Dr. F. J. Bollum for preparing the yeast extract.) Photoreactivation was carried out at 37° on volumes of 0·4 ml. contained in the 2-cm diameter depressions of white porcelain spot plates. The illuminated solution contained final concentrations of 0·5 μgm/ml. DNA and 0·25 mg/ml. protein from the most active ammonium sulphate fraction of yeast extract. Photoreactivating radiation was supplied by two General Electric 15-W 'blacklight' bulbs, filtered so as to eliminate all wave-lengths less than 3250 Å. The incident intensity was about 7,200 ergs/mm²/min. The minimum illumination time for maximum photoreactivation was found to be less than 2 h for all the inactivating doses used. Illumination times actually used for maximum photoreactivation were 128 min. The efficiency of the yeast preparation for photoreactivation was unchanged after 2 h of illumination at 37° without DNA.

Figs. 1 and 2 show the results of an experiment in which transforming DNA inactivated with various doses of 2800 Å radiation was afterwards exposed to maximum photoreactivation, to 2390 Å radiation, to photoreactivation before 2390 Å, and to 2390 Å radiation followed by photoreactivation. It can be seen (Fig. 1) that when the 2800 Å irradiated samples have been photoreactivated, subsequent 2390 Å irradiation brings about a decrease in survival. However, when 2800 Å inactivated samples have not been photoreactivated following these large doses, 2390 Å irradiation brings about an increase in activity. Since the 2390 Å radiation apparently reverses 2800 Å damage by breaking thymine dimers[3], and because prior photoreactivation eliminates the reactivating effect of the 2390 Å, we may conclude that at least some of the biological effect of the yeast photoreactivating preparation also involves breaking thymine dimers.

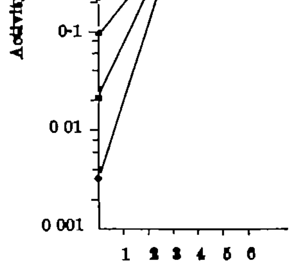

Fig. 1. 2390 Å irradiation following 2800 Å inactivation. The eight points on the ordinate represent the per cent transforming activity remaining after ●○ 2·5 × 10⁴, ▲△ 3·5 × 10⁴, ■□ 4·5 × 10⁴ and ◆◇ 6 × 10⁴ ergs/mm² at 2800 Å, with (white) and without (black) maximum photoreactivation. The increase in activity due to 2390 Å reactivation was earlier (ref. 3) shown not to increase further after a dose of 2·5 × 10⁴ ergs/mm² at 2390 Å

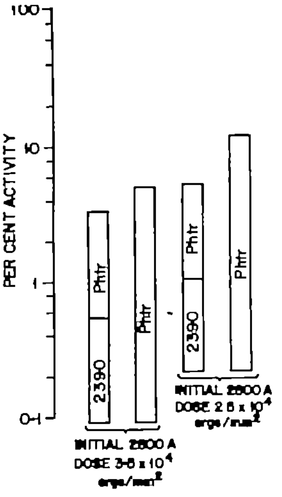

Fig. 2. Photoreactivation (phtr) with and without previous 2390 Å reactivation. Same samples as two of those shown by shaded points in Fig. 1

Fig. 2 indicates that transforming DNA exposed to 2800 Å followed by 2390 Å radiation may be further photoreactivated, but the final activity is somewhat less than that found after 2800 Å followed by photoreactivation alone. The 2390 Å irradiation does not break all the thymine dimers[3], and thus we may conclude that subsequent photoreactivation produces a further increase in activity because of further breakage of thymine dimers. The lower activity found after 2800, 2390 Å and photoreactivation indicates the production of non-photoreactivable damage by 2390 Å irradiation.

If the yeast photoreactivating preparation repairs some type of DNA damage from 2800 Å irradiation other than that repaired by the 2390 Å radiation, we would expect maximum photoreactivation following 2390 Å reactivation to result in a survival higher than that expected from splitting the remaining thymine dimers. Moreover, since we may assume that most types of damage increase with dose, there should be relatively more photoreactivation after larger initial 2800 Å doses, and thus the slope of the 2800 Å dose-curve after 2390 Å reactivation and photoreactivation should be less steep than the 2800 Å dose-curve after reactivation by 2390 Å irradiation alone. Fig. 3 shows survival-curves after 2800 Å irradiation with and without 2390 Å reactivation and photoreactivation. (Similar data were used previously[3] to calculate that about 50 per cent of the biological damage at high doses of 2800 Å is due to formation of thymine dimers. The results in Fig. 3 yield a figure closer to 70 per cent.) It is seen that the slopes of the 2390 Å reactivation and 2390 Å reactivation plus photoreactivation lines are approximately the same. This is interpreted to mean that the yeast photoreactivating preparation has little or no biological effect except that resulting from breakage of thymine dimers. Confirmation of this conclusion is provided by a comparison of the survival-level after maximum photoreactivation of 2800 Å damage with that expected if all thymine dimers were split. An estimate of this latter survival may be made graphically from a plot of reactivation of biological activity and also of relative absorbance change versus 2390 Å dose, in which the scales are adjusted so that the maximum change in survival coincides with the maximum change in absorbance[3]. The survival-level corresponding to complete restoration of the absorbance may be read from the graph. For a dose of 5×10^4 ergs/mm^2 at 2800 Å, as in a previously published graph[3], this survival-level is about 2 per cent, which is close to 2·3 per cent, the actual survival-level found after maximum photoreactivation following this dose.

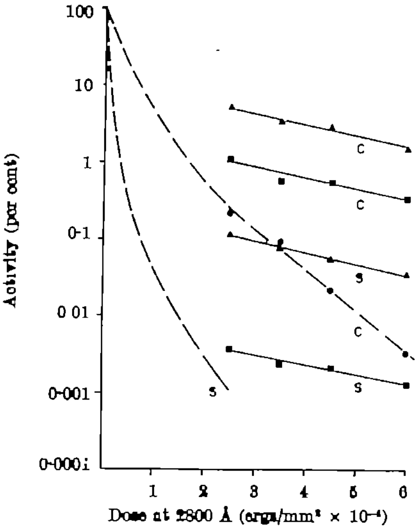

Fig. 3. Inactivation at 2800 Å alone (dashed line) and followed by $2\cdot5 \times 10^4$ ergs/mm^2 2390 Å irradiation with and without maximum photoreactivation. *S*, Streptomycin marker, *C*, cathomycin marker assayed. ▲, 2390 Å + photoreactivation; ■, 2390 Å alone

The conclusion that photoreactivation involves only splitting of thymine dimers makes it probable that the proportion of photoreactivable damage varies with different wave-lengths of inactivating radiation. Fig. 4 shows that this is indeed the case. Inactivating doses of 2800 Å and 2390 Å radiation were chosen so as to yield somewhat similar survival-levels. It can be seen that at the smaller doses there is little difference in the maximum photoreactivation obtained, but at the higher doses there is a much larger increase in activity from photoreactivation of the 2800 Å irradiated DNA. It is apparently more the initial dose than the initial survival-level which determines the point at which the photoreactivation of 2390 Å and 2800 Å radiation damage becomes different. The survival-levels of the streptomycin marker at the small doses are similar to the survival-levels of the cathomycin marker at the large doses, but there is appreciable difference in the photoreactivability of 2390 Å and 2800 Å damage only after large doses. These data may be interpreted to mean that at high doses of 2800 Å radiation there is a relatively higher proportion of damage due to reversible thymine dimerization than at high doses of 2390 Å radiation.

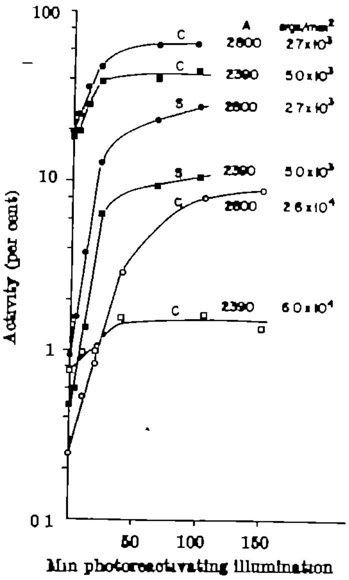

Fig. 4. Photoreactivation of transforming DNA after inactivation at two different wave-lengths. *C*, Cathomycin marker; *S*, streptomycin marker assayed

We have shown that the only photoreactivable lesion in transforming DNA is the thymine dimer, and that it is breakage of the thymine dimer which restores the biological activity. Although the thymine dimer is probably the most important photoreactivable lesion in cells, it is not the only one, for damage to RNA, which contains no thymine, is known to be photoreactivable[5].

This work was carried out under the auspices of the Union Carbide Corporation of the U.S. Atomic Energy Commission.

LOCALIZATION OF TRITIATED 'DIGOXIN' IN THE MYOCARDIAL CELLS OF FROGS AND DOGS BY AUTORADIOGRAPHY COMBINED WITH ELECTRON MICROSCOPY

By DR. JOHN R. SMITH and DR. HARRY A. FOZZARD*

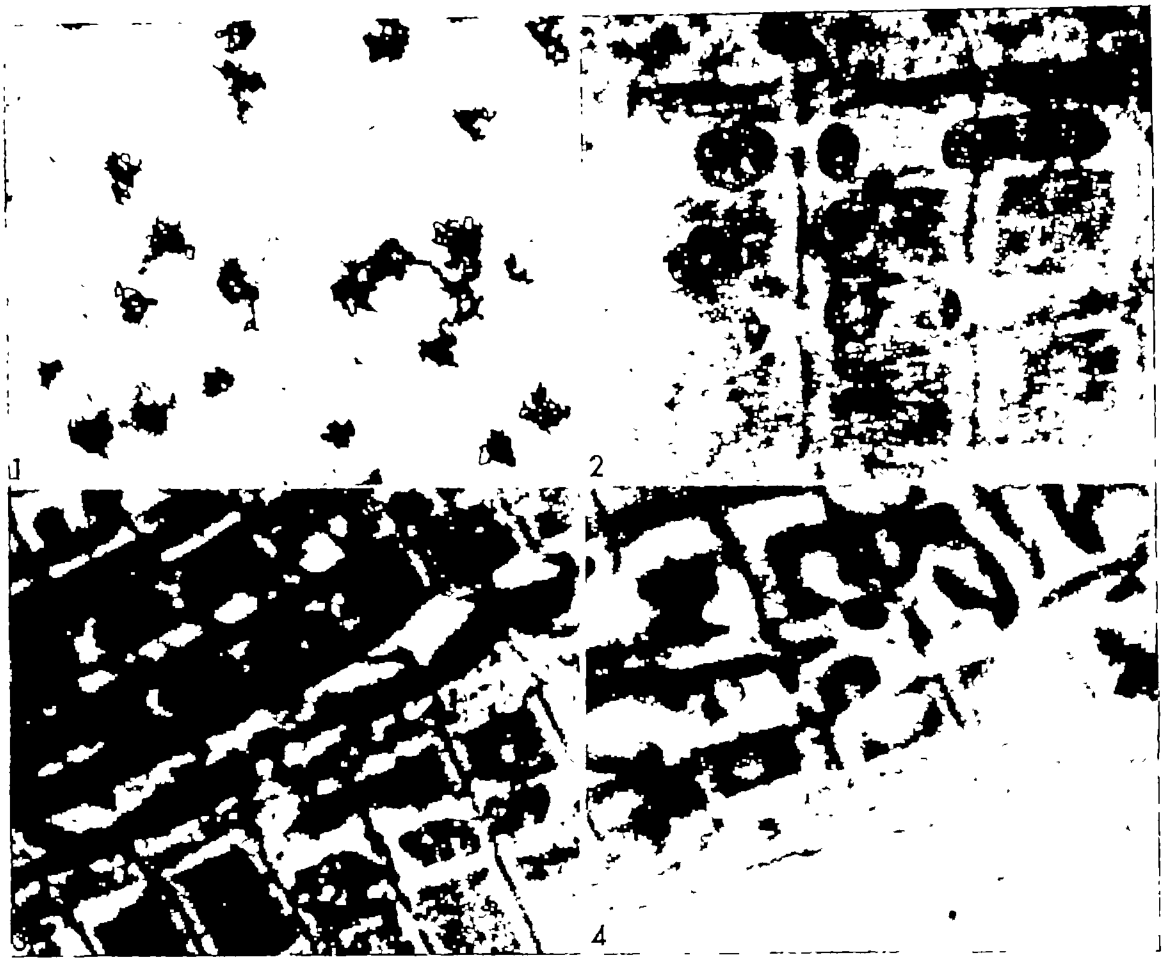
Cardiovascular Division, Department of Medicine, Washington University School of Medicine, St. Louis, Missouri

SINCE the application of autoradiography for use with the electron microscope[1], the technique has been extensively developed and used[2-4] for the localization of isotopically labelled substances within living cells. Recently, Waser[5] utilized the technique for the localization of tritium-labelled digitoxin by light microscopy. In this article we present a method for the localization of tritium-labelled 'Digoxin' by electron microscopy in the myocardium. The method depends on the precipitation of radio-'Digoxin' within the cells in order to retain it *in situ* during the preparation of the tissue. (The 'Digoxin' was kindly supplied by Dr. Stanley Bloomfield, of Burroughs Wellcome and Co., Inc.)

The usual methods for fixing and drying tissue for electron microscopy utilize solutions of ethanol, but this procedure results in extraction of the alcohol soluble

---

* National Heart Institute Fellow in Cardiovascular Disease, Department of Medicine, Washington University (1961–63).



Figs. 1–4. (1) Appearance of exposed silver grains from tritiated 'Digoxin' mixed with 'NTB' liquid emulsion, exposed for 4 days and developed. Gelatin of the emulsion was not removed. (× c. 7,500) (2) Autoradiograph of a typical site of tritiated 'Digoxin' localization (at the A zone of a myofibril) (× c. 12,450) (3) Autoradiograph of tritiated 'Digoxin' localized nearer the Z bands. (× c. 7,500) (4) Autoradiograph of tritiated 'Digoxin' typically related to the A bands. Only occasionally was a silver grain at the sarcolemma.

'Digoxin' from tissue. The glycoside is, however, completely insoluble in acetone. By light microscopy it can be seen that addition of 50 per cent acetone to an alcoholic solution of 'Digoxin' results in its immediate precipitation. For this reason, acetone was used for tissue dehydration in our procedure.

Initial studies for the localization of cardiac glycosides were carried out on the hearts of bullfrogs (*Rana catesbiana*). It was considered advantageous to use this tissue because of the simplicity of preparation and the precision with which the cells may be sectioned longitudinally for study with an electron microscope. The hearts were excised and perfused with Ringer's solution (at room temperature) through a cannula introduced into the right atrium. Contractions were recorded by simple writing levers and kymograph, or by direct observation. When stability of the heart beat was assured, the tritiated 'Digoxin' (66·4 μc./mg) was added to the reservoir in 0·1-mg quantities at 10–20 min intervals until evidence of digitalis toxicity was clearly manifest (auriculo-ventricular dissociation, idioventricular rhythm and final ventricular standstill). Usually, 0·5 mg was introduced into the perfusion fluid before signs of extreme digitalis intoxication were evident. In later experiments dog hearts were studied. Starling heart–lung preparations were set up in the usual way, and tritiated 'Digoxin' was administered into the venous reservoir in 0·1-mg quantities at 15–20 min intervals until digitalis poisoning occurred. A dose of 0·9–1·2 mg of tritiated 'Digoxin' was required to produce digitalis intoxication.

When the influence of the glycoside was plainly evident in the living heart, the ventricles were cut away and trimmed for tissue blocks. The ventricles of the frog hearts were cut into 1-mm wide longitudinal strips with razor blades and fastened to applicator sticks with insect pins under slight stretch. The coronary arteries of the dog hearts were flushed with 50 per cent acetone and 10 per cent formalin solution prior to removal from the chest. Small longitudinal blocks were excised from the papillary and trabecular muscles and fixed to applicator sticks in the same manner.

The muscle specimens, thus pinned, were immersed in a mixture of 50 per cent acetone and 10 per cent formalin for 30 min for precipitation of the glycoside and partial fixation. Thereafter the specimens were transferred to a fixing solution of 1 per cent osmium tetroxide buffered in '*s*-Collidine'[7] for 1·5 h. After the fixing period, the muscle was dehydrated in successive changes of 50, 75, 85, 95 and 100 per cent acetone for 20-min periods each, and was then carried through mixtures of equal parts of acetone and toluene, pure toluene, and equal parts of toluene and methacrylate for 20 min each. The tissues were finally immersed in 70–30 butyl-methyl methacrylate (several changes) for not less than 1 h before final embedding in gelatine capsules. On subsequent sectioning, it was evident that the tissues were adequately fixed, and very thin sections were readily obtained.

Sections were cut in the usual way with a Porter–Blum microtome, and were mounted on 200-mesh steel grids coated with 'Formvar' or 'Parlodion'. When dry, the

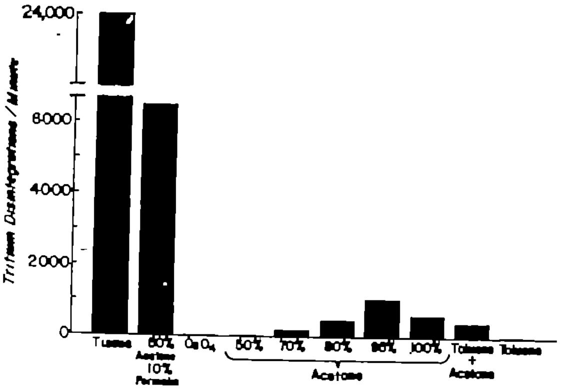


Fig. 5

sections were dipped in a 1 : 5 dilution of E. K. Co. liquid emulsion, 'NTB-3'; the excess emulsion was removed by lightly touching the edge of the grid to filter paper. The coated grids were then placed on filter paper in small Petri dishes and sealed in light-tight boxes. These boxes were kept in the refrigerator for 10–12 days. At the end of this period the specimens were developed in the dark room, washed, fixed in hypo and gently rewashed in distilled water.

Since it was difficult to obtain emulsion films that were sufficiently thin to permit adequate visualization of the underlying cells in an electron microscope, we adapted the method of Revel and Hay[5] to remove the gelatine of the emulsion coat so as to render it largely transparent to the electron beam and to enhance the discernment of cellular detail. Therefore, the grids with mounted specimens were immersed in 0·1 N sodium hydroxide for approximately 1 h. These grids were then placed in distilled water for 10–15 min to rinse away the sodium hydroxide and were allowed to dry on filter paper.

In order to measure the amount of tritiated 'Digoxin' in the tissues and the losses from the tissue during the fixing and drying processes, these fluids and the tissue were analysed using a liquid scintillation counter. With a pulse height analysis circuit, counting efficiency was about 25 per cent. The tissue and samples were prepared by either alcohol extraction or digestion of the dried specimens in 5 N sodium hydroxide. Samples were counted in a toluene solution of 2,5-diphenyloxazole and 1,4-*bis*-2-(5-phenyloxazolyl)-benzene.

The resultant autoradiographs are sufficiently clear so that the emulsion grains exposed by the tritium disintegration can be readily seen against a detailed cellular background (Figs. 2–4). From the micrographs of emulsion exposed directly to the tritiated 'Digoxin' without the presence of tissue, the resultant exposure of silver grains may be seen as fine, irregular traceries (Fig. 1). These same patterns of emulsion exposure may be readily recognized in the autoradiographs of the myocardial cells. Examination of the micrographs likewise indicates that most of the tritiated 'Digoxin' appears to be in close relation to the *A* bands of the myofibrils; rather less activity is noted in the region of the *Z* bands. Rarely, points of activity may be found over, or in the proximity of, the nuclei. On the other hand, there is a paucity of evidence of radioactivity along the sarcolemma, and only rarely does it occur in the sarcoplasm or over the mitochondria.

All attempts to utilize ethanol for dehydration of the tissue resulted in complete extraction of the radioactive 'Digoxin' from the tissue. When acetone was used the 'Digoxin' remained in the tissue in good concentration (0·16–0·60 μg 'Digoxin'/g tissue). The isotope removed during the fixing procedure (Fig. 5) was small, and little additional loss occurred during dehydration. This total amount of glycoside lost was equal to the calculated quantity that would have been present in the extracellular fluid space estimated to be 30 per cent of volume at the same concentration as in the perfusate.

Our greatest difficulty in the production of autoradiographs of intracellular 'Digoxin' has been preparation of the tissue without eluting the glycoside from the cells. It was quickly apparent that the usual procedures utilizing ethanol would not be satisfactory, for no isotope remained in the tissue after preparation. Acetone was found to fix and dehydrate the tissue satisfactorily without excessive loss of 'Digoxin'. It is unfortunate that the treatment of these tissues with acetone is partially destructive to the muscle. For this reason, passage of the muscle specimens through the acetone solutions was kept as brief as was consistent with adequate tissue preparation. Under the conditions reported, thin sections may be prepared with ease and precision without evidence of gross tissue destruction by the glass knives of the microtome.

Examination of many autoradiographs of myocardial cells treated with tritiated 'Digoxin' demonstrates that the radioactivity is usually found in relation to the *A* bands of the myofibrils. Very little activity appeared to be localized in the other sub-cellular structures. It is not certain that the location of the radioactive 'Digoxin' in the cells is actually the physiological site of action of the drug, but its specific concentration in the area of the myofibrils is strongly suggestive of this, and is at present under investigation.

INHIBITION OF VIRUS MULTIPLICATION BY FOREIGN NUCLEIC ACID

By Z. ROTEM*, R. A. COX and DR. A. ISAACS
National Institute for Medical Research, Mill Hill, London, N.W.7

THE cells of many vertebrates can be induced to synthesize interferon by infecting them with many different viruses. In trying to understand what is the essential stimulus that induces cells to make interferon, an important finding is that for many different cell-virus systems, virus multiplication is not essential for the production of interferon. Thus interferon production can be induced by inactivated viruses[1–3], by live virus inoculated into cells which do not support virus multiplication[4,5], or by growth of infected cells at temperatures which do not allow virus multiplication[6]. This would imply that the stimulus to make interferon is provided by part of the virus particle that enters the cell.

There is some indirect evidence to suggest that the stimulus might be viral nucleic acid. Influenza virus

particles containing virus nucleic acid are able to induce virus interference whereas particles lacking nucleic acid are not[7]. The ability of influenza virus particles to induce production of interferon can be abolished by prolonged irradiation with ultra-violet light, which damages the viral nucleic acid without affecting significantly the antigenic or enzymatic (neuraminidase) activities of the particles[8]. However, if viral nucleic acid is the stimulus to make interferon this poses an awkward problem, since both DNA and RNA viruses are able to induce its production. This suggested a hypothesis—that the essential stimulus to make interferon might be nucleic acid that was 'foreign' to the cell[9]. This paper reports a test of this hypothesis which involves the use of non-viral nucleic acids. It was soon found that non-viral 'foreign' nucleic acids induced production of either very small amounts of interferon or no detectable interferon, as measured by interferon liberated from cells. In order to test therefore whether small amounts of interferon were being produced inside the cells the experimental methods were modified so that the direct antiviral action of foreign nucleic acids was measured on cells.

In preliminary experiments chick embryo fibroblasts were first treated with foreign nucleic acids for various periods of time, then infected with virus, overlaid with nutrient agar and viral inhibition measured by the reduction in plaque count. A number of different preparations of RNA and DNA showed viral inhibitory effects (Table 3), but only when very large amounts of nucleic acids (1–10 mg per plate) were used. The antiviral action of nucleic acids in animals has been previously reported[10]; but with the low degree of viral inhibition it was difficult to understand the mechanism involved. A second technique used was to suspend the nucleic acid in M sodium chloride, as is carried out when initiating infection by viral nucleic acid[11]. This technique gave preliminary indications that heterologous, but not homologous, viral nucleic acid inhibited virus growth, but the degree of viral inhibition found was small and inconstant. A third technique used was to mix the nucleic acid with protamine which was thought to increase the uptake of nucleic acid by cells[12]. A difficulty experienced in this work was that protamine itself is apparently an uncoupler of oxidative phosphorylation[13] and shows an antiviral action[14] that somewhat resembles that of interferon[15].

Recently the technique used was modified so that instead of pre-treating cells with nucleic acid, the nucleic acid was present in the medium during the whole time the virus was multiplying. With this modification regular and reproducible viral inhibition by heterologous nucleic acid has been found.

The assay method used was an adaptation[16] of the technique of Postlethwaite[17] by which vaccinia virus induces plaques in cell monolayers kept without an agar overlay. Two types of cells were utilized. Primary cultures of 10-day-old chick embryo fibroblasts were used 24 h after seeding 4-cm Petri dishes with 9 × 10⁶ cells. Secondary cultures of 18-day-old mouse embryo fibroblasts were used 24 h after seeding Petri dishes with 2 × 10⁶ cells. The nucleic acids were chick RNA, obtained from the livers of 3-week-old chickens, and mouse RNA from the livers of 4–6-week-old mice. The RNA was extracted from the ribosomes by the guanidinium chloride technique of Cox and Arnstein[18].

An assay was carried out as follows. The nutrient medium was removed from the cells and replaced by a maintenance medium consisting of 99·7 per cent Gey's buffered salt solution, 0·05 per cent yeast extract and 0·25 per cent lactalbumin hydrolysate, in which the nucleic acid under test and vaccinia virus, diluted to give about 100 plaques in chick cells, were suspended. The plates were incubated for 42–48 h at 37° in an atmosphere containing 3 per cent carbon dioxide. They were then removed, the cell sheets stained for 1 min with 0·1 per cent crystal violet, washed and drained to dryness. The plaques were counted with the help of either a hand-lens (if plaques were clearly visible) or with about ten-fold magnification in a viewing box. Chick and mouse RNA were tested at the same time with chick and mouse cells, so that essentially what were compared were the effects of heterologous and homologous RNA.

The results showed a striking viral inhibition by heterologous RNA with a smaller inhibition, or a lack of inhibition with homologous RNA. Two experiments illustrating this are shown in Table 1. In four experiments in which the chick and mouse cells were tested at the same time this type of result was found, and in a number of additional experiments in which, for technical reasons either the chick or the mouse cells did not provide good cell sheets, it was always found that heterologous RNA showed definite viral inhibition whereas homologous RNA at the same dosage showed a weaker effect or no effect. The degree of viral inhibition produced by homologous RNA was variable. Thus in Exp. 1 of Table 1, chick RNA (50 γ/ml.) showed definite antiviral activity in chick cells whereas mouse RNA at the same dosage showed no antiviral activity on mouse cells. In Exp. 2 of Table 1 there was minimal inhibitory activity of homologous RNA. The reasons for this behaviour of homologous RNA are discussed below. When very small doses of protamine were added (1γ protamine + 100γ RNA) the antiviral action of the heterologous RNA was reduced and homologous RNA plus protamine showed no viral inhibition or showed occasionally enhancement of viral growth. When experiments with nucleic acids were carried out in stoppered bottles with no added carbon dioxide the antiviral action was less than when cells were kept in parallel in open Petri dishes incubated in an atmosphere of carbon dioxide. In another experiment the time at which the nucleic acid was added to the cells was varied but with the same technique of assay[16] used throughout. Pretreatment of cells with nucleic acid for 6 h before virus was added gave a much weaker antiviral effect than when the nucleic acid was present along with the virus.

It is known that the cells of 6-day chick embryos are less sensitive to the antiviral action of interferon and produce lower yields of interferon than the cells of 10-day chick embryos[19]. If the antiviral action of heterologous

RNA were mediated through production of small amounts of interferon, it should be less evident when tested in 6-day-old than in 10-day-old chick embryo cells. Two experiments were carried out both of which clearly showed this to be the case. The results of one of the experiments is illustrated in Table 2. It is clear that the cells of 6-day chick embryos (7 days old at the time of assay) were less sensitive to the antiviral action of interferon and also to that of mouse RNA than the cells of 10-day chick embryos (11 days old at the time of assay).

Table 2. ANTIVIRAL ACTION OF MOUSE RNA AND CHICK INTERFERON ON 6-DAY AND 10-DAY CHICK CELLS

Material tested	Concentration	10-Day chick cells		6-Day chick cells	
		Plaque counts	Mean count	Plaque counts	Mean count
Control	—	161, 179, 174, 185	175	110, 105, 129, 107	113
Mouse RNA	50 γ/ml.	0 0	0	72, 65	69
	10 γ/ml.	35, 23	29	108, 104	106
Chick interferon	1/100 dilution	0, 0	0	30, 42 (faint)	36

Another point that is known about interferon is the fact that some viruses are more sensitive to its antiviral action than others[16]. This was difficult to test with the present assay since very few viruses produce plaques without an agar overlay. However, it was tested by the less-sensitive technique by which cells were treated with nucleic acid before being infected with two different viruses. The results shown in Table 3 indicate that Chikungunya virus was more sensitive than Newcastle disease virus to the antiviral action of both interferon and DNA from calf thymus.

Table 3. EFFECT OF TREATMENT WITH NON-VIRAL DNA AND INTERFERON ON THE ABILITY OF CHICK EMBRYO FIBROBLASTS TO GROW CHIKUNGUNYA AND NEWCASTLE DISEASE VIRUSES

Material tested	Concentration	No. of virus plaques with	
		Chikungunya virus	Newcastle disease virus
DNA from calf thymus	5·8 mg/ml.	1	88
	1·16 mg/ml.	6	75
Chick interferon	1/20 dilution	0	95
	1/100 dilution	3	102
Control	—	12, 16	104, 128

DNA was prepared by the technique of Kay *et al.* (ref. 21).

The findings with 6-day chick cells and with the two different challenge viruses furnish indirect evidence that the antiviral action of nucleic acids may be mediated through the production of interferon. More direct evidence for this was sought by treating chick embryo fibroblasts with 100γ of mouse RNA for 3 h at 37°, washing the cells twice, removing the RNA and replacing it with maintenance medium in which the cells were then incubated overnight at 37°. This medium was then tested for antiviral action against vaccinia virus in fresh chick cells when it showed a weak but definite antiviral action. This effect could have been due to a new substance produced by the cells or to some residual mouse RNA. However, the former explanation was favoured when it was found that chick cells pre-treated with this material and then challenged with Chikungunya virus showed definite viral inhibition. In addition, the inhibitory substance produced was found to be non-dialysable, stable at pH 2, inactivated by incubation at 37° and pH 2 for 1 h with 10 γ/ml. of pepsin, stable on heating at 60° for 30 min but largely inactivated by heating at 100° for 5 min. In all these properties it resembled interferon.

The weak antiviral action of some preparations of homologous RNA (Table 1) might be accounted for by the fact that neither the mice nor the chickens used in these experiments were inbred. It is possible, therefore, that small differences would be present between the extracted RNA and the RNA of the homologous animal cells. This point is now under investigation using isologous and homologous RNA with cells from two inbred strains of mice. However, so far as they go, the present experiments favour the hypothesis that interferon production occurs as a reaction of cells to foreign nucleic acids.

VIRUSES, GENES AND CISTRONS

ORIGIN of viruses. My suggestion[1] that the pathogenesis of viruses involves primarily an interference inflicted on the metabolism of the host by the expropriation of nucleotides by the virus from the host had been expressed earlier by Pirie[2], who has recently suggested further[3] that viruses "(1) . . . can be the extreme form of degeneration of micro-organisms so that, from merely being able to multiply in a host, they have become totally parasitic and dependent on the host's synthetic systems. (2) They can arise in a cell when, as a result of an aberration in metabolism, it produces a structure robust enough to withstand normal scavenging processes, and able to act as a model for further synthesis. (3) They can be structures with qualities similar to those needed in possibility (2) but coming into the cell from outside—from another species, for example.

"Of these three possibilities (1) and (3) are probably the most generally accepted. The possibility that anything similar to the viruses we now study was a stage in the evolution of more elaborate organisms, though often touted, need not be taken seriously. Present-day viruses demand so much from an environment before they can multiply in it that they are improbable components of the pre-biotic world."

Pirie's pronouncement that substances like viruses need not be considered seriously by those interested in the origin of life must have been made with his tongue in his cheek, because he is only too well aware of the fact that the basic hypothesis which directs the scientific activities of most of the foremost geneticists and biochemists of the present time is founded on precisely that assumption.

Receptor-hypothesis of gene-action and gene-structure. I[4,5] have proposed the receptor-hypothesis of gene-structure according to which the gene comprises: (1) a side-chain of DNA embedded in the histone backbone of the chromosome; (2) a segment of RNA, corresponding to the exposed DNA segment which is transcribed *in situ* and bound to the DNA segment by hydrogen bonds; (3) the receptor, which is an adjacent side-chain on the histone comprising a folded protein which resembles the enzyme. The application of the inducer to the outer surface of the receptor produces an excitation which passes from the receptor to the DNA side-chain and causes the release of messenger RNA. Mutations in the receptor are heritable changes in the coiling of the receptor which determine which one of one or more inducers may act as initiators of adaptive enzyme synthesis. The nucleic acid components of the chromosome replicate according to the Watson–Crick[6] theory of nucleotide-pairing; but the chromosome, as a whole, is a coacervate[7] and each new chromosome is produced by coacervation of all the respective components from the nuclear vacuole. The specific folding of the protein is heritable and the protein in each parent receptor directs the folding of the protein which is coacervated on its lateral surface to produce the 'new' receptor. The structural DNA holds the RNA messenger in a relatively stable complex, but the union of inductor with the receptor makes the complex unstable and leads to the release of messenger RNA. Induction and cessation of enzyme synthesis is an automatic homeostatic process beginning when the inductor or inductors make contact with the receptor, and ceasing when all the inductor molecules have been altered by the induced enzyme. According to this hypothesis, gene-systems are exclusively adaptive.

Viruses as fragments of gene-systems. On the basis of the recent biochemical advances which have specified the relation between genes and proteins, one may assume that vegetatively transmitted, non-infective RNA and DNA (prophage) are segments of nucleic acid which are somehow resistant to the ribonucleases and the deoxyribonucleases which must abound in the cytoplasm to prevent the replication of either RNA or DNA in the cytoplasm. Under normal conditions, the replication of DNA and the transcription of RNA from DNA must be confined to the nucleus in a region free from nucleases[8]. The controlling devices which lead to the emergence from the nucleus into the cytoplasm of a limited number of specific RNA templates must be capable of being reversed almost completely from instant to instant. An enzyme needed for a few seconds or minutes in the life-cycle of a micro-organism may be exceedingly detrimental a few moments later. The activity of the nucleases makes the cytoplasm particularly rich in nucleotides, and any nucleic acid which persisted in the cytoplasm would be presented with an abundance of the materials essential to its replication. If a segment of RNA, which was relatively resistant to the cytoplasmic ribonuclease, appeared in the cytoplasm, it might (after replication) become attached to a ribosome and effect the transcription of a protein which could envelop and protect the replicated RNA segment as soon as it was detached from the ribosome just as the TMV–RNA (ref. 9) virus is protected by a protein particularly resistant to proteases.

One might expect, as Pirie suggests, that the RNA templates which develop into viruses generally originate in another species. Parallel considerations suggest that DNA viruses are segments of 'structural' DNA capable of surviving in the cytoplasm to transcribe RNA templates which, when attached to ribosomes, could control the transcription of these proteins, which comprise the envelope essential to an infective virus particle. Neither the RNA nor the DNA viruses would be expected to have an independent life outside the cytoplasm because only the cytoplasm can supply the ribosomes, the enormous pool of nucleotides, the amino-acids and the energy sources necessary for their replication. The growth of an infective virus would be expected to come to a final end when the stored reserves present in the host were exhausted. On this hypothesis, viruses may not be compared with the functional genes of higher organisms, but only to parts of gene-systems. Instead of genes which have taken up a cytoplasmic existence, viruses represent nucleic acid fragments of gene-systems which are normally destroyed in the cytoplasm by the natural scavenging processes. They are related only to the structural DNA and the template or messenger RNA of the gene-system.

Vegetatively propagated viruses (like prophage or kappa) which persist in the host from generation to generation without producing particles capable of initiating infection and which replicate at a rate more or less in synchrony with the replication of the cell may be looked on as persistently transmitted hereditary 'garbage', outside the normal metabolic requirements and, hence, dispensable, and only slightly, if at all, detrimental to the host.

Bacteriophage as an end-to-end sequence of structural elements. Although a single gene carries only a single structural element capable of specifying the amino-acid sequence of a single protein, a bacteriophage requires a variety of different proteins to produce an infective particle, and must be capable of producing many different RNA templates which specify a variety of different kinds of proteins. Thus, the bacteriophage virus must comprise a linear array corresponding to the end-to-end attachment of a number of different structural elements arising from many different and probably rearranged nucleotide sequences derived from structural elements of pre-existing genes. Since each single gene-system controls the synthesis of only a single enzyme (or a single protein) the amount of nucleic acid present in a gene-system would be expected to be much less than that in a bacteriophage, which must specify the synthesis of a great variety of different proteins.

Mapping and crossing-over in chromosomes and in viruses. The receptor-hypothesis (which is consistent with the Taylor–Freese[10] model of the chromosome) implies that there are, at least, two different kinds of cross-overs; (1) those which occur in the histone backbone between genes; (2) those between nucleotides in the structural DNA within a gene. The theory suggests that the former are much more frequent than the latter, and it also implies that synapsis at meiosis is controlled by the mutual attraction of two exposed complementary single-stranded DNA side-chains. Thus, the phenomenon of two-by-two pairing in triploid synapsis, described by Darlington[11], in which one of three chromatids is excluded at any given level, is finally comprehensible.

Mapping and crossing-over occurring in viruses has no direct relation to the mapping of genes on the chromosome because, in mapping genes, the cross-overs which are counted are only the relatively numerous breakages and reunions in the histone backbone of the chromosome occurring at the four-strand stage between the genes, while in the mapping of bacteriophages (and structural elements of genes) the much rarer cross-overs which are counted are those which occur between two nucleotides within a nucleotide sequence to produce a change in the nucleotide sequence. (Gene-conversion, which results in non-reciprocal recombination, involves loss, alteration or transfer of receptors.)

The cistron. The cistron[12] of a bacteriophage comprises that particular portion of the nucleotide sequence which specifies the amino-acid sequence in a single one of the proteins essential either to protection from the cytoplasmic nucleases or the development of a mature infective particle. A cistron becomes non-functional when a deletion occurs in a region of the segment essential to the structure of its specific protein. A cistron is identified as a limited region within which respectively overlapping deletions produce the same defective phenotype. If the deletions present in two different defective bacteriophage mutants overlap in a given cistron, no amount of recombination between two mutant bacteriophages can produce a functional infective particle. The test for the identification of a cistron, therefore, resembles the test for allelomorphism of genes, but this operational similarity does not equate genes and cistrons.

LINDEGREN'S suggestion that I might have made a comment without wholly serious intent is not likely to commend itself to anyone who knows me. Nevertheless, the comment that he finds surprising may be worthy of a little amplification. Even supposing Lindegren is right in saying that the idea that viruses resemble an early stage in biopoesis, is basic to the activities of the "foremost geneticists and biochemists of the present time", it is not necessary that we should all accept the idea. To argue the contrary seems to be carrying the principles of democracy, and the validity of anything agreed by majority vote, too far. Heretics may not be often right, but the history of science suggests that they sometimes are.

One essential quality in any system proposed as an early stage in biopoesis is that it should have been able to carry out its characteristic activity, whatever that was, in the absence of more highly integrated vital forms. The absence of this capacity is the characteristic unifying quality of the viruses. It may be that there are undiscovered systems (in the sea, for example) with some virus-like qualities but able to engineer their own synthesis without the help of a host. It will be time enough to discuss the relationship between such a system and the accepted viruses when it has been discovered. The discovery may be difficult for so far it is not we who have found viruses, it is viruses that, by modifying the behaviour of hosts in which we are interested, have found us. As I have remarked, reviewing a discussion on the origins of life[1]: "It is unfortunate therefore that so much attention was devoted at the Symposium to viruses and autotrophic bacteria. The former are irrelevant because they do too little, and the latter because they do too much. Viruses only exist by courtesy of the synthetic mechanisms of a more elaborate host cell, which has a normal metabolism that is concerned with making a wide range of substances such as polysaccharides, steroids, peptides and also nucleoproteins. The viruses about which we have any chemical information seem to be predominantly nucleoprotein. There is no reason to think that when a virus invades a cell it does more than upset the normal cell metabolism, so that the cell then makes copies of the invader instead of making the things it was accustomed to. The manner in which this switch over is brought about is not yet understood. It is the central problem of virus research, but it has no close connexion with biopoesis. Autotrophs, on the other hand, contain mechanisms for making every type of molecule used in biochemistry and they do this without help from any other organism. This implies a biochemical complexity and competence greater than that of man or of the other organisms that have to get vitamins, amino-acids, and so on, pre-formed by other organisms. The apparent morphological simplicity of an autotroph should not mislead us into looking on it as a primitive form. All these capacities could not have developed simultaneously, but are more likely to have been slowly accreted in response to the competitive stresses of one or two thousand million years of evolution."

Two further comments may be made on Lindegren's communication. The three ways in which viruses could reasonably be expected to originate were all discussed by the virus workers in the 1930's and, in my opinion, some viruses have arisen in each way. Lindegren's picture of gene structure and action is plausible but may well be too precise. Scientists rarely discover a phenomenon outside the domain of their interest. This is the era of the nucleic acids; phenomena involving them are therefore very often discovered and very readily credited. When general interest moves, perhaps to initiating the intensive study of fats or the renewed study of specific polysaccharides, other mechanisms parallel to those dependent on nucleic acids will probably be found: and these mechanisms are just as likely to be primitive as mechanisms based on nucleic acids.

QUANTITATIVE HISTOCHEMISTRY OF SUCCINATE DEHYDROGENASE IN TISSUE SECTIONS

By G. R. N. JONES, A. J. MAPLE, E. K. AVES, J. CHAYEN and PROF. G. J. CUNNINGHAM

Royal College of Surgeons of England, Lincoln's Inn Fields, London

ALTHOUGH methods of estimating succinate dehydrogenase quantitatively in tissue sections have been described[1–3], such techniques do not appear to have been widely adopted. In these communications tetrazolium salts have been used as electron acceptors, and enzymatic activity has been estimated by relating formazan production to the area of the section at constant thickness. The main disadvantage of these methods is that the thickness of sections is not easy to control accurately or to measure directly; thus determinations of activity as related to area of section will inevitably reflect variations in thickness. Greater accuracy can be gained by the use of more sections per tissue determination, but the method can thereby become cumbersome and tedious. In the present investigation a simple and more accurate method is described in which formazan production is related to the total nitrogen content of the section itself.

Portions of liver taken from male August rats fed on a diet low in protein and supplemented with methionine[4] were frozen and sectioned at 8μ by the controlled-temperature freezing sectioning technique[5]. The sections were mounted on slides and dried at room temperature for 10–15 min prior to incubation, which was carried out in

25 ml. of solution in Coplin jars. The jars were maintained at 37° C in a water bath in the dark. The solutions contained sodium succinate (0·05 M), sodium phosphate buffer (0·05 M) at various *p*H values, neotetrazolium chloride (0·75–0·80 mg/ml.) and ethylenediamine tetraacetic acid (0·001 M). The time of incubation was usually 1 h. The reaction was stopped by placing the slides in distilled water; after a further rinse in distilled water the slides were dried and used immediately or stored unmounted in the dark for not longer than two weeks.

Small squares of glass bearing the intact sections were cut from the slides. Each square was placed in a 16 × 150 mm 'Pyrex' test tube. The formazan was extracted by adding 0·5 ml. of 10 per cent *n*-heptanol in chlorine-free *sym*-tetrachloroethane. Extraction was usually rapid, but if the section was folded it was sometimes necessary to wait 15–20 min to obtain total extraction. The extinction of the formazan solutions was measured at 550 mμ in a Hilger spectrophotometer with a microcell attachment (volume of microcells, 0·25 ml., path-length, 10 mm). Solutions of the formazan obeyed the Beer–Lambert law up to extinction values of 1·2. The colour of the solutions was fairly stable, but faded by 0·5–1 per cent in 30 min. Excess solvent was removed with a Pasteur pipette; the sections were washed with a few ml. of ether, and dried at 80°–90° C for at least 2 h.

The micro-method of Long and Staples[6] has been made more sensitive in order to estimate the total nitrogen of each section. To each tube was added 0·1 ml. 72 per cent perchloric acid. A 'Teflon' chip was added to prevent bumping and loss of acid during digestion[7]. The acid was refluxed gently at 195°–200° C for 90 min and cooled. 0·5 ml. water was added and the tubes were cooled in a refrigerator. 1·0 ml. chilled Nessler's reagent was added, and the absorption of the solution was read at 450 mμ. Under these conditions 0·5 μmoles of nitrogen gave a reading of approximately 0·60 in the spectrophotometer. Nessler's reagent was prepared according to the method of King[8] except that an equimolar proportion of sodium iodide was substituted for potassium iodide[9]. Areas of sections were obtained by tracing the projected outline of the stained section on paper at a ten-fold magnification, and by measuring the area of the tracing with a planimeter.

A typical set of results is given in Table 1. The spectrophotometric readings for both the formazan and nitrogen values are sufficiently high to be determined accurately. When enzymatic activity is related to the total nitrogen of the section, the percentage deviation is ± 2·7, but when the activity is related to the area of the section the percentage deviation becomes ± 6·0, that is, more than twice as great. It can also be seen from the table that there is an approximate correlation between formazan production per unit area and section thickness as given by total nitrogen per unit area; in other words, thick and thin sections show high and low activity respectively. Sections incubated in a medium from which succinate had been omitted gave a very weak reaction, which was about 0·5 per cent of that obtained in the presence of substrate. Formazan deposition was obtained only on the section.

The *p*H activity curve of succinate dehydrogenase with neotetrazolium as electron acceptor is shown in Fig. 1. Five sections were used for each point on the graph. When succinate was omitted from the medium a negligible reaction was recorded. It has been found that the inclusion of sodium azide at a concentration of 0·01 M enhances the production of formazan under anaerobic conditions. Several workers[10] have directed attention to the qualitative histochemical finding that cyanide produces an identical effect when substituted for azide. The enhancement of anaerobic activity was attributed to the blockage of the cytochrome system which was otherwise possibly activating traces of oxygen still present despite anaerobiosis, thereby permitting competition for electrons at some site on the transport chain.

From Fig. 1 the *p*H optimum of the succinate dehydrogenase–neotetrazolium reductase system is 8·0. A visual examination of the unmounted sections showed that it was evident that the intensity of the stain at *p*H 7·4 was very much stronger than that obtained at *p*H 6·8, but the staining reaction between *p*H 7·4 and 8·6 was so similar that it was impossible to make any assessment of where the *p*H optimum lay. It can, however, be seen from the

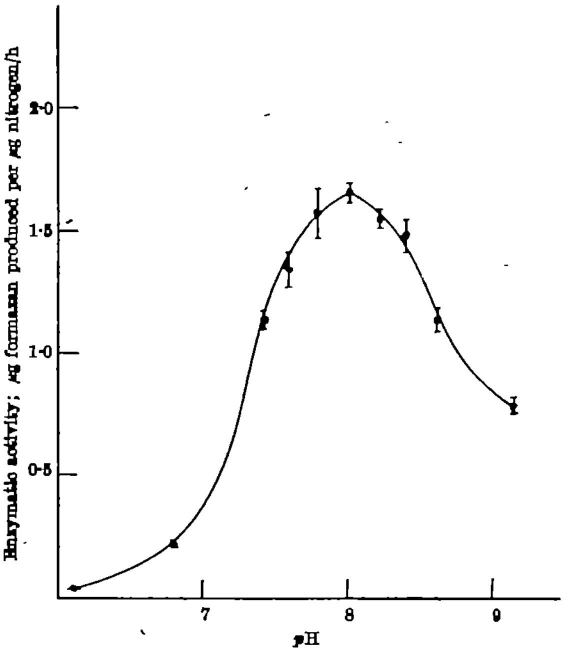

Fig. 1. Variation of succinate dehydrogenase activity with *p*H; sections incubated in neotetrazolium–succinate mixture for 45 min

graph that the activity at pH 8·0 is 50 per cent higher than the activity at pH 7·4, and that the differences in activity of adjacent points is very slight. It is often difficult to assess microscopically the intensity of a dehydrogenase reaction. Granular deposition is generally taken as being indicative of enzymatic activity, but under given conditions with the same material the size and number of formazan granules can vary. Qualitative comparisons may not be necessarily valid even when differences between sections are apparently clear. Moreover, sections of different thickness which have been treated in the same way can show considerable differences in intensity of staining both microscopically and to the naked eye. When such sections are subjected to the procedure described and formazan production related to total nitrogen the agreement between the values obtained is very close.

No comparison of enzymatic activity at this, the cellular level, has as yet been made with succinate dehydrogenase activity as determined with neotetrazolium in an homogenate preparation, but a comparison with the results of Slater[11] shows that the activities reported here are of the order of two-thirds of those obtained at the homogenate-level. Jardetzky and Glick reported a value of 0·27 μg formazan produced per μg nitrogen per hour, but their nitrogen determinations were performed indirectly on untreated sections.

The amount of tissue needed for each sample is very small, and is but a fraction of the amounts required for assay by manometric methods. It is, however, of the same order as that required for methods involving a direct measurement of rate of fumarate formation[12]. The accuracy obtainable here is probably no better than ± 7 per cent. It is likely that the error arises largely in the nitrogen determination; further work on this is in progress. The outstanding advantage possessed by this technique is that it is possible to examine microscopically the section itself before analysis and, if necessary, to examine a serial section stained with hæmatoxylin and eosin. With standard biochemical procedures the sample is homogenized, and the only histological appraisal of the material which can be made must rest on pieces removed from the material prior to a treatment which often involves disruption. The danger then exists that the histological section can give information which is no more than an approximation to the real composition of the sample. At present this quantitative method is probably not sufficiently sensitive for different areas of the section to be analysed separately, but this should be possible when the nitrogen estimation method is made more sensitive and reliable.

The potential value of this quantitative microtechnique is considerable, even if it is used only as a means of microsampling for enzymatic assay. It is stressed, furthermore, that this technique enables dehydrogenases to be studied at the level of the intact cell instead of at the level of individual cellular components at various stages of isolation after the cell has been disrupted. The simultaneous combination of a quantitative enzymatic determination with direct microscopical examination of the material studied should reduce experimental ambiguity of tissue sampling when heterogeneity is a problem, especially in the study of tumours.

We gratefully acknowledge financial assistance from the British Empire Cancer Campaign. We thank Mr. H. J. Cotes, without whose generous gift of a spectrophotometer this work could not have been accomplished.

BETA-GALACTOSIDASE OF *SHIGELLA SONNEI*

By CARLA R. CLAUSEN and PROF. MITSURU NAKAMURA

Department of Botany and Microbiology, Montana State University, Missoula

β-GALACTOSIDASE is an inducible enzyme in many organisms[1–4]. Lederberg[5] developed an assay method for β-galactosidase which was based on the hydrolysis of a chromogenic substrate, *o*-nitrophenyl-β-*d*-galactoside (ONPG), to *o*-nitrophenol (ONP). Electrophoretic analysis has shown that the hydrolysis of lactose and ONPG was catalysed by the same enzyme[6]. According to Monod *et al.*[7] the induction of β-galactosidase in *Escherichia coli* was limited to substances possessing an intact galactosidic radical. β-Galactosidase production was increased by sugars which were not its specific substrate[8]. Certain inducers such as melibiose, which is a β-galactoside, are not hydrolysed by β-galactosidase[7]. Galactose was found to be a good inducer of β-galactosidase in *Bacillus megaterium*[8], *Staphylococcus aureus*[9] and *E. coli* B[10], whereas it was a poor inducer in a wild type of *E. coli*[11]. Methyl-β-*d*-galactoside and methyl-β-*d*-thiogalactoside (TMG) were good inducers of β-galactosidase but phenyl-β-*d*-thiogalactose was not[12]. Fluoro-β-*d*-galactoside was reported to be a good inducer but not as efficient as TMG (ref. 11). This was because the fluorogalactoside was hydrolysed by the enzyme whereas TMG was not. It is considered advantageous to use 'gratuitous' inducers which do not influence general cellular metabolism since their effects would not mask the true induction process[1]. Lactose was found to be the only inducer of β-galactosidase in *Paracolobactrum aerogenoides*[13]. Attempts have been made to induce the enzyme in *Shigella sonnei* with lactose, melibiose, and TMG (ref. 14). TMG was the most efficient inducer particularly in toluene-treated cells.

The purpose of the present investigation was to study the properties of the β-galactosidase in *S. sonnei* and to determine the factors which affected this induction process. Concurrently, we studied the lactose fermenting patterns of *S. sonnei*[15].

Four strains of *S. sonnei* were used. In addition, *S. boydii*, *S. flexneri*, *S. dysenteriae*, *alkalescens-dispar* group, and *E. coli* were studied. The cells were collected, washed and suspended to yield an optical density reading of 1·0 (420 mμ). The enzyme assay was based on the colorimetric determination of ONP released from ONPG[5]. Intact cells and toluene-treated cells were assayed simultaneously; toluene-treatment procedures were those utilized by Koppel *et al.*[10]. The amount of ONP liberated in the reaction tubes was determined from a standard calibration curve which was prepared by measuring the spectral changes for varying concentrations of

ONP. 1 ml. of the original cell suspension was dried in the hot-air oven at 85° C to determine the enzyme activity on a per weight basis. The activity of β-galactosidase was recorded as the number of μmoles of ONP liberated from ONPG in 20 min at 37° C per mg dry weight of cells. Cell-free extracts were obtained by shaking the cell suspensions for 60 min at 4° C with glass beads in the Mickle tissue disintegrator. The disrupted cells were then assayed for enzyme activity. Extracts were also prepared by alternate freezing and thawing for 5 times at – 20° C.

Attempts to increase the production of β-galactosidase were made by growing the organisms in the presence of various carbohydrates (lactose, galactose, glucose, melibiose, raffinose and TMG) for 3 days prior to the assay. The enzyme was also induced in washed cell suspensions with either lactose or TMG. The inducers were added to the cell suspensions 2–18 h before the assay. The induction was carried out at 37° C, which was found to be the optimum temperature for enzyme induction. Starved cells were also induced. The cells were starved by placing washed cells at 37° C for 24 h prior to the addition of the inducer. Starved cells were also induced in the presence of an exogenous carbon source (0·5 per cent maltose, glucose, or lactose). The organisms were grown at 15°, 25°, 37° and 40° C for 7 days prior to the assay to determine the effects of growth temperature on enzyme production. We also grew the organisms at pH values of 6, 7, 8 and 9 for 3 days to determine the effects of pH on enzyme production. We also examined the stability of the enzyme by assaying cell suspensions which were stored at 4°–40° C for periods up to 7 days.

Conventional manometric methods[16] were utilized to measure oxygen uptake of cells using lactose as the substrate. Both induced and uninduced cells were examined. In some experiments the inducing agents were placed directly into the Warburg flasks to measure induction during the observation period. The concentration of the substrate was varied in other experiments. Attempts were made to isolate mutants by ultra-violet irradiation. Cells were assayed immediately after irradiation and also following growth of the irradiated cells in nutrient broth for 7 days. Three different irradiation doses were used.

In order to determine the role of the composition of the culture media on β-galactosidase production the organisms were grown in nutrient broth and in a defined medium[17]. The enzyme was induced during the growth of the organisms in these two media and in other experiments casamino-acids and polypeptides were added during enzyme induction to learn if additional nitrogen sources increased the enzyme formation.

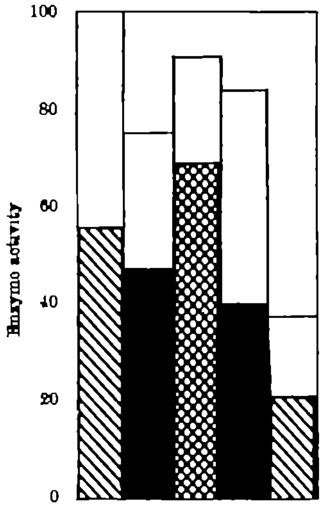

Fig. 1. Effect of toluene treatment on β-galactosidase activity of *S. sonnei* and *E. coli*. Lower portion of bars indicate activity of intact cells; upper (unfilled) portion of bars represent the enzyme activity of cells treated with toluene
The strains are listed by numbers from left to right: *B*–2506–3, *F*-6, *F*-141, *B*–2509–2, *E. coli*

S. sonnei exhibited β-galactosidase activity as reported previously by many workers. There was, however, considerable strain difference in the level of enzyme production. The other species of *Shigella* possessed no β-galactosidase. The enzyme-level in uninduced *E. coli* was approximately half that in *S. sonnei*. Toluene treatment for 10 min increased the enzyme activity; additional treatment resulted in diminished enzyme activity. Toluene treatment for 10 min did not lyse the cells; however, the cells appeared larger and elongated under microscopic examination. Fig. 1 shows the results of enzyme assays with intact and toluene-treated cells in four strains of *S. sonnei* and one of *E. coli*. The enzyme activity of cells prepared by standard methods is compared with cell-free extracts in Table 1. Cells disrupted by the tissue disintegrator possessed more enzyme than intact or toluene-treated cells. Freezing and thawing reduced the enzyme-level.

Table 1. VARIATION IN β-GALACTOSIDASE ACTIVITY OF DIFFERENT CELL PREPARATIONS

Cell preparation	Enzyme activity *E. coli*	 *S sonnei*, *F*–6
Intact cells	21	48
Toluene-treated cells (10 min)	38	77
Cell-free extract (disrupted in Mickle)	82	115
Cell extract prepared by freezing and thawing	0	25

The β-galactosidase activity of cells grown in the presence of several inducers for 3 days is recorded in Table 2. The inducing sugars were used at a concentration of 0·5 per cent and TMG was used at a concentration of 5 × 10^{-4} M. Neither of the monosaccharides found in lactose, namely, glucose and galactose, induced enzyme formation in *S. sonnei* and *E. coli*. Lactose was an effective inducer of β-galactosidase in *E. coli*, but had only a slight stimulatory effect on *S. sonnei*. Specifically, lactose increased the enzyme activity of *E. coli* 17 times the basal level and only 1·3 times the basal level in *S. sonnei*. Melibiose, which also consists of glucose and galactose (α-linkage), induced the β-galactosidase in *E. coli* but not in *S. sonnei*. Raffinose, a trisaccharide containing galactose in an α-linkage with sucrose, failed to induce the enzyme. Only TMG was an effective inducer of β-galactosidase in *S. sonnei*. Enzyme induction was not observed in the other species of *Shigella*.

Table 2 EFFECT OF INDUCERS ON THE β-GALACTOSIDASE ACTIVITY OF *E. coli* AND *S. sonnei*, STRAIN *B*–2506–3

Inducer	Enzyme activity *E. coli*	 *S. sonnei*
None	38	101
Glucose	0	7
Galactose	20	30
Lactose	638	131
Melibiose	568	100
Raffinose	145	100
TMG	682	482

Maximum enzyme induction occurred at 4 h in *E. coli* when 0·5 per cent lactose was used as the inducer; on the other hand, in *S. sonnei* maximum induction occurred after 18 h. When TMG was used as the inducer maximum enzyme induction occurred after 18 h in both *E. coli* and *S. sonnei* (Fig. 2). A comparison was made of the inducibility of the enzyme in distilled water and in nutrient broth; the induced enzyme-level was approximately 30 per cent higher in nutrient broth. Attempts to induce β-galactosidase in cell-free extracts of *S. sonnei* with TMG met with variable results but was generally unsuccessful. Washed cell suspensions of *S. sonnei* starved for 24 h were induced with TMG. Starved cells still retained their capacity for β-galactosidase production at a level comparable to unstarved cells. However, cells starved for 48 h produced less enzyme under TMG induction. Cells starved for 96 h exhibited no detectable enzyme.

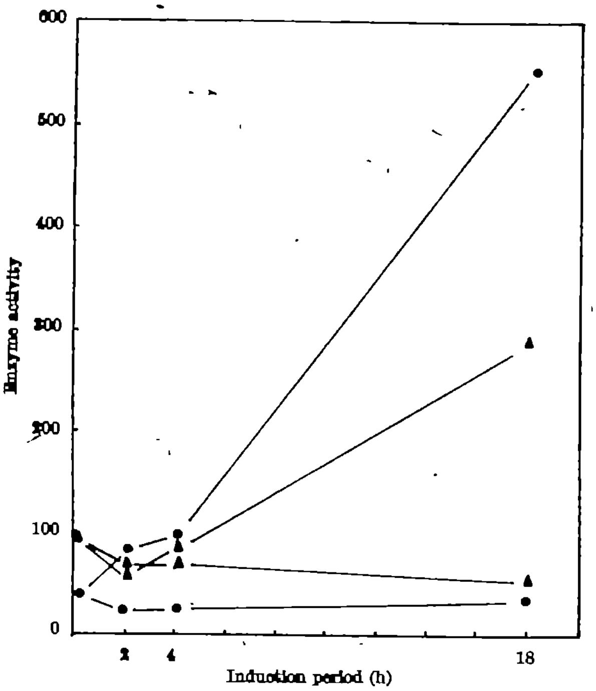

Fig. 2. Induction of β-galactosidase with TMG at 37° C for 0–18 h. The cells were treated with toluene
●, *E. coli*; ▲, *S. sonnei*. The two lower lines represent uninduced controls

Fig. 3 illustrates the optimum temperature for the induction of β-galactosidase. In Fig. 4 is shown the effect of the temperature of growth of *S. sonnei* on the production of β-galactosidase. Cells grown at various *p*H values were examined for their enzyme activity; between values of 6 and 9 there was little difference in the enzyme-levels of *S. sonnei*. The stability of the β-galactosidase of *E. coli* and *S. sonnei* was studied next. Washed cells were stored at 4° C and enzyme assays were performed from aliquots after 1, 3, 5 and 7 days of storage. There was no appreciable loss in the enzyme activity within the time that we studied the cells. As a matter of fact, there was only a slight decrease in enzyme activity even when the cells were stored for 7 days at 15°, 37° or 40° C. Induced cells of *S. sonnei* respired (took up oxygen) at a more rapid rate and to a greater extent than uninduced cells. When the inducing agent was added directly to the Warburg flasks during the observation period, TMG produced an increase in respiratory rate. The increase was slight at the beginning and gradually became accelerated after several hours. TMG was the only effective inducer among the several tested.

Washed cells were irradiated with ultra-violet light and assayed immediately for β-galactosidase activity. The results are illustrated in Fig. 5. Irradiation, in general, produced a slight decrease in enzyme activity which stabilized at a minimal level. It is possible that increased doses would have completely eliminated enzyme activity. Repeated attempts to obtain a mutant of *S. sonnei* by irradiation that produced more or less enzyme failed. When enzyme induction was attempted in the presence of casamino-acids, polypeptides and peptone preparations, there was a considerable increase in the enzyme-level. However, when the organisms were grown for several days in media containing these nitrogen sources the enzyme-levels remained unchanged.

In our investigations *S. sonnei* possessed β-galactosidase activity and the other *Shigellae* were devoid of the enzyme. Rickenberg[14], on the other hand, was able to detect the enzyme in several other *Shigella*. Lowe[15] was unable to observe β-galactosidase activity in *S. alkalescens*, which agrees with our findings. *S. sonnei* produced 2–3 times more basal (uninduced) enzyme than *E. coli*. Others have reported that *Paracolobactrum aerogenoides* possessed 10 times more basal enzyme than *E. coli*[13]. We have found that mechanically disrupted cells revealed more detectable enzyme than intact cells. It is possible that this procedure released the enzymes into solution thus increasing total enzyme activity. On the other hand, cells treated by alternate freezing and thawing were devoid of β-galactosidase activity. Possibly the procedure was sufficiently damaging to inactivate the enzyme. We cannot fully explain the fact that melibiose, which was reported as an excellent inducer in several organisms[2,7,20–22], failed to induce the enzyme in *S. sonnei*. It is possible that *S. sonnei* is only poorly induced, as was suggested by Anderson and Rickenberg[16] for the low level of induction in *P. aerogenoides*. From our work it appeared that the presence of nutrients favour enzyme induction. However, it has been reported that the addition of glucose, ribose, xylose and glycerol as exogenous energy sources to nitrogen-deficient media blocked enzyme formation[23]. We have found that additional nitrogen

sources were necessary for good enzyme induction and therefore suggest that the endogenous nitrogenous supply is inadequate in *S. sonnei* for optimal enzyme induction. Washed cells irradiated with ultra-violet light possessed less enzyme than unirradiated cells. The irradiation procedure may have destroyed pre-existing enzyme and also inhibited the synthesis of new enzyme. Kameyama and Novelli[24] reported that β-galactosidase induction in *E. coli* was inhibited by ultra-violet irradiation.

In summary, the β-galactosidase of *S. sonnei* behaves quite differently from that of *E. coli*. We have compared the enzymes in these two organisms, studied various factors which affect their activity, and examined the stability of the enzyme.

This investigation was supported by a research grant (*E*–3734–*C*1) from the National Institutes of Health, U.S. Public Health Service. One of us (C. R. C.) was the recipient of a Summer Fellowship for Graduate Teaching Assistants.

DIFFERENTIATION OF PHASE I AND PHASE II *COXIELLA BURNETII* BY EQUILIBRIUM DENSITY GRADIENT SEDIMENTATION

By BILL H. HOYER, RICHARD A. ORMSBEE, PAUL FISET* and DAVID B. LACKMAN

U.S. National Institutes of Health, National Institute of Allergy and Infectious Diseases,
Rocky Mountain Laboratory, Hamilton, Montana

FRESHLY isolated *Coxiella burnetii* cells from animals and ticks are characteristically in Phase I and when serially passed in embryonated chicken eggs are converted to Phase II after a variable number of passages[1–3]; conversion of cells from Phase I to Phase II is determined by the serological reactivity of Phase II cells with early convalescent sera from animals infected with *C. burnetii* cells of either phase[3]; Phase I cells do not react with early convalescent sera. Phase I cells can also be converted to Phase II serological reactivity by oxidation with periodate or by physical treatment such as ultrasonication[4].

Ormsbee[5] has noted qualitative physical differences in Phase I and Phase II cells during purification, and this article describes the difference between these two phases as determined by equilibrium density gradient sedimentation in cæsium chloride solution as described by Meselson *et al.*[6].

Yolk-sac suspensions of *C. burnetii* cells, strains Ohio and Nine Mile, were purified by various techniques[5,7], including differential sedimentation in M potassium chloride or M sodium chloride, treatment with ethyl ether, and the use of linear gradients of sucrose or glycerol, and various combinations of these procedures. In most instances the starting material was treated initially with 0·2 per cent formaldehyde. Some purified preparations were lyophilized prior to use in cæsium chloride gradients.

About 1 mg of Nine Mile strain cells, fifth egg passage (Phase I) and seventeenth egg passage (Phase II) were uniformly suspended in 4 ml. cæsium chloride solution, relative density 1·3, and centrifuged in a Spinco *SW*-39 rotor for 16 h at 35,000 r.p.m. (about 100,000*g*). The Phase I cells formed a granular band 22 mm from the meniscus and a homogeneous, well-dispersed band 20 mm from the meniscus. The relative density of the cæsium chloride solution in the zone between these two bands was about 1·33. The Phase II cells formed a dense pellicle at the meniscus (relative density 1·25) which had to be slightly stirred to obtain satisfactory photographs. A mixture of the two preparations gave bands characteristic of the Phase I and II preparations examined individually. The bands are shown in Fig. 1. In addition, Nine Mile cells in Phase I were treated with periodate, shown to have Phase II serological activity, and centrifuged as above in 1·3 relative density cæsium chloride solution. Bands at the 20- and 22-mm levels characteristic of the original Phase I suspension were observed and no detectable material was present at the meniscus.

Cells of Ohio strain, fifth egg passage (Phase I), and twenty-second egg passage (with Phase II serological

---

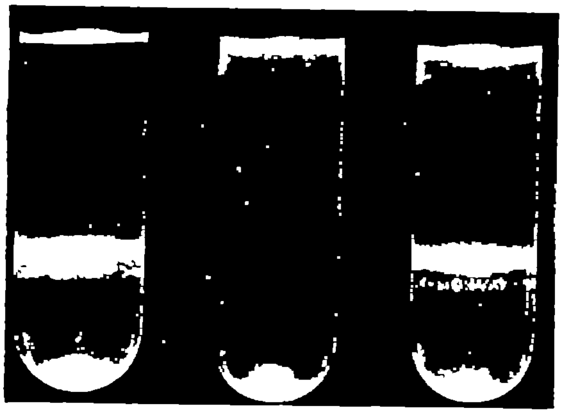

Fig. 1. Bands obtained by equilibrium density gradient sedimentation (16 h, 100,000g) of Phase I and II *Coxiella burnetii* cells in caesium chloride solution, initial relative density, 1·3. I, Nine Mile (Phase I), II, Nine Mile (Phase II), II–I, mixture of Phase I and Phase II cells

reactivity) were also centrifuged as previously described in a 1·3 relative-density caesium chloride solution. The Phase I Ohio cells formed bands at 20 and 22 mm as did the Phase I Nine Mile cells, and in addition some preparations formed a band with weak turbidity at 17·5 mm. There was no material at the meniscus. Ohio cells with Phase II reactivity, unlike the Phase II Nine Mile cells, formed principal bands at 20 and 22 mm from the meniscus and in addition a pellicle at the meniscus indicating that the cell population consisted of a mixture of Phase I and Phase II cells. Mixtures of fifth and twenty-second egg passage cells yielded principal bands at 20 and 22 mm and a pellicle at the meniscus. To determine the density of the material at the meniscus, twenty-second egg passage *C. burnetii* cells of Ohio strain were centrifuged as above in caesium chloride solutions with initial relative density of 1·2. Material collected at the meniscus of this gradient was amorphous and a band which appeared at 22 mm from the meniscus (1·21 relative density region) was composed of rickettsial cells. A pellet at the bottom of the tube was composed of the denser Phase I cells.

Thus, it appeared that natural and artificial mixtures of Phase I and Phase II rickettsiae could be separated by reason of their different densities. To confirm this observation, material collected from appropriate bands was examined by darkfield, phase and electron microscopy as well as complement fixation and slide agglutination tests.

Microscopy confirmed that the material in the 1·33 relative density region consisted of rickettsial cells which, when washed free of salts, were not observably contaminated when viewed by the electron microscope. Material from the meniscus of the same gradient consisted of rickettsial cells and amorphous material. However, the 1·21 relative density region of a different gradient formed from caesium chloride solution with 1·2 initial relative density contained only rickettsial cells as determined by phase microscopy and preparations stained with Machiavello stain.

Complement fixation tests were done with early convalescent guinea pig sera (Phase II antibody only) which reacted with material collected from the meniscus of the density gradient (initial relative density 1·3) and in some instances with material collected from the zone 20 and 22 mm below the meniscus. If cells were not treated with formaldehyde early in the purification process, the cells from the zone characteristic of Phase I often showed Phase II reactivity. This is most probably explained by an unmasking of Phase II reactive sites by treatment of the cells prior to equilibrium density gradient sedimentation; it was necessary to suspend thoroughly preparations prior to sedimentation, and this was often done by vigorous shaking with glass beads or by ultrasonication. Presumably these treatments disturbed the surface of unfixed cells sufficiently to uncover Phase II reactive sites; formaldehyde treatment 'fixed' the surface sufficiently to prevent this uncovering. These minor changes in cell surface were not reflected in observable density differences. Cells from both density regions reacted with hyperimmune (Phase I, II) guinea pig antisera.

Cells were also examined for serological reactivity in a slide agglutination test read by darkfield or phase microscopy. A few drops of early convalescent (Phase II) or hyperimmune (Phase I–II) guinea pig sera were mixed with suspended, washed cells from the appropriate density region sufficient to give several thousand cells per oil immersion field. A cover slip was sealed over the cell-antibody mixture with clear nail polish and the preparation observed with an oil immersion objective. Cells from the less-dense (Phase II) zones were characteristically slightly clumped, but this clumping increased dramatically as incubation with either antiserum proceeded. Cells from the denser (Phase I) zones were characteristically uniformly suspended and clumped dramatically as incubation in Phase I–II antiserum proceeded, but either did not clump at all (formaldehyde-treated cells) or formed scattered small clumps in Phase II antiserum.

With two strains of *C. burnetii*, morphological as well as serological evidence, therefore, supports the observation that Phase II rickettsiae (relative density about 1·21) can be separated from Phase I rickettsiae (relative density 1·33) by equilibrium density gradient sedimentation in caesium chloride. Cells with Phase I density characteristics, however, can exhibit some serological reactivity with Phase II antisera if treated by physical or chemical means; fixation of the surface of Phase I cells early in the purification procedure prevents this unmasking of Phase II reactive sites.

IN VIVO STUDY OF CELL KINETICS IN ACUTE LEUKÆMIA

By DR. A. M. MAUER and VIRGINIA FISHER

Children's Hospital Research Foundation and Department of Pediatrics, University of Cincinnati College of Medicine

THERE have been several reports of *in vitro* studies designed to assess the proliferative capacity of leukæmic cells, from patients with acute leukæmia, with tritiated thymidine as a cell label[1–4]. A preliminary report of an *in vivo* study in a patient with acute myeloblastic leukæmia has been made[5]. In this communication we present the results of an *in vivo* study with tritiated thymidine in a child with untreated acute lymphoblastic leukæmia.

The patient, a five-year-old white girl, was admitted to the hospital because of pallor. The initial laboratory values were: hæmoglobin, 7·3 g per cent; white blood

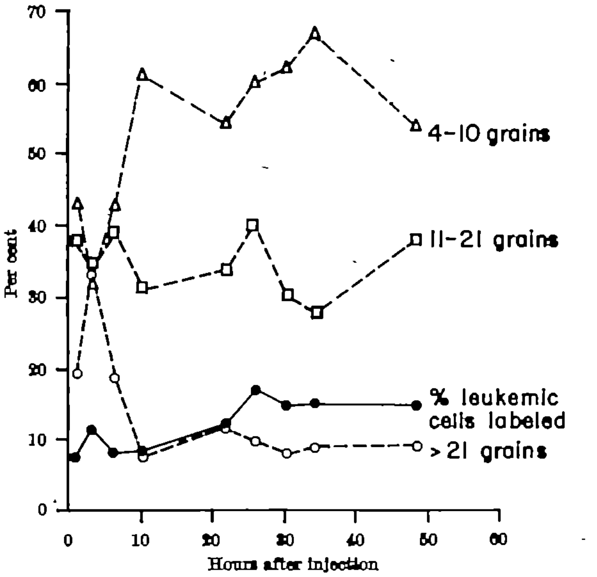

Fig. 1. Time-course of label in the leukaemic cells of the bone marrow. The closed figures represent the percentage of leukaemic cells having greater than four grains over the nucleus and the open figures represent the percentage of labelled leukaemic cells in the three groups of label concentration

cell count, 7,650/mm^3 with 31 per cent lymphoblasts; and platelet count, 86,000/mm^3. On the second hospital day at 11.45 a.m. she was given intravenously 200 μc. of tritiated thymidine (specific activity 360 mc./m.mole) per kg body-weight. One h after the injection and at intervals afterwards blood and bone marrow samples were obtained for the preparation of autoradiographs. A transfusion of 500 ml. of stored bank blood was given 50 h after the injection and treatment with prednisone and 6-mercaptopurine was begun 76 h after the start of the study. During the course of the study, the white blood count varied between 5,800 and 8,000/mm^3 with 25–35 per cent lymphoblasts.

The autoradiographs prepared from the blood and bone marrow smears were exposed for 90 days. After developing and staining the smears, 2,000–2,500 nucleated cells were observed from each sample and the number of labelled cells and the grain count above each cell were determined. All differential cell counts were compared with those obtained from examination of directly stained smears of the samples.

The time-course of the label in the leukaemic cells in the bone marrow is shown in Fig. 1. In the 1-h sample 7·5 per cent of the leukaemic cells contained label, with 20 per cent of the cells having greater than 21 grains over the nucleus, 38 per cent of the cells having 11–21 grains and 42 per cent of the cells having 4–10 grains. Any cell having less than 4 grains was not considered to be different from the background grain count. In the 3-h samples the percentage of heavily labelled cells had increased at the expense of the other two groups. At 6 h, the percentage of heavily labelled cells decreased as the other two groups increased. By 10 h, both the groups containing heavy and intermediate amounts of label had decreased as the lightly labelled cells increased further in percentage. A similar cycle of change in the percentage of labelled cells in each compartment was found starting with the samples obtained 22 h after the injection of the label.

One possible explanation for this time-course is that early division of cells incorporating thymidine more rapidly near the end of the deoxyribonucleic acid (DNA) synthesis phase of the mitotic cycle at the time of injection of the label resulted in the observed increase of heavily labelled cells in the 3-h sample. Afterwards, division of cells in earlier stages of DNA synthesis at the time of the injection and incorporating label at a slower rate, resulted in the increase of cells with less label. The repetition of these changes, beginning with the 22-h sample, suggests redivision of the labelled cells indicative of a generation time for these cells.

Changes in the percentage of leukaemic cells containing label occurred with the changes in concentration of label described here. An increase in labelled cells was found at 3 h, but a decrease at 6–10 h. In part this decrease might have resulted from the division of lightly labelled cells producing daughter cells containing insufficient label to be detected above the background grain count. Another increase in the percentage of labelled cells was found on the second day, with the maximal concentration occurring at 26 h.

Analysis of these results leads to the suggestion that a considerable part of the marrow leukaemic cell population either divided very slowly or not at all. At the time of labelling, about 7·5 per cent of the cells incorporated the thymidine or were in the DNA synthesis phase of the mitotic cycle. Thereafter, progressive changes in the concentration of label were observed during an 8–10-h period, which would likely reflect the time required by these cells for DNA synthesis. Repetition of those changes in label concentration and an increase in labelled cells occurred 22 h after the injection, which would indicate a generation time of about 20–22 h for the labelled cells. Thus, if the actively proliferating segments of the leukaemic cell population acted in a uniform manner, the 7·5 per cent of the leukaemic cells found to be labelled were in a phase of the mitotic cycle requiring about one-third of the generation time. Therefore, the size of the actively proliferating pool of cells represented only about 22·5 per cent of the total population of leukaemic cells in the marrow.

Further evidence that the labelled cells were dividing in a mixed population was the increase in the percentage of labelled cells which occurred during the second day. Only if the labelled cells increased by division in comparison with a static or slowly dividing group of leukaemic cells could this observation have been made.

A comparison of the labelling of leukaemic cells in the blood and bone marrow is shown in Fig. 2. Once again the difference in the initial labelling and subsequent time-course of the label in the two compartments is in favour of a concept of non-uniform leukaemic cell populations in acute leukaemia[7]. The appearance of labelled leukaemic cells in the blood is most reasonably explained by immigration of labelled cells from the bone marrow or other tissues rather than proliferation of labelled cells within the blood. The effect of the blood transfusion on the time course of the label after 50 h cannot be evaluated, although no change in total white blood count or percentage of lymphoblasts was found.

The appearance of label in normal blood cells is shown in Fig. 3. The rate of maturation of the myeloid cells

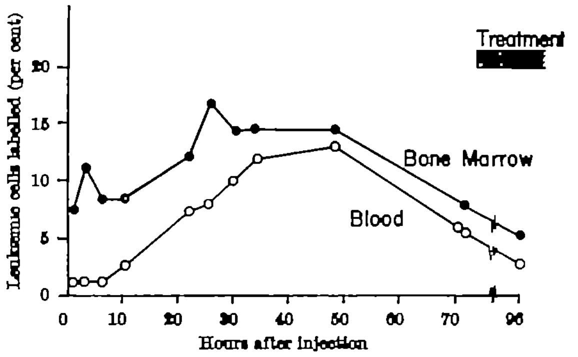

Fig. 2. A comparison of the percentage of leukaemic cells in the blood and bone marrow having greater than four grains over the nucleus. Treatment with prednisone and 6-mercaptopurine was begun 76 h after the injection of label

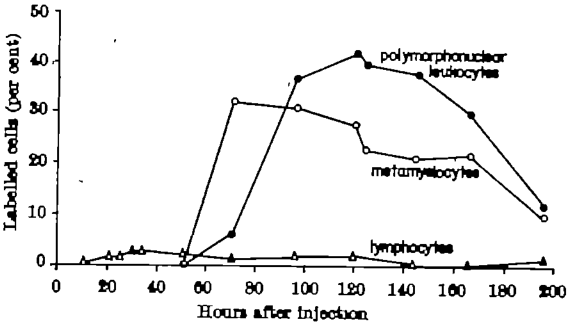

Fig. 3. The percentage of normal blood lymphocytes and granulocytes containing label

was similar to that described by Bond *et al.* in hæmatologically normal subjects[8]. The number of erythroid and myeloid cells in the marrow was too small for an adequate evaluation of the kinetics of proliferation in these cells.

Considering the variability of the clinical and laboratory findings in patients with acute lymphoblastic leukæmia, the findings presented here cannot be assumed to be characteristic of the kinetic pattern of cell proliferation in all patients with this disease. From this investigation, however, there is further evidence that the leukæmic cell population cannot be considered to be homogeneous for the purpose of the calculation of various kinetic measurements. It is of interest that Mendelsohn[9,10] has recently reported *in vivo* studies of the proliferative capacity of mouse autochthonous breast tumour cells with tritiated thymidine and similarly found a non-uniform population of cells in these tumours.

This investigation was supported by a Public Health Service research grant, *CY*–4826, Cancer Institute, U.S. Public Health Service.

HAPTOGLOBIN TYPES

Haptoglobin Sub-types in Three Racial Groups

SMITHIES, Connell and Dixon[1-3] have shown that purified haptoglobin, after reductive cleavage by urea and mercaptoethanol, is electrophoretically separable into two polypeptide chains, α and β. The β-chain is apparently unaffected by the genes at the Hp locus, but the α-chains, differentiated by migration rate and staining intensity, represent the expression of a series of alternative Hp genes. Four distinctly different α-polypeptides, called hp 1F, hp 1S, hp 2 and hp 2J have been demonstrated. A fifth polypeptide, hp 2M, found in individuals having the phenotype Hp 2–1(mod), is characteristically reduced in quantity, but its mobility is very similar, if not identical, with that of hp 2.

Investigations of inheritance studies[1] indicate that these five polypeptides represent the alleles Hp^{1F}, Hp^{1S}, Hp^2, Hp^{2J} and Hp^{2M}, although further subdivisions, particularly of hp 2, are likely to exist[4]. Of the 15 possible genotypes, the phenotypic expressions of nine have been differentiated (Fig. 1). Three of the remaining six, Hp^{2J}/Hp^{2J}, Hp^{2J}/Hp^{2M} and Hp^{2J}/Hp^{1F}, are very rare, and no appropriate subjects have yet been studied. The genotypes Hp^{2M}/Hp^{2M} and Hp^{2J}/Hp^2 appear to be associated with greatly reduced haptoglobin synthesis[5,6]; while the two polypeptides associated with Hp^2 and Hp^{2M} are so similar that the Hp^2/Hp^{2M} genotype is at present indistinguishable from Hp^2/Hp^2 (ref. 5).

Smithies *et al.*[1] sub-typed 93 random blood donors in the United States and Canada, estimating the frequencies of Hp^{1F} and Hp^{1S} to be 0·16 and 0·24 respectively, assuming a value of 0·60 for Hp^2. The work recorded here was undertaken in order to obtain further information on the racial distribution of the various Hp genes, particularly Hp^{1F} and Hp^{1S}.

Random donors at the King County Central Blood Bank were classified into three groups: Caucasoid, Negro and Oriental on the basis of general appearance. The surnames of the Oriental group were considered as a rough index of geographic origin; nearly all were Japanese. Starch-gel electrophoresis was carried out in the usual manner[7] to determine the haptoglobin phenotype, and from these data the frequency of the Hp^1, Hp^2 and Hp^{2M} genes was calculated.

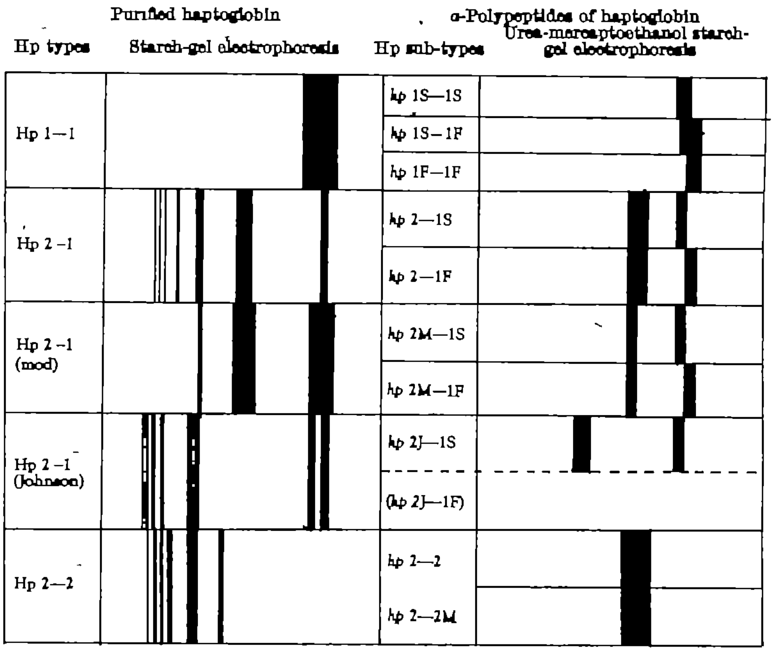

Fig. 1. Diagrammatic representation of the starch-gel electrophoretic patterns of the haptoglobin phenotypes and their respective sub-types. Those examples of Hp 2–1 (Johnson) which have so far been sub-typed have had the α-polypeptides hp 2J and 1S. The starch-gel pattern associated with hp 2J and hp 1F may vary from Hp 2–1(Johnson)

Table 1. HAPTOGLOBIN TYPES AND SUB-TYPES IN BLOOD DONORS OF THREE RACIAL GROUPS

The gene frequencies of the Negro subjects were calculated by subtracting those with Hp 0 and obtaining the approximate incidence of Hp^{2M} from the ratio of Hp 2–1 to Hp 2–1(mod). Hp^{1F} and Hp^{1S} frequencies were obtained by applying the sub-type proportions to the respective Hp^1 frequencies. All results fit Hardy-Weinberg equilibrium with a probability of $>0·05$ for the Negroes and $>0·2$ for the Caucasoids and Orientals

Ethnic group	No. tested		Haptoglobin types					Gene frequencies		
			1–1	2–2	2–1	2–1(mod)	0	Hp^1	Hp^2	Hp^{2M}
Caucasoid	409	No.	54	149	206	—	—	0·384	0·616	—
		%	13·2	36·4	50·3	—	—			
Negro	1,657	No.	472	307	641	181	56	0·552	0·349	0·099
		%	28·5	18·5	38·7	10·9	3·4			
Oriental	494	No.	34	270	190	—	—	0·261	0·739	—
		%	6·9	54·7	38·4	—	—			

		Haptoglobin sub-types of selected donors (see text)							Gene frequencies	
		1S–1S	1F–1F	1S–1F	2–1S	2–1F	2M–1S	2M–1F	Hp^{1F}	Hp^{1S}
Caucasoid	66	4	0	5	36	21	0	0	0·133	0·251
Negro	222	26	20	49	61	55	6	5	0·259	0·293
Oriental	80	14	0	1	64	1	0	0	0·005	0·256

Serum of Hp types 1–1, 2–1 and 2–1M, containing adequate amounts of haptoglobin and no visible hæmoglobin, were selected for sub-typing, since the haptoglobin–hæmoglobin complex is not suitable for haptoglobin polypeptide identification. Partial purification by DEAE cellulose chromatography, reductive cleavage, and electrophoresis in starch gels containing urea, mercaptoethanol and formate buffer were performed as described by Smithies *et al.*[1]. In most instances, a duplicate specimen was afterwards tested, and the results recorded prior to comparison with the previous test. The two readings agreed in all but a few instances, when the haptoglobin-level was not sufficiently high to produce an adequate yield of polypeptide.

Table 1 indicates the haptoglobin types of 409 Caucasoid, 1,657 Negro and 494 Oriental donors, as determined by conventional starch gel electrophoresis, as well as the calculated Hp^1, Hp^2 and Hp^{2M} gene frequencies. The lower portion of the table shows the results of sub-typing 66 Caucasoids, 222 Negroes and 80 Orientals, and the frequencies of Hp^{1F} and Hp^{1S} in those populations. The Caucasoid figures are in good agreement with those of Smithies *et al.*[1] and the calculated probability figures for all three groups are consistent with the hypothesis that Hp^{1F} and Hp^{1S}, like Hp^2 and Hp^{2M}, are alleles at the Hp locus.

Although only 11 specimens of type 2–1(mod) were sub-typed, the nearly equal distribution of Hp^{1F} and Hp^{1S} confirms the fact that the peculiarity in the pattern representing this phenotype is not dependent on a variant of the Hp^1 gene[5].

Among American Negroes, the incidence of Hp^1 is higher than that of Caucasoids and much higher than in Orientals. Similarly, the percentage of Hp^1 genes which are Hp^{1F} is highest in the Negroes, intermediate in the Caucasians and extremely low in the Orientals. The latter group, whose Hp^1 genes are nearly all Hp^{1S}, are of particular interest in view of the possibility that they might provide some information about the frequency of intragenic cross-over. Smithies *et al.*[4] suggest that the Hp^2 gene may have originated from the very rare phenomenon of non-homologous cross-over occurring in a Hp^{1S}/Hp^{1F} heterozygote, and that subsequent cross-overs involving the Hp^2 gene and either Hp^{1S} or Hp^{1F} may have produced two or even three Hp^2 variants. Most, but not all, of the hp 2 α-polypeptides which they have analysed contained those peptides characteristic of both hp 1F and hp 1S. It is conceivable that in a population such as the Japanese, the very low frequency of Hp^{1F} might be associated with an increased incidence of hp 2 α-chains lacking the peptides characteristic of hp 1F, as the result of unequal cross-over in Hp^2/Hp^{1S} individuals. Lack of information concerning cross-over frequencies and selective factors makes such a correlation entirely speculative at present. However, it is possible that further data on the fine structure and distribution of the hp α-polypeptides among various populations may provide useful clues about the evolution of their respective genes under different environmental circumstances.

This investigation was supported in part by research grant H-5780 from the National Heart Institute, U.S. Public Health Service.

Haptoglobin Types of the Nez Perce Indians

THE genetic determination of the three common haptoglobin types, Hp 1–1, Hp 2–1, Hp 2–2, was first discussed by Smithies and Walker[1,2]. Subsequent population surveys have shown marked variations in the frequencies of the Hp^1 and Hp^2 alleles in different races. In general, the focus for the lowest Hp^1 frequency appears in India, where Kirk *et al.*[3] reported a Hp^1 frequency of 0·09. An easterly increase is also noted in comparing the Japanese Hp^1 frequency of 0·24 (ref. 4) with the frequency of 0·33 in the Alaskan Eskimoes[5]. The highest Hp^1 frequency so far encountered, 0·93, is exhibited by the Lacondons of southern Mexico[6].

Recently, Connell *et al.*[7] found that after purification and reductive cleavage of haptoglobin in the presence of 8 M urea two types of polypeptides could be distinguished corresponding to the gene Hp^1. They therefore suggested that the gene Hp^1 is not a unique entity but can have one of two closely similar forms, Hp^{1F} or Hp^{1S}. The Hp 2–1 heterozygote can consequently have two forms distinguishable after reductive cleavage, Hp 2–1F or Hp 2–1S, and Hp 1–1 can be either Hp 1F–1F, Hp 1F–1S, or Hp 1S–1S. Subsequent sub-typing of families[8] confirmed their hypothesis that there are three common alleles at the Hp locus, Hp^2, Hp^{1F} and Hp^{1S}.

This communication concerns the *Hp* gene frequencies found among the Nez Perce Indians residing in Idaho and Wyoming. The specimens were collected in acid citrate dextrose and flown to Madison, where the blood typing, haptoglobin and transferrin determinations were done. (Serum samples were provided in the course of blood typing by Dr. R. Littlewood of the Department of Sociology and Anthropology, University of Washington, Pullman, Washington.) Determination of the Hp 1–1, Hp 2–1 and Hp 2–2 types was carried out according to the vertical electrophoretic method of Smithies[8], and the sub-types determined according to the method of Smithies *et al.*[8]. The results obtained are summarized in Table 1. No Hp 0 or Hp 2–1M phenotypes were encountered. One exception to the hypothesis of three common alleles, Hp^2, Hp^{1F}, Hp^{1S}, was encountered in this sample. An offspring of type Hp 2–2 was noted among four offspring of a type Hp 1S–1S male. No sample was obtained from the mother. The other three siblings were Hp 2–1S. Probably this exception is due to illegitimacy, but this could not be confirmed by the blood groups of the father and child. Since some of the specimens were obtained from related individuals, the gene frequencies were calculated by the weighting method of Cotterman[10]. The Hp^1 frequency obtained is 0·477. The population studied shows evidence of Caucasian admixture since it contains the Rh factor, *cde*; the extent of this admixture was estimated by using the per cent admixture $=\frac{q_h-q}{Q-q}$, where q_h is the gene frequency in the hybrid population, q is the expected gene frequency in the absence of admixture, and Q is the Caucasian gene frequency. For the Rh factor, *cde*, in the Nez Perce population, q_h was calculated as 0·129. The Caucasian frequency (Q) of *cde* used was 0·40, and the assumed aboriginal Nez Perce frequency (q) used was 0·00 (ref. 11). The percentage of Caucasian admixture calculated was 32·3. Using this calculated admixture, the aboriginal Hp^1 frequency in this population is estimated to be 0·50, using the Caucasian Hp^1 frequency of 0·43 (ref. 12). This frequency agrees with those reported for other North American Indian tribes: Anaktuvuk, 0·52 (ref. 13); North Athabascan, 0·42 (ref. 13); Tlingit, 0·44 (ref. 13); Apaches, 0·59 (ref. 12); Navajo Indians, 0·45 (ref. 14).

Recently, Smithies *et al.*[8] reported a gene frequency for Hp^{1F} and Hp^{1S} of 0·16 and 0·24 in 26 Caucasians, and Giblett and Brooks reported a corresponding frequency of 0·133 and 0·251 in 66 Caucasians and 0·259 and 0·293 in 222 Negroes (preceding communication). In the Nez Perce sample, only one Hp^{1F} gene was encountered in a Hp 1–1 individual; all other Hp 1–1 and Hp 2–1 samples were Hp 1S–1S and Hp 2–1S. This is of considerable interest, since Giblett reported a Hp^{1F} frequency of 0·005 in 80 Hp 2–1 and Hp 1–1 Orientals tested in her laboratory. The Oriental descent was determined by general appearance; by the surnames she concluded that most of them were Japanese. Possibly the Hp^{1F} gene is absent in the Mongoloid race.

By using the Caucasian Hp^{1F} frequency of 0·133 obtained by Giblett, the expected Nez Perce hybrid Hp^{1F} frequency is 0·043 on the bases of 32·3 per cent admixture. Due to hæmolysis in some cases and inadequate amounts in others, not all Hp 2–1 and Hp 1–1 samples were sub-typed. A separate *wx* value was therefore calculated based only on the Hp 2–1 and Hp 1–1 samples sub-typed; this value is 89·7, which represents the effective number of independent Hp^1 genes sub-typed. Of these 89·7 independent Hp^1 genes, one or 1·115 per cent were observed to be Hp^{1F}. Similarly, of the 75 or 38·4 per cent Hp^1 genes reported by Giblett for Caucasians, 26 or 34·6 per cent of them are Hp^{1F}. Assuming an aboriginal Hp^{1F} frequency of 0·00, the percentage Caucasian admixture based on 1·115 per cent Nez Perce Hp^{1F} genes and 34·6 per cent Caucasian Hp^{1F} genes, is 3·2 per cent. A test of significance of the difference between these two values (that is, 32·3 and 3·2 per cent) gives a t value of 2·82, corresponding to a probability of $< 0·01$ The discrepancy could be accounted for by postulating an early nineteenth-century introduction of one or several *cde* genes that became established by genetic drift in the small Nez Perce population. This would cause the calculated percentage admixture to be spuriously high when calculated from the *cde* frequency. The other possible explanation for the discrepancy would be a selective force acting against the Hp^{1F} gene. As of yet, no selective force has been found which influences the haptoglobin polymorphism.

This work was supported by grants from the National Institutes of Health (*RG* 8217, 2 *G* 398).

I thank Dr. O. Smithies and Dr. J. F. Crow for advice, and Dr. R. Littlewood for supplying the serum samples.

LETTERS TO THE EDITOR

SPACE SCIENCE

Measurement of Ionospheric Electron Content Regardless of Approximations

THE forthcoming advent of the Polar Beacon Ionosphere Satellite[1] has again focused scientific interest on the use of simultaneous Faraday rate and Doppler measurements for obtaining further new data about the integrated electron density along paths in the ionosphere. It might be useful, therefore, to describe a method by means of which the electron content can be obtained without approximation assumptions other than the following: isotropic and static medium, validity of reciprocity theorem, and equal propagation paths (for the various frequencies used simultaneously).

The well-known equations for the Faraday fading rate $\mathrm{d}a/\mathrm{d}t$, and for the Doppler shift Δf in a static ionosphere are:

$$\frac{\mathrm{d}a}{\mathrm{d}t} = \frac{K}{f^2}\,\overline{B\cos\varphi}\,\frac{\mathrm{d}}{\mathrm{d}t}\int_0^{S(p)} N_t\,\mathrm{d}s \tag{1}$$

$$\Delta f = \frac{f}{c}\,\frac{\mathrm{d}S}{\mathrm{d}t} - \frac{k}{cf}\,\frac{\mathrm{d}}{\mathrm{d}t}\int_0^{S(p)} N_t\,\mathrm{d}s \tag{2}$$

where the constants $K = 2\cdot36 \times 10^4$ and $k = 4\cdot03 \times 10^7$ are in C.G.S. units; f is the transmitted frequency; the line integral from the observer O to the satellite's position p has the geometrical length S; the integral is extended over the local electron density N_t along the radio path; c is the velocity of light in free space; and $\overline{B\cos\varphi}$ is the component of the geomagnetic field in the direction of the ray path (it is assumed that this field component remains constant during each single observation of one or a few seconds' duration, and can be replaced by an effective value of $\overline{B\cos\varphi}$). We solve equation (2) for the differential of the integral and write for equation (1):

$$\frac{\mathrm{d}a}{\mathrm{d}t} = \frac{K}{k}\,\overline{B\cos\varphi}\left[\frac{\mathrm{d}S}{\mathrm{d}t} - \frac{c\Delta f}{f}\right] \tag{1a}$$

The fading rate is, other things being equal, proportional to the difference between the change of the geometric path length and the change of the optical path length. At the moment of Doppler inflexion the sign of the rate $\mathrm{d}a/\mathrm{d}t$ changes, but not the sense of rotation. This effect is seldom observed because the temporal changes of $\overline{B\cos\varphi}$ are dominant for most passages. However, such passages for which $\overline{B\cos\varphi}$ is nearly constant (low orbital inclination, small changes in altitude, close to overhead passage) reveal the influence of the foregoing difference (see Fig. 1).

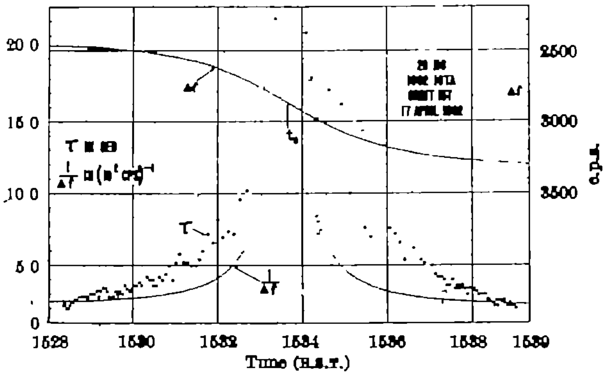

Fig. 1. Simultaneous measurement of Doppler shift and Faraday fading rate. Note the parallel trend of the centre part of the curves for $1/\Delta f$ and for τ; τ is the time-interval between two successive fade-outs; the incoming and outgoing 2-min section of the τ data is not true Faraday fading but is disturbed by simultaneous antenna fading from ground reflexions at very low elevations

With two simultaneous Doppler shift observations Δf_1 and Δf_2, we obtain from equation (2) the following expression for $\mathrm{d}S/\mathrm{d}t$:

$$\frac{\mathrm{d}S}{\mathrm{d}t} = c\,\frac{\Delta f_2 f_2 - \Delta f_1 f_1}{f_2^2 - f_1^2} \tag{3}$$

At the same moment, we measure Δf_1, Δf_2 and at the frequency f_1 the fading rate $\mathrm{d}a_1/\mathrm{d}t$. These values, together with the result from equation (3), are substituted in equation (1a), which is solved for the magnetic field component $\overline{B\cos\varphi}$ as follows:

$$\overline{B\cos\varphi} = \frac{\mathrm{d}a_1}{\mathrm{d}t}\,\frac{k}{cK}\,\frac{f_2 - f_1\dfrac{f_1}{f_2}}{\Delta f_2 - \Delta f_1\dfrac{f_2}{f_1}} \tag{4}$$

The numerator of the fraction in equation (4) is close to f_2 for $f_2 > f_1$; the denominator is the so-called 'differential Doppler'; for absolute values of Δf_1 and Δf_2 it is always positive, it changes sign together with $\mathrm{d}a_1/\mathrm{d}t$. (At the Doppler inflexion point equation (4) is no longer applicable.)

A precise measurement of the differential Doppler has to be performed with great care. First, the equality of the radio paths has to be checked, for example, by a comparison of the time moments of the occurrence of Doppler inflexion at the two frequencies. Experience shows that this condition does not apply for a good number of passages (mainly because of frequency scintillations at the lower frequency). Secondly, the application of equation (4) has to be restricted to observations at small zenith angles (this condition is synonymous to the path equality). Thirdly, the values of the Δf have to be measured against the observed value of f at inflexion moment.

Having obtained the value for $\overline{B\cos\varphi}$ in equation (4) we recall the origin of equation (1), which is :

$$a = \frac{K}{f^2}\,\overline{B\cos\varphi}\int_0^{S} N_t\,\mathrm{d}s \tag{5}$$

and which with the help of equation (4) is converted to:

$$\int_0^{S(p)} N_t\,\mathrm{d}s = \frac{c}{k}\;a_1\left(\frac{\mathrm{d}a_1}{\mathrm{d}t}\right)^{-1} f_1^2\;\frac{\Delta f_2 - \Delta f_1\left(\dfrac{f_2}{f_1}\right)}{f_2 - f_1\;\left(\dfrac{f_1}{f_2}\right)} \tag{6}$$

The total phase shift a_1 of the frequency f_1 at the time moment of observation of $\mathrm{d}a_1/\mathrm{d}t$, Δf_1, and Δf_2 is gained[2] by counting the total number of phase rotations (one-half of the number of fading periods) from the moment when the Faraday effect disappears, that is, when φ becomes close to $\pi/2$ (larger than 80°). With amplitude recording systems it is often difficult to observe this moment exactly. Further, it is important to consider the change of sign of $\mathrm{d}a/\mathrm{d}t$ when counting a. Reliable results are obtained when the resultant phase is continuously measured. G. Vogt of our laboratory has designed an analogue phase-follower system which measures the phase shift during the entire passage of the satellite. In case the foregoing method cannot be applied (for example, when as in the case of Fig. 1 the angle φ never comes close to $\pi/2$). other methods for the final calculation have to be considered. Then the above values of $\overline{B\cos\varphi}$ can be used in the differential rotation method or in other methods described in the literature[3]. However, with the polar orbit of the planned S-66 Satellite such unfavourable geometry will not apply.

The method described is free from additional assumptions about path length, path curvature, altitude, ionospheric stratification, geomagnetic field. The method needs experimental care, but gives results without ambiguity.

RADIOPHYSICS

38-Mc/s Radiation from Jupiter

Soon after the discovery by Burke and Franklin[1] in 1954 of 22-Mc/s sporadic-type radiation from Jupiter, an attempt was made by F. G. Smith[2] to detect similar radiation at higher frequencies from old records taken with the Cambridge 38- and 81-Mc/s interferometers. Suitable records were available for 16 days in 1952 and 1953 at 38 Mc/s and for 10 days in 1955 at 81 Mc/s. In spite of the fact that both aerial systems were considerably more sensitive than anything normally utilized in the study of Jupiter at frequencies close to 20 Mc/s no emission was detected. For the next few years it was tacitly assumed by most workers, with the notable exception of Douglas[3], that some frequency below 38 Mc/s represented an upper limit to the Jupiter radiation.

As other investigations progressed, however, it became clear that, not only did the radiation become much less intense at higher frequencies (see, for example, accounts of 27-Mc/s observations by Franklin and Burke[4], Gardner and Shain[5], and Carr *et al.*[6]), it also became much less prolific. I have pointed out[7] that the emission mechanism might be such that at higher frequencies, on rare occasions, an event might occur which would contain bursts of a sufficient strength to be detectable on the Earth. It is possible that if F. G. Smith had had records of 38 Mc/s observations available for a longer period he might have found a Jupiter event recorded.

Warwick[8] has recently reported that a few events extending to frequencies in the 38 Mc/s region have been recorded by the High Altitude Observatory dynamic spectrograph. Radiation at 38 Mc/s has also been detected at Florida State University during 1962 using a phase-switched interferometer consisting of two square corner reflectors, each containing a single half-wave dipole and separated by six wave-lengths. A more sensitive system was not desirable for the purpose of the experiment, which was to demonstrate low day-by-day frequency of occurrence as the dominant feature rather than low radiated power. The records examined by F. G. Smith should already have revealed some emission were it simply a matter of using higher sensitivity.

Observations were made nightly during April 25–August 25, 1962. All observations were monitored by an observer. During this period two events from Jupiter were recorded. The first, recorded on June 18, lasted for about 1 min only. The second, recorded on August 18, lasted for about 30 min and contained a number of weak bursts of estimated intensity about 5×10^{-22} W m^{-2} $(c/s)^{-1}$. On both occasions strong bursts of noise were observed simultaneously on lower frequencies between 16 and 22 Mc/s and receiving conditions were good. The second event was recorded while the most active region of the planet was facing the Earth. This is shown in Fig. 1. A histogram of 18 Mc/s observations for the corresponding period is shown for comparison. The histograms have been made on the basis of a rotation period of 9 h 55 m 29·37 s, the value which has been provisionally adopted by the International Astronomical Union for Compilation of a System III Ephemeris[9]. The first event was of such short duration that it cannot be represented on the histogram, which is computed for 5° intervals of central meridian longitude. This event occurred when the System III central meridian longitude was 325°. The experiment is to be repeated at a slightly higher frequency next year.

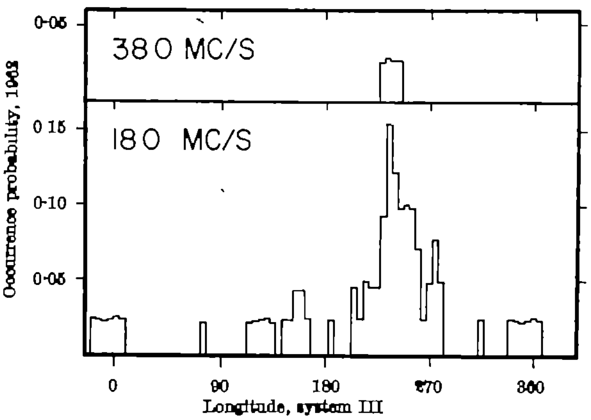

Fig. 1. Histograms comparing occurrence probability of Jupiter radiation at 38 and 18 Mc/s for 1962 as a function of System III central meridian longitude

It is worth noting that there are indications[10,11] that the increase in day-by-day frequency of occurrence continues to the lowest frequencies of observation, close to 5 Mc/s rather than reaching a maximum around 18 Mc/s as was originally suspected. Some disagreement exists, however, concerning average intensities at the lowest frequencies. Those reported by Ellis[10] are rather less than typical values for 18 Mc/s, whereas those reported by Carr *et al.*[11] are higher.

I thank Mr. S. Brudno and Mr. W. M. Houghton for assistance and the National Aeronautics and Space Administration for financial aid.

Abrupt Phase Shifts on *MSF** (60 kc/s)

Watt-Carter and Corke[1] have reported phase variations on the *GBR* (16 kc/s) transmissions from Rugby as a result of aerial detuning by changes in weather conditions and aerial sway. We report here man-made phase jumps on the *MSF* (60 kc/s) transmissions.

Daily phase measurements of *MSF* (60 kc/s) against local frequency sources are made at the Signals Research and Development Establishment and our chart records show occasions when abrupt phase changes of about 12° occurred. Between April 25 and July 11, 1962, there were 20 days on which one abrupt phase change occurred. It was always in the same sense and was completed in less than a few seconds. The changes were always found within −3 to +10 min of the nominal start of the *MSF* transmission at 1430 G.M.T.

Investigation revealed that the phase jumps resulted from earthing the *GBR* aerial system during its maintenance period—which coincided with the start of the *MSF* transmission. The resultant detuning of the nearby *MSF* aerial system was responsible for the abrupt phase shifts observed.

It remains necessary to earth the *GBR* aerial system from time to time, but so far as possible this will be done only when *MSF* (60 kc/s) is not transmitting. The corrections for *MSF* (60 kc/s), published by the National Physical Laboratory, are based on the average rate of phase accumulation with time over the daily one hour transmission period. They are intended to be representative of the average frequency over this period. For this reason, on the days when the foregoing phase jumps occurred, the jump of 12° was not included as part of the total accumulated phase. If the jump had been included the *MSF* correction would have been in error by 1·5 parts in 10^{11}*.

These results emphasize the care necessary in operating and using the standard frequency transmissions when high-precision measurements are required in a limited time-interval.

GEOPHYSICS

Motion of Current Systems in the Ionosphere

THEORETICAL studies of the behaviour of electric current systems in the lower ionosphere, treated as a rigid anisotropic shell, indicate that the Hall-current conductivity produces a rotation of these systems from west to east about the geomagnetic axis. When a given current system is expressed in terms of spherical harmonics, it is found that the components of the system corresponding to harmonics of different order n rotate with different speeds, because the angular velocity contains a factor $(2n + 1)/(n^2 + n)$ (refs. 1 and 2). It follows that the pattern of the current system is distorted as it rotates, but the rate of distortion may be fairly slow if only a few close values of n are involved. Using the conductivity tensor adopted by Ferris and Price, the corresponding velocities of the current pattern at latitude λ range from $8{\cdot}3 \times 10^4 \sin \lambda$ cm/sec for $n = 1$ to $1{\cdot}06 \times 10^4 \sin \lambda$ cm/sec for $n = 10$.

In the course of an investigation of the spatial distribution of rapid geomagnetic fluctuations during a typical magnetic storm (November 9–13, 1956) evidence has been found of a general motion eastwards of the pattern of disturbance, and, since the velocity found is of the same order as that given here, it is tempting to interpret this motion as due to the afore-mentioned effect of the Hall current. If this interpretation is correct further studies of geomagnetic fluctuations may assist in evaluating the conducting properties of the ionosphere more precisely.

Various comparative investigations of magnetograms from Thule, Godhavn, Lerwick, Lovo, Rude Skov, Wingst, Abinger, Chambon-la-Foret and Tamanrasset were made. In particular, simultaneous polar diagrams for these stations showing the projections of the disturbance vectors in the *HD* plane, and also when possible in the *DZ* or *HZ* plane, were constructed from measurements made at 20-sec intervals for the period 10*d* 1125 to 1135 G.M.T. These diagrams showed many similarities at neighbouring stations. Taking in turn the *HD* diagram for each station, time-intervals were selected corresponding to distinct magnetic field changes, the beginning and end of each interval being estimated to the nearest 10 sec. Many of these bounding times were found to correspond at different stations, particularly the European ones, though the times were not exactly the same at all stations. The stations lie roughly on two lines, broadly north–south and east–west, and an attempt was made to detect phase differences in each direction. In Fig. 1 the times are plotted against geomagnetic latitude, and in Fig. 2 against geomagnetic longitude. The lines running from top to bottom in the figures are the best fitting straight lines, and their slopes to the vertical are a measure of the apparent phase gradients. The averages of the two sets of phase gradients were tested for significance. With respect to longitude (Fig. 2), the *t*-test shows that there is less than 5 per cent probability of the calculated average having arisen from pure chance. This average is approximately 10^{-7} sec/cm, events being later towards the east. Likely estimates of timing errors or instrumental lags are rather too small to account for this phase gradient. The average with respect to latitude (Fig. 1) is, however, not significantly different from zero.

The longitudinal phase gradient implies some motion of the disturbance field pattern from west to east. Assuming the form and amplitude of this pattern does not change too rapidly, the mean velocity is approximately the reciprocal of the phase gradient, that is, 10^7 cm/sec.

A different method of studying the field also indicated a general motion eastwards of the field pattern. Vector diagrams of the horizontal field deviations at specified epochs were plotted on charts showing the geographic positions of the stations. It was found that the vectors for the European stations tended either to converge to or to diverge from a small area, and this area progressed towards the east with a speed of order 10^4 cm/sec, suggesting the existence of a pulsating current circulation travelling eastwards.

It will be noted that there is no evidence of any north–south motion, while the velocity derived for the west–east motion is approximately that suggested by the above theory. The detailed analysis of the observations is being

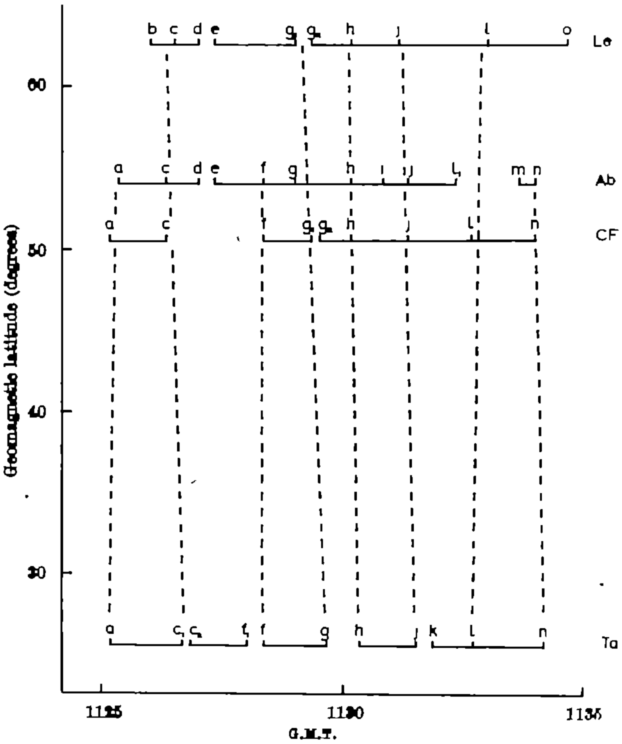

Fig. 1. Bounding times at various stations, indicated by the letters *a*, *b*, . . . *o*, plotted against geomagnetic latitude. Dotted lines are best fitting straight lines through corresponding points

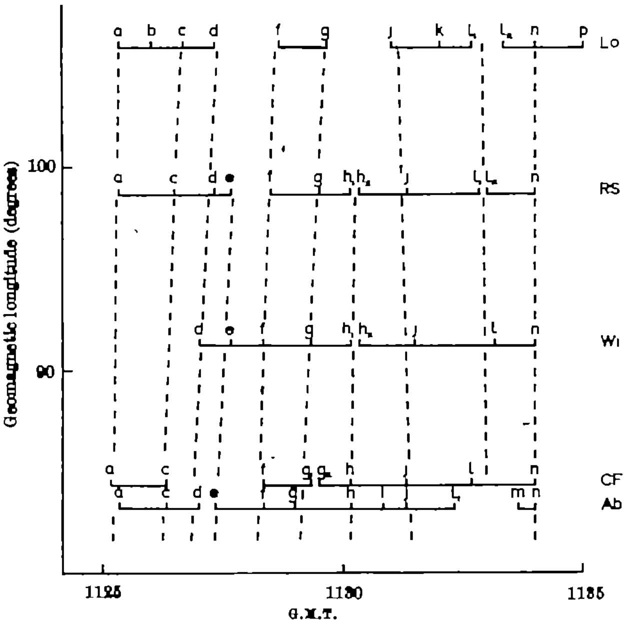

Fig. 2. Bounding times at various stations indicated by the letters *a*, *b*, . . . *o*, plotted against geomagnetic longitude. Dotted lines are best fitting straight lines through corresponding points

published by one of us (J. L.) elsewhere. It is clearly desirable to make more extensive analyses of a similar character, but if ordinary magnetograms are used the work involved would be very considerable. If a sufficient number of automatic observatories were established giving the field deviations in digital form[3], it would be possible to programme such an analysis for an automatic computer.

A New Mechanism for Convection in the Mantle and Continental Accretion

THE study of palæomagnetism has necessitated the contemplation of continental drift and the most plausible explanation appears to be convection in the mantle[1,2]. It has been assumed that the convection is thermal, being maintained by heat from the core. The purpose of this communication is to point out that there is another, quite natural cause for convective-type motion, which avoids certain difficulties encountered in the purely thermal explanation.

Ringwood[3] has summarized the evidence for the existence in solution in the core of 10–20 per cent silicon and pointed out that this metallic silicon would react with iron oxide in the bottom layers of the mantle. Further, there is seismic evidence[4] for a light layer approximately 200 km thick at the bottom of the mantle, and it is natural to interpret this as a product of iron–silicon exchange between the core and mantle. Metallic silicon from the core reduces iron oxide in the mantle, so that liquid iron falls into the core leaving silica in the bottom of the mantle.

It must therefore be supposed that any convective overturn of the mantle will bring material from the silica-rich layer to the surface, which accounts for the accretion of the continents. Since this material is substantially less dense than the bulk of the mantle the so-called convection is really a geological differentiation, with thermal gradients having only a secondary role.

The mantle must be presumed to yield slowly under a steady stress of 10^8–10^9 dynes/cm^2 (ref. 5); for the present purpose it is assumed that the necessary stress is 3×10^8 dynes/cm^2. A density difference of 6×10^{-4} g/cm^3 between up- and down-going convective columns with radii of 3,000 km would produce a stress of this magnitude. Such a density difference would result from a relative enrichment of the up-going columns with 0·2 per cent of the silica-rich, continental or granitic material, the density of which differs from that of the bulk of the mantle by about 0·3 g/cm^3.

The average rate of convective motion must be close to 1 cm/year, since this is the minimum consistent with palæomagnetic data and probably the maximum consistent with the geothermal flux[5]. It gives a rate of accumulation of continental material equivalent to the addition of a layer of thickness 4×10^{-3} cm/year to continents occupying a quarter of the Earth's surface. At this rate, continents of average thickness 30 km could accumulate in $0{\cdot}75 \times 10^9$ years little more than one-tenth of the age of the Earth. The explanation must depend on the 200 km reservoir of silica-rich material at the bottom of the mantle. Assuming that continental accretion equivalent to 4×10^{-3} cm/year is in equilibrium with the rate of production of silica at the bottom of the mantle, then, allowing for its compression, the 200 km layer would have taken about 10^{10} years to accumulate. However, the initial silicon–iron reaction through a thin layer of silica must have been more rapid, so that these figures are mutually consistent.

The proposed model for the history of the mantle is therefore a gradual accumulation of silica at the bottom of the mantle by reaction with the core, until a layer about 200 km thick was built up. When irregularities arising from minor convective motions accompanying the core–mantle interaction became sufficiently large to cause the instability of the layer as a whole to exceed the limit which the mantle would support, they initiated convective-type movements by which the silica layer was maintained at an average thickness of about 200 km and the surplus was carried to the surface to form continents.

It may be noted that in the foregoing model there is no need to maintain the conventional concept of convection with up-going and down-going currents of similar dimensions. Rather the motion might be expected to have relatively narrow silica-rich up-currents depositing the surplus silica and causing a general lowering of the rest of the mantle without recognizable down-currents. We must even allow the possibility of irregular, spontaneous overturn, involving rising 'blobs' of silica.

The convective instability of a 200 km layer of density lower than that of the material above it by as much as 0·3 gm/cm^3 is enormously greater than the instability which could result from any temperature gradient. Indeed, the presence of such a layer makes the thermal gradient of no consequence to the convection mechanism. It now becomes reasonable to suppose that convective-type motion can begin in the crystalline solid mantle, the creep law of which (on any time scale) cannot be that of a pseudo-Newtonian liquid[5], as it appears necessary to assume in the hypothesis of thermal convection[6].

[The settling into the core of any iron not already there will also contribute to the chemical differentiation of the mantle, but we cannot suppose, as Runcorn[7] has done, that the whole core has accumulated in this way over the past 3×10^9 years, because such a settling process would release an enormous amount of gravitational energy which would have to escape as geothermal flux. Neglecting any change in size of the Earth, this energy is about 6×10^{38} ergs, equivalent to about 30 μcal. cm^{-2} sec^{-1} for the whole Earth for 3×10^9 years, that is, nearly 30 times the present average geothermal flux. Lyttleton[8] pointed out that the greater compressibility of core material would lead to an overall contraction of the Earth during settling of the core and hence an even greater release of gravitational energy. It is therefore necessary to assume that the core was substantially complete at an early stage in the Earth's history and that its subsequent growth has been slight.]*

DR. STACEY's suggested mechanism is a specific one by which convective overturn can be brought about by the chemical separation which must occur if the Earth has been formed by accretion and the iron core has grown gradually in radius. It seems doubtful, however, to me that the rate of release of gravitational energy by chemical separation can be as great as that released by the decay of radioactive elements, although in any event it appears that the form of convection should not depend on the cause of the density differences which give rise to convective instability.

However, Dr. Stacey's mechanism of chemical segregation makes the specific proposal that there is a silicon-rich layer 200 km thick at the bottom of the mantle which is as much as 0·3 g/cm^3 less dense than the material above it. It can be shown that for any reasonable value of viscosity such a layer would be highly unstable. This can perhaps best be seen from calculations made by me[1] which show that for a viscosity as high as 10^{21} poise convection velocities of 1 m/sec are to be expected with a temperature difference between the up-going and down-going streams of as little as 1/3°, which of course means density differences between the up-going and down-going streams of one part in ten thousand.

Further, I think there is now evidence that there may be a thin layer of solid iron at the base of the mantle of variable thickness not exceeding about 10 km. It has long been known that the geomagnetic secular variation and the non-dipole field are systematically small over a large area of the Earth roughly co-extensive with the Pacific[2].

A convective mantle essentially means one with very nearly uniform physical properties and it is hard to suppose that the turbulence in the Earth's core which gives rise to the secular variation of the Earth's magnetic field can for long be systematically different in its properties below one area of the Earth, especially as the core is slowly rotating relative to the mantle. The cause has long been a puzzle to geomagneticians.

New interest in the problem has been raised by palæomagnetic observations on recent lavas from Hawaii by Doell and Cox[3], who find that the low secular variation in the Pacific seems to have been a property of the Earth over the past few tens of thousands of years. In a full account of this topic elsewhere, I am suggesting that the cause is electromagnetic screening by a layer of iron which has collected at the base of the mantle by separation from the descending convection currents, but which has not freed itself completely from lighter silicates and may, in fact, be similar to the Palliasite meteorites. As this is a thin layer it is reasonable to suppose that its distribution may be highly irregular, although any one distribution would be expected to persist for the order of a million years.

While this does not exclude the specific mechanism of chemical separation suggested by Dr. Stacey it seems more likely to me that it results from convection currents of a fairly regular kind existing throughout the whole of the mantle.

METEOROLOGY

Meteorological Conditions Dependence of Radon Concentration in the Air above the Atlantic Ocean

CONCENTRATION of radon in the air above the Atlantic Ocean at the *K* ('kilo') point was measured during May 28–June 28, 1962, and now we are attempting to relate the values of natural radioactivity to meteorological conditions.

In previous papers[1,2], an apparatus for measuring the natural radioactivity of the air was described. We have examined the meteorological conditions by referring to the daily weather information of the Meteorologie Nationale, and the local data obtained at the *K* point, especially the wind direction (front-crossings).

We have systematically examined the way followed by the air, at ground-level, getting the *K* point. We have also investigated whether the *K* point was concerned with cold descending air, although such a phenomenon is not very likely to happen in June, and, finally, we have connected the concentration of radon and of its descendants to the origin of the air masses, for the air reaching the *K* point. As a first approximation, taking into account the mean speed of movement of the air masses, it may be assumed that the air takes one day to move from Brittany and Ireland, and half-a-day from the Cantabric coast.

The following results were obtained:

(1) If the air comes from the north-west of France or from Great Britain, its radon concentration is always between 10 and 27 pc./m^3; the mean speed wind blowing from east to north-east which has brought this air during the observed period was generally weak ($\leqslant$10 m/sec), mostly when leaving the coast, but a stronger wind could give higher values. We noticed, during the morning of June 1, a decrease in radon activity, and we are inclined to impute this to a descending draught of descending cold air, poorer in radon.

(2) When the air comes from the north of Spain, its radon concentration is greater than 27 pc./m^3. The maximum activity obtained was 40 pc./m^3. The arrival of this air at the *K* point is always conditioned by an isobaric constriction prevailing for 12 h at least above the north-western side of the Iberian Peninsula, and on the neighbouring oceanic zone. This constriction is bound sometimes to a centre of depression located above western Spain or Portugal. If, in this centre, the minimum pressure comes down enough (1,005 millibars) the air supply feeding the *K* point will be deviated towards the south before it reaches that point. Such a phenomenon occurred, for example, on June 27.

(3) During the recording time, there was no crossing of warm fronts, but there were four crossings of cold fronts with one quasi-stationary front: we observed in three of these five cases that maximum radioactivity was always very low ($<$ 6 pc./m^3) when the front was running. Then, the cold air located behind the front comes from the northern to the north-western direction, but it seems risky to take into account its previous behaviour. As we noticed before, there was only one cold front subsidence, and the

supply of air from the Continent for the *K* point was disturbed at its origin, along the seashore, by a slight north-western flow. Thus, so far as this is concerned, we are not able to draw any conclusions.

PHYSICS

Electrical Breakdown in High-temperature Gases

Relatively few experimental results are available for the breakdown of high-temperature gases at atmospheric pressure and above. Alston[1] has confirmed Paschen's law for air up to 1,100° C and obtained flashover voltages which were independent of electrode material. On the other hand, it is well known from investigations of the decaying properties of freely recovering arcs[2] that 'thermal' breakdown can occur at considerably reduced voltages while the charge concentration remains high and the electrodes retain their heat. Similar low voltages of breakdown have been observed in shock tube investigations[3]. Forman[4] has recently described experiments with rare gases up to 300 mm pressure and for refractory cathodes at temperatures up to 3,000° K. The cathode was a filament of 0·01-in. diameter and the concentric anode had a diameter of 1 cm. Breakdown occurred at anode voltages considerably lower than the ionization potential of the gas for argon and xenon and cathode temperatures greater than 2,400° K, but was not observed for helium. Although the gas in the immediate vicinity of the cathode was assumed to be in thermal equilibrium at the cathode temperature, the bulk of the gas and certainly the anode were considerably cooler.

The experiments recorded here were carried out in high-temperature (1,500–2,500° K) argon and helium between concentric graphite electrodes with an arrangement leading to a more uniform temperature distribution. In this case the outer $\frac{1}{2}$-in. diameter electrode was made the heating element and the inner $\frac{1}{4}$-in. diameter electrode is heated by radiation, conduction and convection in the gas. Measurements with an optical pyrometer through a small hole in the outer electrode indicated a temperature difference between the electrodes of not greater than 25° C at 2,500° K. Results were obtained both with d.c. voltages between the electrodes and also with 400-c/s a.c. voltages to permit display of the current/voltage characteristics on an oscilloscope. The latter frequency was chosen so that a complete characteristic could be displayed over a time during which the 50-c/s a.c. heating current in the outer tube is relatively small, thus reducing any effect of the electrical field of the heating element. Fig. 1 shows typical current/voltage characteristics for argon at 2,200° K and 1,200 mm pressure (with the right-hand side representing the outer electrode as cathode) and for two different values of circuit resistance. Four regions are in evidence:

(1) For low applied voltages where an excess of electrons is available at the cathode, the characteristic rises approximately linearly. An effective 'conductivity' for the gas can be measured in this region, by enlarging this region of the trace.

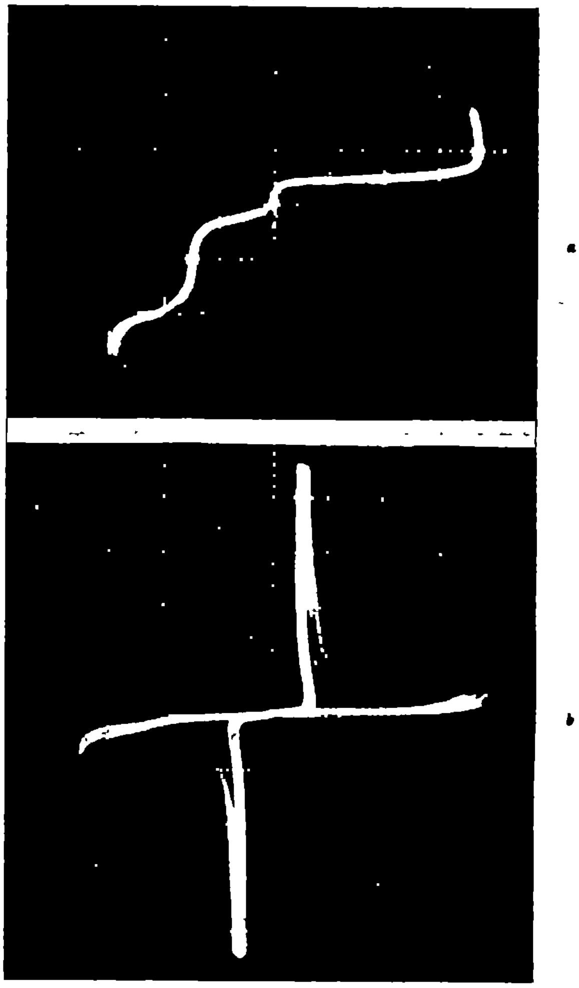

Fig. 1. Current/voltage characteristic for argon at 2,200° K and 1,200 mm pressure. Vertical axis is current and horizontal axis voltage. *a*, Series resistance, 700 Ω; voltage scale, 50 V per division current scale, 50 m.amp per division *b*, Series resistance, 80 Ω, voltage scale, 50 V per division; current scale, 0 5 amp per division

(2) At intermediate voltage, a constant current is obtained corresponding to the saturated thermionic emission current of the cathode. No more electrons are available and a voltage gradient is built up at the cathode as the applied voltage increases.

(3) At a particular voltage, characteristic of the temperature, a very rapid increase in current occurs for no further increase in applied voltage. The maximum current reached is restricted by the circuit resistance, but if permitted to rise to a high enough value (also characteristic of the temperature) will result in a transition to a fourth region.

(4) This region (Fig. 1*b*) is the normal current/voltage characteristic of the arc for this geometry and has been confirmed with 'cold' tests. Once established, the discharge remains in this mode until the voltage reduces to zero.

Hysteresis effects are in evidence if the transition (4) is prevented, but these have been darkened out in Fig. 1*a* for clarity. Also it is seen that the lower saturation current for the inner electrode as cathode (corresponding to the smaller surface area) is followed by a transition to region (3) at a much lower voltage than for the outer electrode as cathode. A further saturation of current occurs before the final breakdown voltage is reached. Not all these regions are observed throughout the temperature-range 1,500° K–2,500° K; but in general the effect of increasing temperature is: (*a*) an increase in the effective 'conductivity' in region (1); (*b*) a higher saturation emission

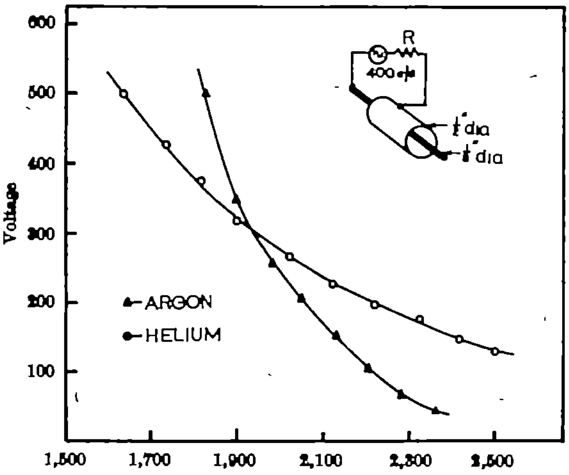

Fig. 2. Transition (or breakdown) voltage as a function of temperature for outer electrode as cathode

current in region (2); (c) a steady reduction in the transition voltage (3), but an increase in the maximum stable current at that voltage; (d) a transition to the same arc characteristic irrespective of initial electrode temperature.

In Fig. 2 the transition (or breakdown) voltage is shown as a function of temperature for both argon and helium. Similar forms of breakdown have been obtained with commercial and reactor-grade graphites and recently with a tantalum outer electrode and tungsten inner electrode.

Smooth transitions from glow discharges into arcs have previously been observed for refractory cathodes both at low pressures[5] and more recently at atmospheric pressures[6]. In such experiments the only source of heat is the discharge current itself, and the transition is associated with a steady increase in the thermionic component of current as the cathode temperature rises. In our experiments the thermionic component of current is established prior to breakdown occurring and is an independent variable.

Representation of a Group in Relativistic Quantum Mechanics

ESSENTIALLY all infinite unitary representations of semi-simple Lie groups are known[1], they are of Murray–von Neumann[2] type I. Further, while it has been known for a long time that non-relativistic quantum mechanics is such a representation for the rotation group of space[3], the same does not carry over to relativistic quantum mechanics. Infinite representations of the Lorentz group[4] do not correspond to anything physically identifiable. This, among other things, suggests that the underlying group of relativistic quantum theory is not the Lorentz group but rather one for which non-unitary representations have a special significance.

Previously[5] a physical argument was given for the exceptional Lie group F_4 as candidate for the above. This turned on the interpretation of the wave equation as not being (Hermitian) self-adjoint, thus implying the existence of a non-unitary representation. An attempt[6] was made to give a path integral form to the latter, in which paths oppositely oriented in 'time' belonged to different measure spaces A, Ω say. It was conjectured that the uniqueness of A, Ω depends on a special relation which exists between the co-homology structure of F_4 and certain algebraic number fields. Here I give some preliminary details to substantiate this idea.

The structure of a semi-simple Lie group G of rank L and dimension R is determined[7] by its so-called Weyl group $W(G)$, which is a group generated by reflexions $S_1 \ldots . S_L$ and is at the same time irreducible and 'crystallographic' (in L dimensions). The period h of $W(G)$, given by $S_0^h = (S_1 \ldots . S_L)^h = 1$, is $(R - L)/L$ and the co-homology structure of G is determined by the 'form problem' for $W(G)$ which was shown by Coxeter[8] to be equivalent to finding the characteristic roots of S_0 as g_i/h^{th} roots of unity. For $W(F_4)$, $h = 12$ and $g_i = 1, 5, 7, 11$ and the latter, less $g_0 = 1$, are the same (in the representation given by Klein) as for the octahedral group $G_{24} \sim W(C_3)$, which explains the appearance of these numbers in the many results of algebraic field theory which depend on elliptic functions.

The invariant forms $F_i(z)$ of degrees $(g_i + 1)$ for G_{24} were given by Klein[9], who observed that the parametrizations $(z_1, z_2) = \theta_{10}(\tau,0), \theta_{00}(\tau,0)$ in terms of Jacobian elliptic functions gives an infinite representation of G_{24}, for $p = 4$, under the action of the factor group Γ_∞/Γ_p, where Γ_p is the modular congruence group, $T\tau = -1/\tau$ and:

$$S_p = \frac{a\tau + b}{c\tau + d}$$

$$\left.\begin{matrix} a, d \equiv 1 \\ b, c \equiv 0 \end{matrix}\right\} \text{mod. } p, |S| = 1$$

However, one notes that G_{24} is contained in Γ_p for all primes $p \equiv \pm 1$ (mod. 8) and therefore the possibility exists of constructing a measure in the closure of all such p The details require considerably more; namely, first, for $p_i \equiv \pm 1$ (mod. 24) the least primitive roots a_i have maximum density for just the values g_i; secondly, if $\tau = \omega_1/\omega_2$ is restricted to the quadratic number field $K(\sqrt{g_i})$ then we have complex multiplication[10] by $\gamma_1 = \sqrt{g_i}$ for elliptic functions, the effect of which is to change the normalization $|S| = 1$, to $|S_\gamma| = g$. Then the operations $S_g = S_\gamma S_p S_\gamma^{-1}$ form the so-called transformation group which leaves invariant a modular form of degree $g + 1$.

It was shown by Hasse[11] that something like the converse of the foregoing is possible. The field $K(\theta, p)$ of elliptic functions mod. p admits a non-commutative (quaternion) multiplication ring depending on the residue class $p_i \equiv g_i$ (mod. 12). It thus appears that there does exist a quasidual approach for the construction of the measure spaces A, Ω.

The underlying phenomenon here is the following. First, the elementary fact[12] that 24 is the highest resolution modulus (erklärungsmodul) with all real characters, which therefore can be represented by a quadratic residue character. Secondly, the fact noted here about the least primitive roots, which has to be completed by $a_j = 2, 3$ for $p_j \equiv \pm g_j$ (mod. 24). Consequently the fields $K(e^{2\pi i/24})$ and $K(\sqrt{g_i})$ 'contain each other' in the approximate sense of ignoring those primes p_j for which $a_j > 11$.

Lastly, the group $W(F_4)$ leaves invariant a 24-cell in 4-space or, with an involution, a system of 3 desmic tetrahedra[13] in 3-space. It therefore involves two independent representations of G_{24} which, if associated with A, Ω, must include an operation interchanging them. As pointed out previously[6], this should introduce a very large number N into a theory with physical interpretation. A rough guess is $N = \exp 2\pi(\sqrt{D} - \sqrt{D'})$, where $D = 5.7.11$ and $D' = 24$ (so that $N \approx 10^{44}$) since this is the factor that might be expected to appear in the functional equation for elliptic functions over these fields.

ENGINEERING

An Elastohydrodynamic Lubrication Experiment

THE thickness and shape of the lubricant film between highly loaded rollers is the feature of elasto-hydrodynamic lubrication which has received most attention in recent years. The efficacy of hydrodynamic lubrication in such contacts is directly related to the thickness of the lubricant film compared with the surface irregularities on the solids, and the recent activity reflects the significance of this quantity to the designer of machine components.

Another aspect of elasto-hydrodynamic lubrication which is of interest to the designer is the stress field within the solids. In this respect the distribution of pressure within the lubricant is of paramount importance, and it is the purpose of this communication to report a preliminary investigation of the pressure and temperature distributions in a highly loaded sliding contact.

One of the difficulties associated with the measurement of pressure and temperature profiles in contacts representative of gear teeth is the very small width of the contact zone in relation to the size of conventional sensing elements. Higginson[1] overcame this difficulty by using a low modulus elastic solid for the stationary component in a sliding contact. In order to examine the pressure and temperature distributions in a highly loaded metal contact a novel disk machine has been constructed which opens out the contact zone and yet retains the essential features of elastohydrodynamic conditions. A stationary phosphor bronze shoe having a 6·5-in. concave radius is loaded against the periphery of a rotating phosphor bronze disk of 6-in. radius in the manner of a brake shoe as shown in Fig. 1. A mineral oil supplied to the disk surface ensures the existence of a coherent oil film between the shoe and the disk. The shoe is provided with a small central oil pressure tapping and four thermocouples buried at various depths below the working surface. The pressure tapping hole communicates with a cylindrical, wire wound pressure transducer. The position of the shoe is varied circumferentially with respect to the line of action of the applied load, thus traversing the pressure tapping and thermocouples through the pressure zone.

Results have been obtained for various speeds and loads. A typical pressure traverse is shown in Fig. 2 for a load of 1·35 tons per in. of face width and a disk peripheral speed of 64 in./sec. Also shown in Fig. 2 are contours of rise in temperature above ambient for the bulk metal of the shoe. The lower curves show the distribution of shoe surface temperature and the lubricant viscosity related to the local pressure and the shoe surface temperature.

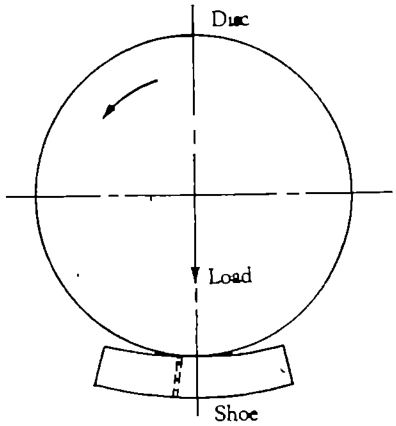

Fig. 1. Disk machine

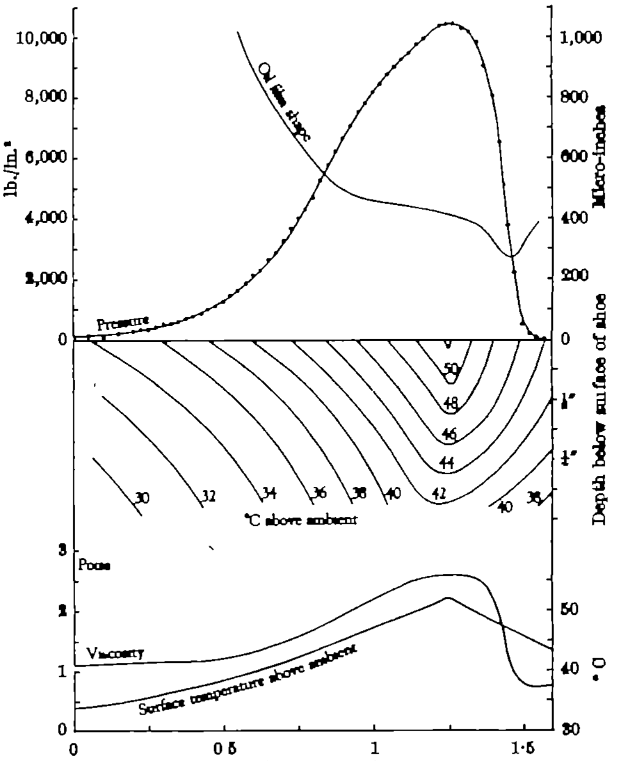

Fig. 2. Pressure and temperature profiles

The shape of the pressure curve is consistent with the predictions of elasto-hydrodynamic theory[2], the most notable feature being the very steep pressure gradient at the outlet end of the zone. If side leakage is neglected, the shape of the oil film corresponding to the measured pressure distribution can be determined according to a method described in ref. 2. The shape of the oil film shown in Fig. 2 exhibits the well-known characteristics of elastohydrodynamic films. The similarity between this shape and the picture presented by Crook[3] based on a direct measurement is striking. This result demonstrates that the local restriction in film thickness at the outlet end of the zone does not necessarily imply the existence of the pressure spike exhibited by some theoretical solutions. It should be recalled that theoretical solutions demonstrate the dependence of the pressure spike on material properties[4]. An interesting feature of the surface temperature profile is that the maximum temperature is attained before the end of the pressure zone is reached; a result attributable to the rise in lubricant viscosity in the vicinity of the peak pressure.

METALLURGY

G Phases containing Scandium

We have noted the occurrence of a *G* phase (structure type *D8a*) in the Sc-Ni-Si, Sc-Co-Si and Sc-Ni-Ge systems. Alloys were made by arc melting in a water-cooled copper crucible under argon. Diffraction patterns were taken with copper radiation on powder annealed at 900° under vacuum. The composition and lattice parameters of the newly found *G* phases are given in Table 1.

Table 1. LATTICE PARAMETERS OF *G* PHASES

Composition	a_0 (Å)
$Sc_6Ni_{16}Si_7$	11·429
$Sc_6Co_{16}Si_7$	11·438
$Sc_6Ni_{16}Ge_7$	11·663

We failed to detect a *G* phase in the following alloys: $U_6N_{16}Si_7$, $Y_6Ni_{16}Si_7$ and $Th_6Ni_{16}Si_7$, but we confirm the existence of a *G* phase in $Nb_6Ni_{16}Si_7$ (ref. 1).

Gladyshevskii *et al.*[1] have reported data for *G* phases of the generalized formula $A_6Ni_{16}Si_7$ in which *A* may be Ti, Zr, Hf, V, Nb, Ta, Cr (with 1 *a*/0 Ta) or Mn. Our data extend this list to include Sc but not Y. It is noted that the *A* element may come from groups IIIb to VIIb of the Periodic Table, but is restricted to atoms having small to intermediate size, that is, Mn to Sc.

This work was performed at the Argonne National Laboratory under the auspices of the U.S. Atomic Energy Commission.

Aluminium Nitride Whiskers

In the course of an investigation into the stability of certain nitrides, whisker growth has been observed on aluminium nitride. Aluminium nitride powder was prepared from the elements, cold pressed at 15 tons/in.² and sintered for 4 h at 1,750° C in high purity argon. The sintered compacts measured approximately 8 mm in diameter by 4 mm high. X-ray powder photographs of filings of the sintered nitride showed the structure to be hexagonal, close-packed (a near-wurtzite structure according to Jefferey and Parry[1]) with $a = 3{\cdot}11$ Å and $c = 4{\cdot}98$ Å. The sintered density was 68 per cent of theoretical and the Vickers micro-hardness 1,010 ± 15 kg mm^{-2}.

A stack of three compacts was mounted under a bell jar in an arc image furnace[2] and the uppermost one heated, in an atmosphere of high-purity nitrogen. The initial nitrogen pressure was 745 mm and the pressure at the end of the heating period was 750 mm. The following sequence of events was observed on the heated surface as the temperature was increased: (*a*) short 'woolly' filaments formed; (*b*) longer filaments grew normal to the surface; (*c*) nodes formed on these filaments and growth continued; (*d*) 'fir-tree' growth occurred from these nodes. This latter growth appeared to act as centres of sublimation and the needles decreased in height. There was no sign of melting. Stage (*d*) was accompanied by the formation of a thin film (presumably aluminium nitride) on the inside of the bell jar.

When heating was stopped after stage (*b*) it was found that the needles were hexagonal prisms about 1,600μ long by 20μ thick and almost transparent. They could be bent through an angle of about 15° before fracture occurred.

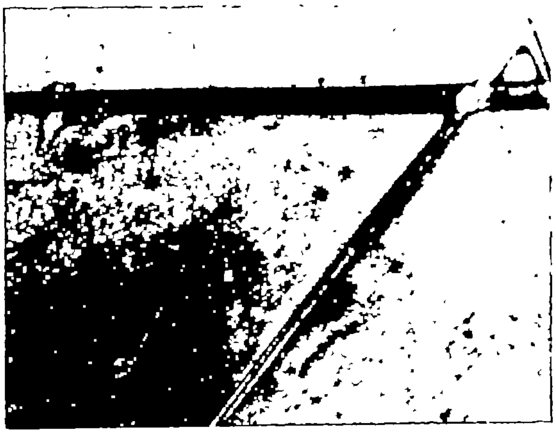

Fig. 1. Aluminium nitride needles, reflected light. (× c. 375)

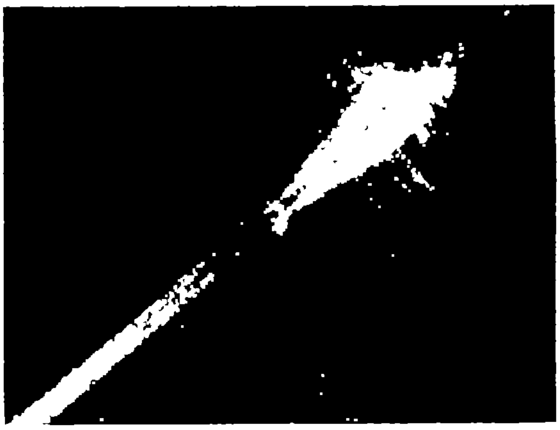

Fig. 2. Sublimation stage ('fir-tree' growth) during heating of aluminium nitride whiskers; transmitted light. (× c. 560)

Specimens examined after stage (*c*) showed well-defined nodes (Fig. 1.) separating transparent hexagonal prismatic crystals. The fir-tree growth (stage (*d*)) is shown in Fig. 2.

CHEMISTRY

Oxidation of Plutonium in Moist Air and Argon

The only published works on the oxidation of plutonium are by Waber[1], Poole[2] and Sackman[3]. Waber and Sackman's work was carried out only in air at temperatures < 100° C, whereas Poole's work was at 320°–480° C in air. In order to understand the mechanism of oxidation, we have found it necessary to compare the oxidation-rate of plutonium in air and in argon under both dry and humid conditions at a temperature sufficiently low that changes in oxidation behaviour are readily detected. Results presented here indicate that oxidation is anodically controlled.

Abraded specimens of plutonium (both cast disks and rolled sheet) were oxidized for 1,800 h in air and in argon at room temperature and 95 per cent relative humidity. Despite some irreproducibility of results caused by varia-

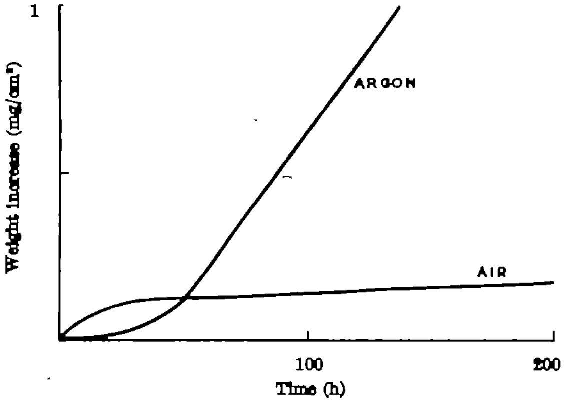

Fig. 1. Uptake of oxygen by plutonium in moist air and in moist argon at 25° C

tions in microstructure and purity of different casts, oxidation proceeds many times faster in moist argon than in moist air and extremely slowly under dry conditions (Table 1). This suggests that oxidation proceeds primarily by reaction with moisture and is under anodic control. The only other example of a metal oxidizing in this way is uranium[4]. At this temperature, oxidation of plutonium is paralinear after the initial deviations from linearity caused by the protective oxide film on the metal in air (Fig. 1). This protective oxide film continues to be built up to its maximum thickness in moist air; thereafter, the oxidation-rate is reduced as the oxygen seals the oxide surface, thus reducing the anodic surface area and the rate of reaction with moisture. In moist argon, the protective film takes some time to be broken down; thereafter, oxidation proceeds quickly because there is no oxygen to inhibit the reaction with moisture.

Electrochemical Generation and Visible Spectrum of Nitrobenzene Free Radical Anion in Dimethylformamide

POLAROGRAPHIC behaviour and electrolytic reduction of nitrobenzene in a solution of 0·2 N sodium nitrate in dimethylformamide show that free radical anions of nitrobenzene are formed[1,2]. In this solution nitrobenzene is reduced in two polarographic waves, the first of which corresponds to the formation of the free radical anion $C_6H_5{-}NO_2^-$. These anions can be generated, in a special electrolytic vessel containing the solution, by electrolysis at a mercury pool cathode at a potential corresponding to the diffusion current of the first polarographic wave of nitrobenzene in dimethylformamide. The nitrobenzene anions generated were relatively stable in the absence of oxygen and were of a yellow-brown colour in solution. The anions formed gave a polarographic oxidation current (Fig. 1) corresponding to the formation of nitrobenzene: $C_6H_5{-}NO_2^- - e \rightarrow C_6H_5{-}NO_2$.

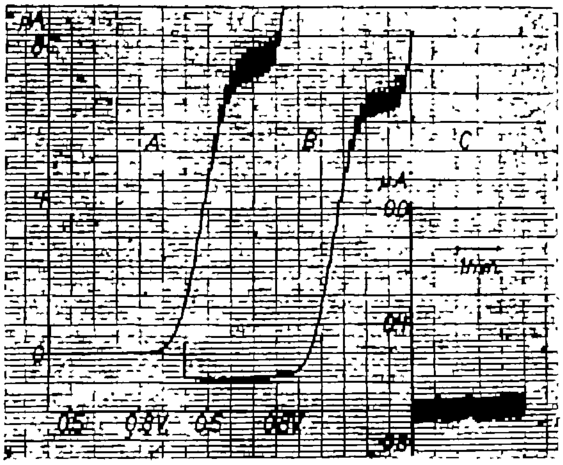

Fig. 1. Polarograms of solution of 2·7 × 10⁻⁴ M nitrobenzene in 0·2 N sodium nitrate in dimethylformamide. *A*, first one-electron wave before electrolysis; *B*, the same after electrolysis; *C*, registration in time of anodic current at potential –0·65 V (for standard calomel electrode) of nitrobenzene free radical anion. Height of anodic current corresponds to about 2·5 × 10⁻⁴ M concentration of nitrobenzene anions

On the assumption of the equality of diffusion coefficients of nitrobenzene and its free radical anion, it was possible to determine from the height of the anodic oxidation curve the concentration of these anions in solution[2].

In the present communication we are concerned with the visible spectrum of the free radical anion of nitrobenzene formed in the solution.

Weissman *et al.*[3] and Hoijtink *et al.*[4] investigated the optical spectra of negative ions produced by the action of alkali metals on aromatic hydrocarbons in aprotic solvents. Pointeau and Mme. Favede[5] investigated spectra of free radical anions of aromatic hydrocarbons after their generation by electrolysis in dimethylformamide. The latter workers, however, did not give in their method the concentrations of generated free radical anions and hence the extinction coefficients.

We performed our experiments using a special cylindrical, electrolytic cell made of quartz. Electrolysis was carried out with 2·5 × 10⁻³ M solution of nitrobenzene in 0·2 N $NaNO_3$ in dimethylformamide at a mercury pool cathode against a standard calomel electrode at a potential corresponding to the first polarographic reduction wave of nitrobenzene. The solution was mixed during electrolysis by passing through a stream of hydrogen which had been very carefully purified to exclude oxygen and water. After the electrolysis mixing was continued for a few minutes in order to achieve a uniform concentration of the anions formed. A stream of hydrogen was passed above the solution to prevent the entry into the cell of small amounts of air through the joints. Spectrophotometric measurements were made with a single-beam Optica-Milano '*CF-4*' spectrophotometer. Simultaneously, the spectrophotometric measurements of extinction and the polarographic anodic oxidation current (Fig. 1c) of the nitrobenzene anions present in solution at potential –0·65 V for the standard calomel electrode were recorded. From the height of this oxidation current it was possible to determine the actual concentration of the nitrobenzene free

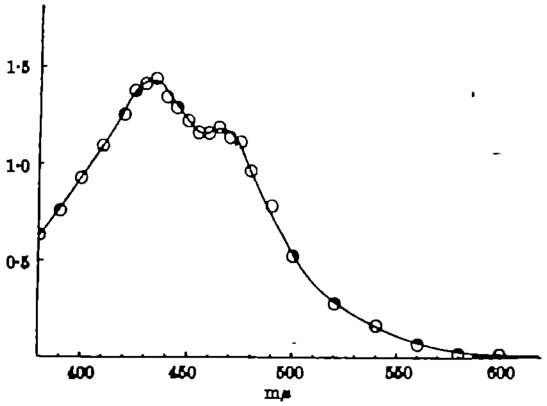

Fig. 2. Visible spectrum of nitrobenzene free radical anion in solution of 0·2 N sodium nitrate in dimethylformamide. Spectrum was made for concentrations of the free radical anion of about $1·3 \times 10^{-4}$ M and for a cell length of 35 mm

radical anion. By combining this with measurements of extinction for different wave-lengths caused by the presence of the free radical anion, the extinction coefficients of the whole spectrum were calculated.

The visible spectrum of nitrobenzene free radical anion exhibits two distinct maxima: the first is at 435 mμ region and the second at 465 mμ (Fig. 2).

The method applied by us for simultaneous measurements of the optical properties and oxidation current of the nitrobenzene free radical anion can be used for determining the extinction coefficients and spectra of different free radical anions which are stable, or which only slowly decay with time. This method also enables the measurement of the kinetics of the decay of radical anions to be made.

Electron-donating Properties of Central Sympathetic Suppressants

ELECTRON-TRANSFER reactions between organic substances have often been implicated in various biological processes[1-3]. Recently, Karreman, Isenberg and Szent-Györgi[4] have suggested that certain central sympathetic suppressants act by donating electrons on the inside of the electric double layer of the central nervous system. A consequence of this hypothesis would be that pharmacologically active substances should possess relatively low ionization potentials.

Although it has been inferred both from molecular orbital calculations[4-6] and charge-transfer spectra[7] that these substances should be good donors, as yet there have been no reports of ionization potentials of suppressants. Though the direct measurement of ionization potential is quite difficult, it is nevertheless possible to derive values of this quantity from photoelectric measurements on the solid.

The photoelectric threshold, I_C, of a molecular crystal has been shown[8] to be related simply to the molecular ionization potential, I_G, by:

$$I_C = I_G + P \qquad (1)$$

where P is the polarization energy of the crystal. P can be calculated for crystals of known structure.

We have measured I_C for several central sympathetic suppressants and threshold energies are given in Table 1.

Table 1. I_C AND I_G FOR SOME PHARMACOLOGICALLY ACTIVE SUBSTANCES

	I_C (eV)	I_G (eV)
Phenothiazine*	5·14 ± 0·05	6·7
Promazine	5·16 ± 0·05	6·8
Promazine hydrochloride	5·46 ± 0·05	7·1
Chlorpromazine	5·06 ± 0·05	6·7
Chlorpromazine hydrochloride	5·22 ± 0·05	6·8
Trifluoperazine dihydrochloride	5·68 ± 0·10	7·3
Prochlorperazine	5·45 ± 0·10†	7·1
Reserpine	5·40 ± 0·05	7·0

* Inactive pharmacologically.
† As viscous oil.

I_G is estimated from equation (1) by assuming an average value for P of 1·6 eV (ref. 8). We expect the error in P to be no greater than 0·3 eV.

The measurements indicate that these substances have striking electron-donating properties. Chlorpromazine is an even better donor than the readily oxidizable naphthacene for which I_C = 5·25 eV (ref. 9) and I_G = 6·88 eV (ref. 10). Low values of I_C for phenothiazine derivatives are seen to be associated with the parent nucleus.

Though it is appreciated that alternative mechanisms of suppression of the central nervous functions are feasible, the present work is consistent with the electron-transfer theory. It must be emphasized, however, that the possession of a low ionization potential does not in itself render a substance pharmacologically active. Phenothiazine, for example, is not a central sympathetic suppressant.

Since such biochemically important molecules as the chlorophylls and β-carotene also have low values of I_C (ref. 11) it is still possible to maintain that electron-transfer reactions may be of importance in many biological processes.

We thank Prof. S. E. Wright, Mrs. R. Temple and Dr. W. J. O'Reilly for useful discussions.

Photoconductivity of Manganous Phthalocyanine

WE have investigated the dark- and photo-conductivity of single crystals of metal-free and some transition metal phthalocyanines. Some of our results for metal-free, zinc, copper, nickel and cobalt phthalocyanines have been published elsewhere[1]. Meanwhile we have extended our investigations to include ferrous and manganous phthalocyanines. Here we wish to report briefly that we have found manganous phthalocyanine to differ in its behaviour from the other members of the series in a striking manner. The measurements were made on the needle-shaped crystals using two electrodes. No guard ring was used, and the arrangement is therefore equivalent to a surface conductivity cell.

First, we find the dark resistivity of the manganous compound is much lower than that of the other phthalocyanines. The dark resistivities are presented in Table 1, from which it can be seen that while manganous phthalocyanine has a specific resistivity as low as 10^6 ohms/c.c.,

Table 1

Phthalocyanine	Specific resistance (ohm/c.c.)
Metal-free	c. $10^{[illegible]}$
Manganous	4×10^4
Ferrous	4×10^9
Cobalt	9×10^9
Nickel	6×10^{10}
Copper	2×10^{11}
Zinc	3×10^9

the other members of the series have specific resistivities lying between 10^9 and 10^{13} ohms/c.c.

Secondly, while the photoconductive action spectra of compounds other than manganous phthalocyanine were generally similar, having two or more peaks in the region 5000 Å–8500 Å, and another, usually weaker, peak in the region 10000 Å–12000 Å, manganous phthalocyanine showed its spectral response over the range 7000 Å–20000 Å (the limit of our monochromator) with broad maxima at 13500 Å and 16000 Å. The photocurrent in the infra-red was stronger in this compound than in any of the others.

Thirdly, the photocurrent is depressed in a remarkable way by gases. We have used dry electrolytic oxygen, dry oxygen-free nitrogen and water-vapour, and find all three, but particularly water-vapour, to have a marked effect on the photocurrent. A pressure of 1 cm mercury of any of these gases was sufficient to depress the photocurrent to the value in air, which is less by a factor of forty than its value at 10^{-5} mm mercury. The effect of evacuation or the introduction of gases was, as far as could be measured, instantaneous, and was repeatable, apparently indefinitely.

We could find no evidence of absorption bands corresponding to the spectral response of manganous phthalocyanine in its diffuse reflexion spectrum. However, a series of three peaks was found in the solution spectrum in *o*-dichlorobenzene, at 8500 Å, 10900 Å, and 13500 Å, the last being the most intense and corresponding to one of the maxima of the action spectrum. The extinction coefficients of these absorption bands are less by a factor of at least one hundred than the extinction coefficient in the very intense first singlet absorption band of the phthalocyanines. We are, as yet, unable to assign these bands definitely; but one possibility is that they are due to triplet transitions. Low optical absorption can give inordinately large photocurrents if they lead to an efficient photoconductive mechanism.

Differential Isotope Effects in the *Ortho*- and *Para*-Bromination of Dimethylaniline

AN account of the kinetic isotope effect observed in the bromination of dimethylaniline in aqueous acid containing added bromide ions has been given previously[1]. We now report that the observed isotope effect varies with the bromide ion concentration, but not with the acid nor with the amine concentration. The relative rates of bromination of dimethylaniline and its 2,4,6-trideutero derivative (0·005–0·0125 M) in sulphuric acid (6·4 M), measured by Bell and Ramsden's method[2], are:

$[Br^-]$ (M)	0·0125	0·025	0·050	0·100	0·250
k_H/k_D	1·9	$1{\cdot}7_5$	1·5	1·3	1·1

Under comparable conditions, similar isotope effects are found for 2,6-dideuterodimethylaniline, whereas 3- and 4-deuterodimethylaniline give no isotope effect at any bromide concentration in the foregoing range. These results, together with the observation[3] that the *ortho*/*para* ratio for the bromination of dimethylaniline in aqueous acid is 2·3 and 0·15 at bromide concentrations of 0·025 and 0·5 M respectively, indicate that the isotope effect is 2·6 for the *ortho*-bromination and unity for the *para*-bromination of dimethylaniline under the conditions described.

The isotope effects obtained imply either that the *ortho*- and the *para*-substitutions proceed by different mechanisms, the rate-determining step involving the fission or the lengthening of the *C–H* bond in the *ortho*-, but not in the *para*-bromination, or that steric effects supervene in the *ortho*-deutero compounds, owing to the smaller amplitudes of *C–D* vibrations compared with the corresponding *C–H* vibrations. The red complexes formed by dimethylaniline and bromine, with molar ratios of 1 : 1 and 1 : 2, may be intermediates in the reaction, since the colour of aqueous bromine deepens on the addition of dimethylaniline, giving a band with an absorption maximum at 4650 Å. *Ortho*-deuterium atoms may stabilize such complexes by allowing fuller conjugation between the dimethylamino group and the benzene ring, resulting in a slower subsequent reaction between the complex and additional bromine. Using an arsenite titration method, which avoids the uncertainties connected with the particular electrode processes involved in the potentiometric method[3], the reaction order is found to be 1·3 in titratable bromine, suggesting that the transition state of the reaction contains more than one molecule of bromine with each dimethylaniline molecule.

BIOCHEMISTRY

Chromatography of Infective Ribonucleic Acid from Foot-and-mouth Disease Virus on Calcium Phosphate

ALTHOUGH it is fairly generally accepted that the molecular weight of the infective unit of several ribonucleic acid-containing plant and animal viruses is approximately 2×10^6, there is still some objection to this conclusion. For example, Fraenkel-Conrat and his colleagues[1] consider that the infective ribonucleic acid of tobacco mosaic virus may be an aggregate of smaller polynucleotide sub-units. Furthermore, Vizoso and Burness[2], using the technique of chromatography on calcium phosphate, have shown that the infective material obtained by phenol extraction of Krebs-2 ascites tumour cells infected with mouse encephalomyocarditis virus is eluted at phosphate molarities ranging from 0·01 to 0·21 M. As this method separates ribonucleic acids according to their molecular weights, the smaller molecules being eluted first[3], it appears that the infectivity is associated with components of several molecular sizes, some with molecular weights considerably smaller than 10^6. This finding is of considerable importance. It seemed of interest, therefore, to apply the same method to the examination of the ribonucleic acid of another virus. Consequently, the chromatographic behaviour of the infective ribonucleic acid obtained by phenol extraction of both pig kidney tissue culture cells and the vesicular fluid from guinea pigs infected with the virus of foot-and-mouth disease has been investigated. Two strains of the virus have been used for the preparation of the infective ribonucleic acid: (*a*) strain 1 (type *O*) from the fluid from vesicular lesions of guinea pigs infected with the virus, and (*b*) strain 997 (type *C*) passaged more than

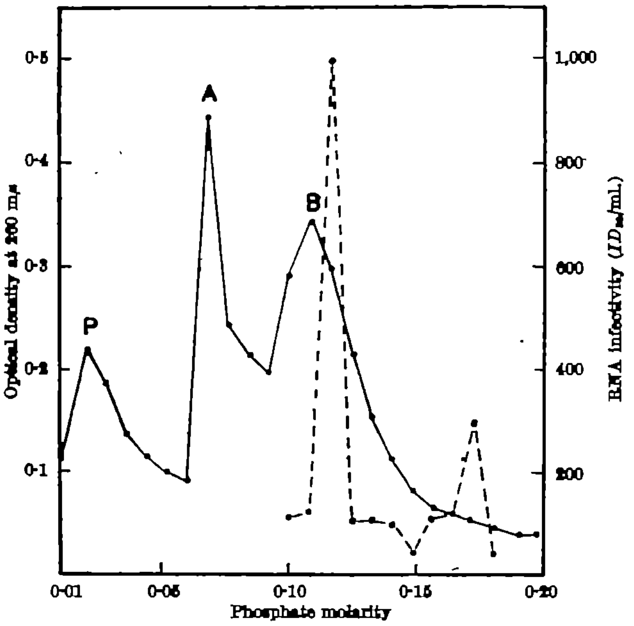

Fig. 1. Chromatography of ribonucleic acid from virus-infected pig kidney cells on calcium phosphate. Optical density at 260 mμ is shown by the unbroken line and the infectivity of the ribonucleic acid by the broken line. Peak *P* is due to residual phenol in the preparation

100 times in pig kidney cell monolayer cultures. Suspensions of each virus strain were extracted with phenol at 2° C in the usual manner and the infective extracts introduced on to 5 × 1 cm calcium phosphate columns (prepared according to the method described by Main and Cole[4]) in equilibrium with 0·01 M phosphate buffer, *p*H 7·2. Gradient elution at 0° C was achieved by adding 0·5 M phosphate to a reservoir containing 0·01 M phosphate. Fractions (5 ml.) were collected and titrated in mice (for strain 1) or pig kidney cell monolayers (for strain 997). In each case the viral ribonucleic acid was mixed with cell ribonucleic acid (prepared by phenol extraction of uninfected pig kidney tissue culture cells) before addition to the column so that the behaviour of the viral and cell ribonucleic acids on the same column could be determined. Ribonucleic acid was estimated in each fraction by the orcinol method or by measuring the ultra-violet absorption at 260 mμ.

A typical elution diagram is shown in Fig. 1. This shows that the two main peaks (*A* and *B*) of ribonucleic acid from pig kidney cells were eluted at the same molarities as the ribonucleic acids from Krebs-2 ascites tumour cells[2]. Recovery of both chemical and infective ribonucleic acid was almost quantitative. Infectivity could not be detected in the first ribonucleic acid peak (*A*) eluted from the column but was found mainly in conjunction with the second peak (*B*). The peak of infectivity did not coincide, however, with the peak of the cellular ribonucleic acid but was eluted at a slightly higher molarity. In addition to the main peak of infectivity a smaller peak was eluted with 0·17 M phosphate (Fig. 1). This second peak represented about 20 per cent of the total infectivity and has been obtained in all the fractionations so far carried out.

A similar elution pattern was obtained with the phenol extracts of pig kidney tissue culture cells infected with the virus and collected 4 h after infection. At this stage of the multiplication cycle, more than 50 per cent of the infective ribonucleic acid present in the cells is in a form which is susceptible to ribonuclease and is probably a virus precursor[5]. This evidence suggests that this ribonucleic acid has the same molecular weight as the viral ribonucleic acid.

The results of Burness and Vizoso[3], obtained with Krebs-2 ascites cells, show that the molecular weight of peak *B*, eluted at 0·11 M phosphate, is of the order of 10^6. Consequently, the molecular weight of the infective unit or units obtained by phenol extraction of foot-and-mouth disease virus is greater than this value. These results thus provide supporting evidence for the figure of $3·1 \times 10^6$ obtained by Strohmaier and Mussgay[6] by ultracentrifugation of the infective ribonucleic acid of the same virus. They differ from those of Vizoso and Burness[2], obtained with the ribonucleic acid of mouse encephalomyocarditis virus, in that no low molecular weight infective units have been detected.

We thank Drs. F. K. Sanders and A. T. H. Burness for their advice concerning the preparation of calcium phosphate for chromatography.

Dextran-gel Filtration in the Purification of a Crustacean α-Amylase

DURING studies[1] on the α-amylase from the hepatopancreas of *Carcinus maenas*, the common shore crab, the need arose for a purified enzyme preparation. Highly purified preparations of α-amylases have been prepared previously using starch as an adsorbent[2,3], but partition systems consisting of starch in water have serious drawbacks for chromatographic purposes since commercial starches are of poorly defined composition[4]. However, by using dextran-gel columns a purification stage has been developed which is reproducible and which gives a good enrichment.

In an early purification scheme a partially purified extract of hepatopancreas tissue was applied to a dextran-gel column, 25 × 3 cm, which had been prepared from 15 g of dry 'Sephadex *G*-75' (AB Pharmacia, Uppsala, Sweden). The internal volume, V_i, of the column was calculated from the mass and the water regain of the dry 'Sephadex.' The void volume, V_0, had been previously determined with hæmoglobin in the normal manner[5]. The enzyme was eluted with a solution containing calcium acetate, 0·02μ, and sodium chloride, 0·03μ, *p*H 7, at a rate of 10 ml./h. The enzymatic activity was assayed in the eluted fractions and the elution volume, V_e, of the enzyme was determined as the volume of eluant which gave the fraction containing the maximum activity.

The values recorded for V_i, V_0 and V_e were substituted in equation 1 to give a value of 0·29 for K_D, the distribution coefficient[5] of the α-amylase:

$$K_D = (V_e - V_0)/V_i \qquad (1)$$

Having established the value of the distribution coefficient it was unnecessary to redetermine the response of the enzyme to gel filtration in subsequent purifications using gel columns of different sizes. This was because the elution volume of the enzyme could be calculated by substitution of the values of K_D, V_0 and V_i in equation 1 and solving for V_e.

The course of a typical gel filtration experiment is illustrated in Fig. 1. A high proportion of the protein content of the partially purified α-amylase preparation applied to the column was found to be totally excluded from the gel phase. This extraneous material could be separated from the enzyme protein provided that the

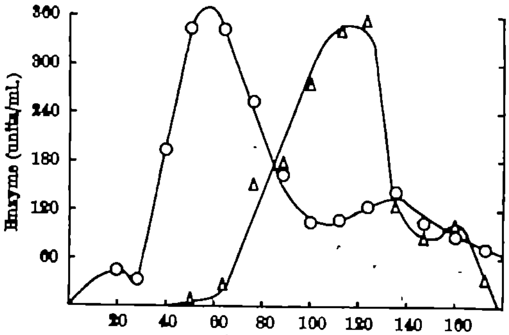

Fig. 1. Gel filtration of a crab α-amylase on a column of 'Sephadex *G*-75' at room temperature. V_0 = 60 ml., V_t = 120 ml. The partially purified enzyme, sample volumes 28 ml., specific activity 1·3, was applied to the column and eluted with a solution of calcium acetate, 0·02*M* and sodium chloride, 0·03*M*, *p*H 7. Approximately 10 ml. fractions were collected and assayed for enzymatic activity (ref. 7) and protein concentration (ref. 8). Total enzymatic activity applied to the column, 2,840 units. Yield, 1,810 units (64 per cent) contained in 75 ml. of eluate with a specific activity of 4·4, enrichment 3·5. ○, Enzymatic activity (units/ml.); △, protein concentration (mg/ml.)

volume of the sample applied to the column did not exceed 0·29 V_t (ref. 6). The enzymatic activity is partially retained on the column enabling the isolation of an α-amylase enzyme preparation with a specific activity 3–5 times greater than that of the partially purified preparation applied to the column and in a 60–80 per cent yield. This preparation was obtained by pooling the two or three fractions obtained on each side of the elution volume. In all cases, any material which appeared after collection of the enzyme was ignored.

The experiments were simple to perform and the purification stage could be carried out within 12–15 h using a freshly packed column. The results were reproducible and each column could be used repeatedly after washing with buffer following each purification.

Details of additional purification and properties of the purified crab α-amylase will be published elsewhere.

Fractionation of a Substance containing Hexosamine, isolated by Precipitation with Calcium Chloride from Normal Urine

In urine there are many dialysable as well as many non-dialysable substances containing hexosamine. Recently, considerable attention has been directed to their examination[1–4]. By a number of methods various substances have been isolated; for the most part they represent complicated mixtures the composition of which depends on the manner of preparation. From the alcoholic supernatant after the precipitation of mucoproteins by precipitation with calcium chloride, Marcotte-Boy *et al.*[5] prepared another, non-dialysable, fraction of unknown nature, containing hexosamine. This communication reports further fractionation of this substance.

The soluble part of alcohol and ether-dried precipitate was extracted with distilled water; the extract was frozen and then thawed. In this procedure a part of the substances not containing hexosamine, giving positive murexide reaction as well as a characteristic ultra-violet spectrum for uric acid, remains unsolved. The supernatant was freeze-dried and used for further work.

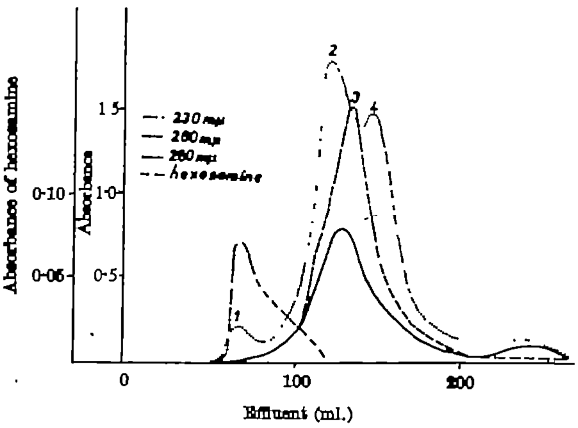

Fig. 1. Gel filtration on the column 'Sephadex *G*-25' medium

By the gel filtration of the solution of this substance on 'Sephadex *G*–25' medium four fractions were obtained among which the first two contained hexosamine (Fig. 1).

By refiltration of the column 'Sephadex *G*–50' as well as '*G*–75' a simple peak is obtained which, however, in the latter case is shifted to higher elution volume. Subsequent fractionation was performed on a DEAE-cellulose (phosphate buffer *p*H 6·0, ionic strength 0·01μ) using linear gradient up to the ionic strength 0·6μ, and after this using linear gradient up to the concentration of 0·2 N sodium hydroxide. By means of chromatography of the first fraction following the gel filtration eight sub-fractions were obtained, five of which contained hexosamine and hexoses (Fig. 2).

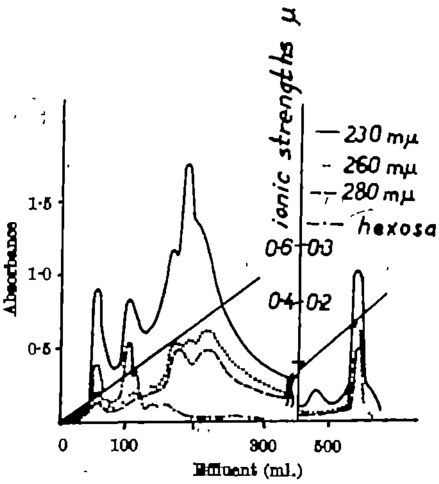

Fig. 2. Chromatogram of fraction I on the DEAE-cellulose column

By means of chromatography also the second fraction could be separated into eight sub-fractions, only the first of them, however, containing both hexosamine and hexoses (Fig. 3). By means of repeated chromatography of this fraction containing hexosamine on the DEAE-cellulose at *p*H 7·0 three fractions could be obtained.

The material isolated using the Marcotte-Boy technique is thus a varied mixture of different substances. Approximately two-thirds of the hexosamine is contained in non-dialysable substances (molecular weight 8,000–50,000) and can be divided into five fractions. The remaining one-third of hexosamine is in the form of dialysable substances, probably having a molecular weight lower than 5,000.

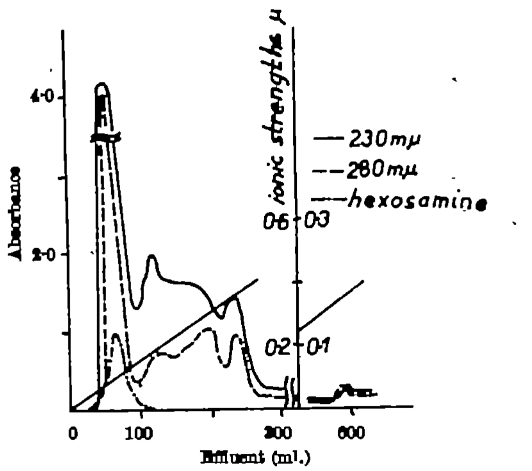

Fig. 3. Chromatogram of fraction II on the DEAE-cellulose column

Detailed chemical composition of these fractions is now being investigated.

Changes in Hydroxyproline-containing Fractions in the Developing Chick Embryo

DURING recent years increasing attention has been paid to free and peptide-bound hydroxyproline in order to explain their role in the metabolism of collagen[1-10]. Since chick embryos contain relatively large amounts of free hydroxyproline at least[1,11-13], it seemed worth while to follow the contents of various hydroxyproline containing fractions during the development of the chick embryo.

The following four fractions were analysed: (1) free hydroxyproline; (2) peptide-bound hydroxyproline soluble in 80 per cent ethanol; (3) hydroxyproline soluble in 1 M sodium chloride, insoluble in ethanol, designated as soluble collagen hydroxyproline; (4) total hydroxyproline. In addition, the amount of insoluble hydroxyproline could be calculated from these four values. The values for cortisone-treated embryos in the same fractions are given in another preliminary report[14].

The amount of peptide-bound hydroxyproline was calculated from the difference of analyses of the ethanol-soluble fraction before and after hydrolysis. Hydroxyproline was determined by the method previously described[15], with some modifications, except for the soluble-collagen fraction, for which the method of Prockop and Udenfriend[16] was used, since the amount of hydroxyproline in this unpurified fraction is very low as compared with that of other substances. The latter method[16] was also used for all fractions from embryos up to the 8th day of development. The error of the methods of determination was about ± 3 per cent. Up to the 10th day of development each symbol in the figures is a mean value of three pooled samples, thereafter a mean value of 6–18 embryos, analysed separately.

The amount of hydroxyproline in various fractions expressed per unit of dry tissue is presented in Fig. 1 (upper and lower). The amounts of free and soluble collagen hydroxyproline increase to maximum values on the 14th day of development. Thereafter the content of free hydroxyproline decreases rapidly, but the content of soluble-collagen hydroxyproline only slightly. In contrast to the free hydroxyproline, peptide-bound hydroxyproline was found to be present in very low concentrations. A tendency to increase is to be seen during embryonic development, and by the 20th day peptide-bound hydroxyproline forms a noteworthy part of the total ethanol-soluble hydroxyproline. The values are in agreement with those presented for acid-extractable peptides in 10- and 17-day-old chick embryos[13].

Since substances other than collagen compose the bulk of the dry weight used as basis for Fig. 1, the values are given as a percentage of the total hydroxyproline in Fig. 2 (upper and lower). The amount of insoluble hydroxy-

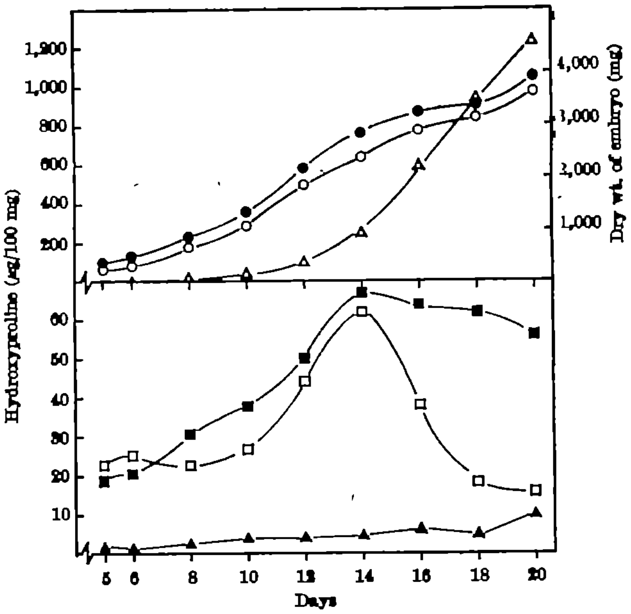

Fig. 1. Hydroxyproline in various fractions expressed per unit of dry matter of the embryo. ●, Total; ○, insoluble; ■, soluble collagen; □, free; ▲, peptide-bound. In addition, in the upper graph, the absolute amount of dry matter per embryo is shown on the ordinate on the right, △

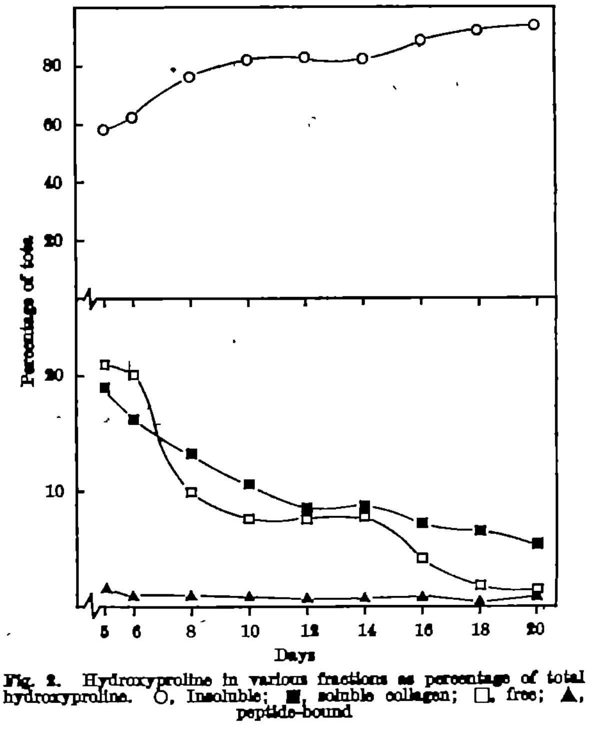

Fig. 2. Hydroxyproline in various fractions as percentage of total hydroxyproline. ○, Insoluble; ■, soluble collagen; □, free; ▲, peptide-bound

proline increases continuously during development. Nevertheless, even on the 5th day of development, 58 per cent of the hydroxyproline is in insoluble form. It is of interest that in young embryos not only soluble collagen but also free hydroxyproline constitute a noteworthy part of the total hydroxyproline. Similar values for free hydroxyproline have also been reported recently during the early development of carrageenin granuloma[4,6] and fibroblast cultures[10]. It has been generally accepted that administered hydroxyproline is not utilized for collagen synthesis and that the collagen hydroxyproline is derived from proline that is hydroxylated in bound form[17]. Therefore the part played by free and peptide-bound hydroxyproline in the metabolism of collagen is of interest. Recent work suggests that the ultra-filtrable hydroxyproline present in tissues during the early development of collagen represents a precursor of collagen[4,8,10]. It is evident, too, that part of the urinary hydroxyproline is derived from collagenic precursors[5,6,7]. The present work, likewise, suggests that in young chick embryos free hydroxyproline may be derived from precursors of insoluble collagen.

Oxidation of β-Carotene: Formation of Vitamin A Acid

Although Moore[1] had demonstrated that β-carotene was transformed into vitamin A in the animal body, the actual process of this transformation has not as yet been fully understood. There are two views: one postulating oxidation of β-carotene at the central double bond, with the formation of, at first, two molecules of retinene[2,3] (vitamin A aldehyde), which are immediately reduced to give two molecules of vitamin A alcohol; the other claiming that if an excentric bond be attacked it would give only one molecule of vitamin A, resulting from the further degradation of the larger fragment. Moore[4] has given an outline of the evidence for and against these views.

The oxidation products of β-carotene therefore are of interest as they can help in giving an insight into the problem of provitamin - vitamin A transformation. A number of investigations in the oxidation of β-carotene, has been reported. When β-carotene was oxidized with chromium trioxide, semi-β-carotenone and β-carotenone were produced[5]. When, however, alkaline permanganate was used β-apocarotenals were formed[6]. Hunter and Williams[7] oxidized β-carotene with hydrogen peroxide in chloroform–acetic acid medium and found retinene as one of the oxidation products which gave vitamin A alcohol on reduction, the yield being only 0·4–0·5 per cent. With osmium tetroxide as catalyst a moderate yield of 30 per cent was reported[8,9]. Meunier[10] reported formation of vitamin A aldehyde, retinene hydrate, and vitamin A alcohol from carotenoids, especially from β-carotene by oxidation with various metallic oxides, namely, TiO_2, V_2O_5, Fe_2O_3. His reported yield of about 95 per cent was, however, disputed by Sebrell and Harris[11], who were unable to reproduce Meunier's results.

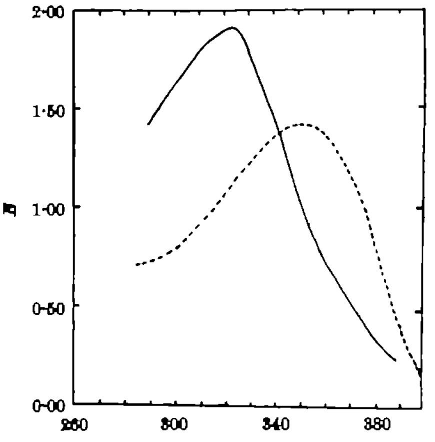

Fig. 1. Broken line, absorption spectrum of vitamin A acid obtained by oxidation of β-carotene and subsequent chromatography; solid line, absorption spectrum of vitamin A alcohol obtained after reduction of vitamin A acid followed by chromatography

In none of the foregoing oxidation investigations, however, was the formation of vitamin A acid reported from β-carotene. In an investigation carried on in this laboratory, it has been possible to obtain vitamin A acid as one of the products of oxidation of β-carotene. When β-carotene in petroleum ether or ether solution was kept over a mixture of V_2O_5/MnO_2 (5 : 2) for about 80–90 h the solution changes to a greenish yellow colour. This was then chromatographed on a column of deactivated alumina[12] (8 per cent water), when three zones separated at the top. The first, second and the third zones gave on extrusion and elution with ethanol, spectra with $\lambda\lambda_{max}$ at 335 mμ, 285–287 mμ, and 350–351 mμ, respectively (solvent–ethanol). The third zone has spectral characteristics corresponding to vitamin A acid (λ_{max} at 347 mμ in petroleum ether, 350–351 mμ in ethanol). With $SbCl_3$, it gave a purple colour having λ_{max} at about 570 mμ. The acid was then selectively reduced and chromatographed on deactivated alumina, when it gave a product spectroscopically identical with vitamin A alcohol (λ_{max} at 325 mμ in ethanol, and with $SbCl_3$ gave a blue colour with λ_{max} at 618 mμ). Fig. 1 shows the absorption spectra in ethanol of vitamin A acid (shown with broken line) and that of vitamin A alcohol obtained after reduction and chromatography (shown with unbroken line).

A Significant Variable in the Rat Hemidiaphragm Assay of Insulin

While using the rat hemidiaphragm method for assay of insulin[1,2], it was noticed that the right hemidiaphragm, when incubated in the presence of insulin (2 milliunits/ml.), takes up significantly more glucose per unit weight, per unit time than the left hemidiaphragm. The basal uptake (without insulin) of the right hemidiaphragm was slightly more than the left, but the difference was not significant. The combined results of seven separate experiments are shown in Table 1.

Table 1

	Basal			Insulin 2 m.units/ml.		
Hemidiaphragm	No. of hemidiaphragm	Weight of hemidiaphragm (mg) ± *S.E.*	Glucose uptake/ g wet diaphragm/ 90 min ± *S.E.*	No. of hemidiaphragm	Weight of hemidiaphragm (mg) ± *S.E.*	Glucose uptake/ g wet diaphragm/ 90 min ± *S.E.*
Right	24	80 ± 1·7	2·56 ± 0·15	24	80·4 ± 1·7	5·22 ± 0·23
Left	17	72 ± 2·3	2·32 ± 0·12	31	72·5 ± 1·5	4·04 ± 0·25
Difference and significance		R > L $P < 0·01$	None $P = 0·3$		R > L $P < 0·01$	R > L $P < 0·001$

Table 2

Comparison	No. of hemidiaphragm	Correlation coefficients (*r*) and significance		Regression coefficients (*b*)		
		Right hemidiaphragm	Left hemidiaphragm	Right hemidiaphragm	Left hemidiaphragm	Difference and significance
Wet weight versus dry weight	30	0·97 $P < 0·001$	0·98 $P < 0·001$	4·00	3·64	None $0·2 > P > 0·1$
Wet weight versus non-collagen N_2	30	0·87 $P < 0·001$	0·93 $P < 0·001$	5·46	4·70	None $0·2 > P > 0·1$

Table 3

Experiment	Hemidiaphragm	No. of hemidiaphragm	Weight of diaphragm ± *S.E.*	Glucose uptake of hemidiaphragm (2 m.units insulin/ml.)/100 mg dry diaphragm/90 min ± *S.E.*	Difference in uptake and significance
Left hemidiaphragm removed before right	R	8	17·1 ± 0·4	2·04 ± 0·08	R > L $P < 0·02$
	L	8	15·2 ± 0·3	1·75 ± 0·07	
Left phrenic nerve cut first	R	8	17·1 ± 0·75	3·03 ± 0·15	R > L $P < 0·02$
	L	8	15·4 ± 0·8	2·45 ± 0·13	

The diaphragms were all dissected out in a standard manner from the ventral aspect. The right hemidiaphragm was always removed before the left and cuts were always made through comparable areas of muscle. The left phrenic nerve was always sectioned after removal of the left hemidiaphragm.

The following factors which might contribute to the difference in uptake of glucose between right and left hemidiaphragms have so far been investigated:

(1) The left hemidiaphragm might hold more water or contain less muscle than the right hemidiaphragm. It has been shown that (Table 2): (*a*) The wet weight of the diaphragm correlates very significantly both with the dry weight (dried at 110° C for 2 h) and with the non-collagen nitrogen content of the diaphragm. The latter[3] has been shown to correlate with the muscle content of a tissue such as the rat diaphragm. (*b*) The regression coefficient for the correlations of: (i) wet weight versus dry weight; (ii) wet weight versus non-collagen nitrogen of right and left hemidiaphragms do not differ significantly from each other.

Thus there is no evidence that right and left hemidiaphragms differ in their water or muscle content.

(2) In the foregoing experiments, the right hemidiaphragm and right phrenic nerve were always cut before the left hemidiaphragm and the left phrenic nerve. Metabolites such as corticosteroids or adrenaline might accumulate in the left hemidiaphragm more than the right and lead to antagonism of the effect of insulin. Buse and Buse[4] have shown that section of the phrenic nerve hours or days before use, can lead to decreased sensitivity of the diaphragm to insulin. It is conceivable that discharges from the sectioned spinal cord down the phrenic nerves might affect the diaphragm longer in contact with its nerve supply. Such effects should be altered by: (*a*) removal of the left diaphragm before the right—any metabolites will now affect the right diaphragm more than the left; (*b*) section of the left phrenic nerve before cutting the right phrenic nerve and hemidiaphragm.

Table 3 shows the results of these two experiments. These procedures do not affect the original pattern of the right hemidiaphragm taking up more glucose, in the presence of insulin, than the left. The difference does not therefore depend on the technique of removing the diaphragm. The possibility that the right and left hemidiaphragms have a different surface area to weight ratio is being explored.

A similar difference between right and left hemidiaphragms was described by Mann[5]. The difference was noted only with smaller concentrations of insulin and under basal conditions. With higher concentrations of insulin, in the range of the experiments recorded here, the difference between the two sides of the diaphragms were minimal or absent. The existence of this difference when concentrations of about 2 m.units insulin/ml. are used is important, as such concentrations are commonly used experimentally. The difference will increase the variability of any insulin assay and may bias results if unequal numbers of right and left hemidiaphragms are used in any one assay.

Œstrogens and Progesterone in Ovaries of the Marine Teleost *Conger conger*

RESULTS of biological assays have shown *Conger conger* ovary[1] as well as other teleost ovaries[2-4] to contain œstrogenic material. No indication of the chemical structure of the steroids present in the ovaries of these fishes has so far been ascertained. Only recently œstradiol-17β has been identified in the ovarian extracts of *Salmo irideus* and œstradiol-17β, œstriol and 16-epi-œstriol in the ovarian extracts of *Cyprinus carpio*[7].

In order to clarify this point, ovaries of the marine teleost *Conger conger* were extracted according to the method of Dean and Chester Jones[8]. From 740 mg of fresh ovarian tissue, obtained from one sexually mature female, 30 mg of neutral material and 75 mg of phenolic material were isolated.

The neutral fraction was resolved by paper chromatography in systems developed by Bush[9] and Zaffaroni[10]. The first chromatography by the Bush *C* system showed the presence of a spot absorbing in the ultra-violet region, the R_F of which was the same as pure progesterone. This spot was eluted and chromatographed successively by two systems (Zaffaroni and Bush *A*); the R_F of this component corresponded in both systems to that of progesterone. The steroid material was eluted and at this stage of purification showed an absorption maximum at 240 mμ. It was again chromatographed by the Bush *A* system, and, likewise pure progesterone, showed a positive Zimmermann reaction on the paper.

According to these findings, therefore, this component is progesterone.

On the basis of the ultra-violet absorption curve, progesterone was calculated to be present in the amount of approximately 15 μg/kg of fresh tissue.

The phenolic fraction was resolved by paper chromatography in 1 : 1·75 per cent methanol–toluene system. In order to detect the position of the œstrogens, 0·5 cm of the paper strip (total width, 1·5 cm) was cut and sprayed with a solution of 1 per cent ferric chloride and 1 per cent $K_3(Fe(CN)_6)$ (ref. 11). The colour reaction which followed this treatment showed the presence of œstriol and œstrone in amounts, as it appeared from semi-quantitative estimations, of about 50 and 80 μg/kg respectively. Traces of œstradiol-17β were also present.

The remaining part of the strip was eluted; the eluates of the zones corresponding to the three œstrogens were acetylated for 3 h by means of acetic anhydride and pyridine. The acetylated derivatives were chromatographed in 1 : 1 benzene – 80 per cent methanol system. After accomplishing hydrolysis *in situ* with ammonia the spots were detected by the colour reaction already described. They showed the same R_F as the authentic pure œstrogen derivatives.

These results show a similarity between the œstrogens secreted by the teleost *Conger conger* ovary and those observed in the case of both mammalian and non-mammalian vertebrates. So far as fishes are concerned, œstrone (not quantitatively), œstradiol-17β (120 μg/kg) and progesterone (although not conclusively) have been identified in the ovaries of the elasmobranch *Squalus suckleyi*[12]; only œstradiol-17β (not quantitatively) has been identified in the ovaries of *Salmo irideus*[7] and œstriol, 16-epi-œstriol and œstradiol-17β (not quantitatively) in the ovaries of *Cyprinus carpio*[7]; while œstriol (700 μg/kg), œstradiol-17β (traces), œstrone (70 μg/kg) and progesterone (60 μg/kg) have been detected in the ovaries of the lungfish *Protopterus annectens*[6].

The only differences existing between these species of fishes appear to be the absence of œstriol in the ovarian extracts of *Squalus suckleyi* and *Salmo irideus* and of œstrone in those of *Salmo irideus*, and the discrepancies in relative concentrations of the various œstrogens. The latter could be due to different concentration of the enzymes involved in the metabolism of the œstrogens.

The presence of progesterone in a teleost, as well as in other fishes, raises the question of its role in the reproductive behaviour of lower vertebrates.

This investigation was supported by a research grant *RG*–6455 from the Division of General Medical Sciences, U.S. Public Health Service, and by the National Research Council, Italy.

Species Difference in Regard to the Distribution of Glucose-6-phosphatase

THE enzyme glucose-6-phosphatase cannot be classified as either acid phosphatase or alkaline phosphatase. It is highly specific and is differentiated from non-specific acid and alkaline phosphatases on the basis of location and behaviour. So far, no systematic study has been made regarding the distribution of this enzyme in different species of animals. Hers and de Duve[1] first reported that in rats it is abundant in the liver, but only present in small amounts in the kidney; it is, however, absent in the intestine and not present in detectable amount in other organs and blood. But afterwards they contradicted their own previous finding and showed that glucose-6-phosphatase was also present in the intestine. The present communication concerns an investigation of the distribution of this enzyme in different species of animals.

The results presented in Table 1 show that in most of the species the glucose-6-phosphatase activity is concentrated mainly in the liver and to some extent in the kidney. The brain and testes have little, if any, glucose-6-phosphatase activity. In mammals like mouse, rat and goat both the liver and the kidney have more or less similar activity. It is interesting to note that in lower forms of animals, namely, toad, tortoise and fish, the kidney tissues possess a very little glucose-6-phosphatase activity. It also

Table 1. DISTRIBUTION OF GLUCOSE-6-PHOSPHATASE IN TISSUE HOMOGENATES OF DIFFERENT SPECIES OF ANIMALS

The test system contains: 0·2 ml. of 0·1 M glucose-6-phosphate, 0·55 ml. of maleate buffer (0·1 M, *p*H 6·5) and 0·25 ml. of enzyme dispersion (homogenate or microsomes as the case may be) in a total volume of 1 ml. At the end of the incubation period (30 min at 37°), 2 ml. of 10 per cent trichloroacetic acid was added. After keeping for a few min in ice, the samples were diluted to 10 ml. and centrifuged. An aliquot (0·5 ml.) was used for the determination of phosphate by the method of Chen *et al.* (ref. 5)

Natural order	Name of the species	Activity of glucose-6-phosphatase in units*				
		Liver	Kidney	Intestine	Brain	Testis
Amphibia	Tortoise	35·0	1·3	1·1	1·8	—
	Toad	36·2	8·6	3·8	1·1	—
Pisces	Mrigal (*Cirrhina mrigala*)	19·0	3·1	1·4	2·8	—
Aves	Chick	38·1	38·8	2·3	2·4	2·2
	Pigeon	34·1	34·2	2·1	1·8	3·2
Mammalia	Mouse	47·5	36·6	1·6	1·8	2·2
	Rat	46·1	48·3	8·5	4·5	5·0
	Goat	41·8	51·8	—	2·9	—
	Guinea pig	23·6	23·4	13·2	2·8	4·2
	Rabbit	18·6	19·1	10·5	1·8	3·6

In one invertebrate species studied, namely, crab, the hepatopancrease homogenate contains only a trace of glucose-6-phosphatase activity, but the microsomes obtained after sedimentation at 88,700*g* for 60 min have been found to possess a fair activity of the enzyme.

* 1 unit = μg of P_i/mg protein/30 min.

appears from the results given in Table 1 that in amphibians and in fish, the liver tissue possesses the maximum glucose-6-phosphatase activity whereas in the avian species and in mammals both the liver and the kidney were almost equally active. It has been observed that intestines of rat, guinea pig and rabbit possess a small activity of glucose-6-phosphatase.

In one invertebrate species examined, namely, crab, it has been found that though the hepatopancreas homogenate possesses a trace amount of activity, the microsomes obtained from the hepatopancreas homogenate contain a fair amount of activity. The reason why the hepatopancreas homogenate of the crab possesses such a low activity is not clear.

In studying the activity of the microsomal fractions sedimented under different centrifugal forces it has been observed that the fraction sedimented at 30,000*g* for 60 min, which was mainly composed of the heavier microsomes, possesses the highest activity in the case of the livers of the rat and goat. A similar finding has also been observed in the case of rat kidney; de Duve *et al.*[4] also reported previously that glucose-6-phosphatase activity resides mainly in the microsomal fraction of the rat liver separated by centrifugation at 20,000*g* for 60–90 min. Regarding the different enzymatic activities of the heavier and the lighter microsomes it has very recently been shown by Kar *et al.*[3] that the heavier microsomes sedimenting at 26,390*g* for 60 min are more active than the lighter microsomal fractions sedimenting at 59,380*g*, 88,700*g* and 109,500*g*, 60 min each time, respectively, in regard to the synthesis of L-ascorbic acid in rat liver.

The microsomal glucose-6-phosphatase can be rendered soluble by treatment with a variety of surface-active agents like sodium deoxycholate, 'Triton *X*–100', sodium dodecyl sulphate and 'Duponol'.

Accumulation of Ribonucleic Acid in *Escherichia coli* due to the Action of 5-Methyl Tryptophan

In bacteria, the syntheses of protein and ribonucleic acid (RNA) are normally closely linked but, under certain conditions, protein synthesis may be slowed down or stopped relative to the synthesis of RNA, so that RNA accumulates within the cells. With *Escherichia coli* this may be achieved by incubation of cells with chloramphenicol[1] or puromycin[2] and also when a certain methionine-requiring mutant strain is starved of this amino-acid[3]. It has been shown that in each of these cases[4–6] at least a part of the accumulated RNA appears in the cells in the form of ribonucleoprotein (RNP) particles which sediment more slowly than ribosomes, at about 14–18*S*. It has been suggested[6] that although these particles have some of the properties claimed for 'messenger' RNA[7], they are more likely to be related to precursors of the ribosomes.

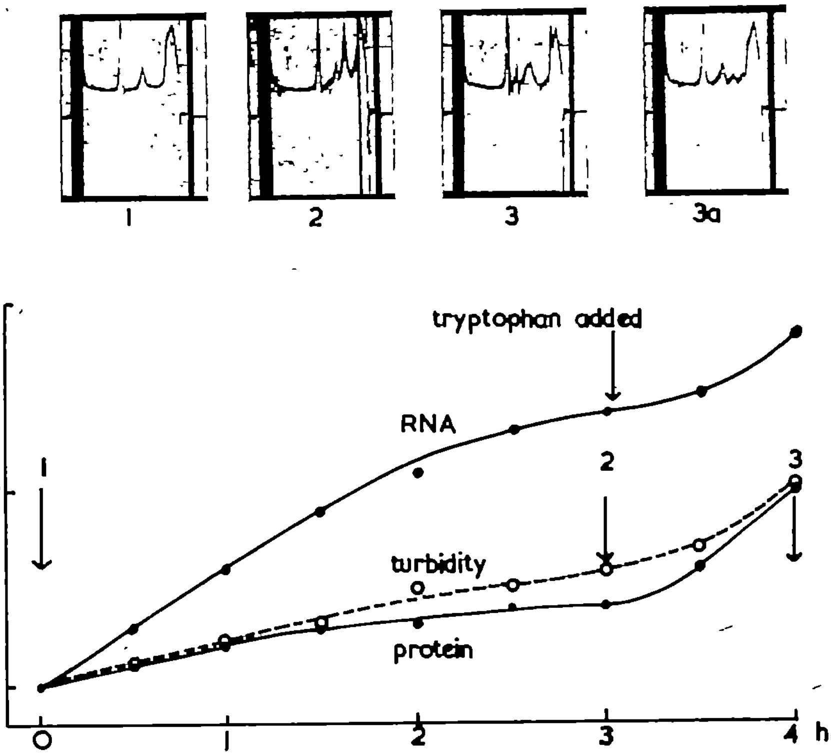

Fig. 1. Ribonucleic acid content of a methionine-requiring mutant of *E. coli*. At zero time, 5-methyl tryptophan (50 μg/ml.) was added to a culture of the bacteria growing exponentially in an aerated glucose and mineral salts medium containing methionine. Curves show the increases in turbidity, RNA and protein of the culture expressed as multiples of initial values. L-Tryptophan (100 μg/ml.) was added after 3 h. Cell-free extracts were prepared at times indicated by arrows and the corresponding Schlieren diagrams are shown. Photograph (3a) shows the extract in photograph (3) after treatment with 1 μg/ml. RNase. Sedimentation at 187,000*g* is to the left and the photographs were taken 16 min after reaching speed. The leading peaks in every photograph are those caused by the 50*S* and 30*S* ribosomes

The mutant strain in which the control of RNA synthesis is relaxed has also been investigated by Stent and Brenner[8]: they found that the ability of the cells to synthesize RNA in the absence of protein synthesis is genetically determined and that, by suitable conjugation experiments, mutants can be obtained which require amino-acids other than methionine and which synthesize RNA in the absence of this 'new' amino-acid requirement. We have now found that if the tryptophan analogue, 5-methyl tryptophan, is added to growing cultures of the 'relaxed' methionine-requiring mutant, growth and protein synthesis are inhibited but considerable synthesis of RNA (and DNA) occurs. In the experiment in Fig. 1, after 3-h incubation with 5-methyl tryptophan, the protein content of the cells had increased by 35 per cent, the RNA content by 140 per cent. If extracts are prepared from inhibited cells and examined in the analytical ultracentrifuge, then additional boundaries sedimenting at 14–18*S* are once again seen (Fig. 1).

In similar experiments with a second methionine auxotroph of *E. coli* which does not synthesize RNA when starved of methionine, inhibition of growth can also be brought about by 5-methyl tryptophan, but there is comparatively little 'extra' RNA synthesis and no new boundaries can be seen in ultracentrifuge diagrams. It therefore seems likely that the production of 14–18*S* material by the action of 5-methyl tryptophan may be confined to the 'relaxed' strains.

When tryptophan is added to a culture of the 'relaxed' mutant which has been inhibited by 5-methyl tryptophan, the cells retain their accumulated RNA as growth and protein synthesis slowly recommence and interesting changes can be observed in ultracentrifuge diagrams (Fig. 1). The 14–18*S* components now sediment very close to the 30*S* ribosomes and an additional small boundary which sediments at about 40*S* appears. Like the 14–18*S* material, these new components are extremely sensitive to RNase. In normal *E. coli* cells, particles sedimenting at about 30 and 40*S* have been implicated in the synthesis of ribosomes[9]. We may therefore be observing in these experiments further stages in ribosome synthesis from 14–18*S* precursors.

PHYSIOLOGY

Transmission of Noradrenaline across the Human Placenta

Fœtal bradycardia during labour is usually taken to be a sign of 'fœtal distress', its occurrence being interpreted as a consequence of fœtal hypoxia. Beard[1] has recently considered the possibility of an endogenous humoral agent such as noradrenaline in the maternal circulation contributing to, or causing, this type of fœtal response. After injecting noradrenaline into the pregnant human subject, he noted a transitory fœtal bradycardia but was not able to decide from his results whether this effect stemmed from uterine vasoconstriction with subsequent fœtal hypoxia or from a direct action of noradrenaline on the fœtal cardiovascular system.

It seemed important to try to elucidate this point. Although the administration of radioisotopically labelled noradrenaline to the mother followed by direct detection of activity in the fœtal blood appeared to offer the best chance of obtaining this information, it was not considered justifiable to perform such an experiment in the presence of a normal fœtus. Procedures have thus been confined to clinical circumstances incompatible with fœtal survival; choice and availability of clinical material have of necessity been limited.

Following intravenous injection of ^{14}C-DL-noradrenaline into the mother, the labelled noradrenaline content of serum deriving from maternal venous, umbilical venous (afferent) and fœtal heart blood was measured (Table 1). In all cases, the placenta appeared to be normal for the stage of pregnancy.

Although there was wide variation, appreciable amounts of labelled noradrenaline crossed the placenta to appear in blood flowing from the placenta to the fœtus. During the passage of this blood through the fœtus, almost all labelled noradrenaline had disappeared from the circulation, presumably by a combination of tissue binding and metabolic change.

In certain circumstances, intravenous noradrenaline will give rise to bradycardia in the human new-born infant[3]. It would be reasonable therefore, in the light of our results, to interpret Beard's findings[1] as indicating that fœtal bradycardia following noradrenaline injection into the mother may be due, in part at least, to a direct action of noradrenaline on the fœtal circulatory system. One proviso, however, must be mentioned; the ^{14}C-noradrenaline used in these experiments was a racemic DL mixture. Even though it is likely that the inactive D- and the physiologically active L-isomers are metabolized similarly[4], we have no information as to whether there is any preferential transfer of either across biological membranes. Final verification of this point must await the availability of radioisotopically labelled L-noradrenaline.

Table 1

Clinical features	Duration of pregnancy (weeks)	Maternal serum	Cord serum		Fœtal heart serum	
		C.p.m./1 ml.	C.p.m./1 ml.	Percentage of maternal count	C.p.m./1 ml.	Percentage of maternal count
Hydrocephalic fœtus	37	1,925	200	10	Nil	—
Anencephalic fœtus	38	314	Specimen lost		4	1·3
Termination of pregnancy by hysterotomy (rubella in pregnancy)	24	417	76	18	9	2·2
Termination of pregnancy by hysterotomy (psychiatric reason)	15	640	13	2	4	0·6

β-[^{14}C]-DL-Noradrenaline (5 μc.) was injected intravenously into the mother over a period of 2–5 min immediately before delivery. Immediately after delivery specimens of blood were collected as quickly as possible from the venous circulation of the mother, from the placental end of the umbilical cord and from the fœtal heart, either simultaneously or within a few minutes of each other. In every case collection of blood was completed within 10 minutes of the end of the injection. Serum was separated without delay.

Noradrenaline was assayed by a modification of the methods of Weil-Malherbe (ref. 2). The *p*H of the serum was adjusted to 8·4 and, without protein precipitation, was passed through a small column of alumina on to which the noradrenaline was absorbed. After washing with *p*H 8·4, 0·2 M acetate buffer, the column was eluted with 0·2 N hydrochloric acid. The eluate was evaporated to dryness, and dissolved in 0·1 ml. water, to which 4 ml. methanol and 16 ml. liquid scintillator (1 l. toluene + 0·8 g 1,4-*bis*-2-(4-methyl-5-phenyloxazolyl)-benzene + 5 g 2,5-diphenyloxazole, were added. Radioactivity was determined in a 'Tri-Carb' liquid scintillation spectrometer. Each sample was counted for a length of time sufficient to give a standard error of ± 1 per cent.

Presence of a Phosphatido-peptide Fraction in Liver Cell Membrane and its Possible Role in the Active Transport of Amino-acids

Previous work in this laboratory has shown that a phosphatido-peptide fraction becomes promptly labelled during the perfusion of the isolated rat liver with rat blood containing labelled amino-acids, and reaches a maximum in its radioactivity a few minutes after the start of the experiment[1–3]. The reaction is strongly inhibited by metabolic inhibitors, such as ethionine, potassium cyanide and 2,4-dinitrophenol. It was also shown that the phosphatido-peptide contained in the 1,000 × g fraction of liver homogenates, which contains at least a large part of cell membranes[4], incorporates the radioactivity more rapidly than that contained in the mitochondrial or in the microsomal fraction and in the 105,000 × g supernatant. The radioactivity bound to the phosphatido-peptide fraction was released after incubation with a liver cathepsin preparation; other proteolytic enzymes so far tested were devoid of such a property.

The results have been interpreted assuming that the phosphatido-peptide fraction may play a part in the active transport of labelled amino-acids and, as a working hypothesis, such a transport was depicted as follows:

$$\text{extracellular amino-acids} \xrightarrow{\text{ATP}} \text{phosphatido-peptide} \xrightarrow{\text{cathepsin}} \text{intracellular amino-acids}$$

This scheme recalls that described by Hokin and Hokin[5], assuming a role of phosphatidic acid in the active transport of cations and hydrophylic secretory materials.

As a first attempt to confirm our hypothesis, the chemical composition of rat liver cell membranes and the incorporation of labelled amino-acids were investigated. Liver cell membranes were isolated by Neville's method[4]. Electron microscope examination, kindly performed by Prof. Pernis, Department of Industrial Medicine, University of Milan, showed that our preparation consisted essentially of cell membranes with the exception of very few dense granules. For each preparation at least two rat livers (16–24 g) were used, and the yield was 10–16 mg dry weight of cell membranes.

The membranes were extracted twice with 5 ml. of cold acetone and twice with 5 ml. of ethanol/diethylether (3 : 1) for 10 min at 50° C. The insoluble residue was next subjected to two extractions with 5 ml. of the mixture chloroform/methanol/hydrochloric acid (200 : 100 : 1, v) and the protein residue washed with diethylether and dried at 50° C. All the operations were carried out in conical centrifuge tubes.

Table 1. COMPOSITION OF RAT LIVER CELL MEMBRANE

Constituent	Percentage of dry weight
Proteins	59·6
Acetone and ethanol-diethylether soluble lipids	22·1
Phosphatido-peptide fraction	18·3

Each value is the average of the analyses performed on five different preparations.

The results are reported in Table 1. It should be noted that the composition of liver cell membrane is very similar to that of blood red cell membrane[6]. The extract obtained with the acidified mixture of chloroform–methanol was taken as the phosphatido-peptide fraction[3]; the presence of a bound peptide was indicated by the increase of amino-nitrogen from 0·89 to 2·38 per cent after hydrolysis for 24 h with 6 N hydrochloric acid. A chromatographic examination showed that acid hydrolysates contain most of the common amino-acids, with the apparent exception of cysteine, tyrosine and tryptophan. All the analyses of the phosphatido-peptide fraction were performed after drying the extract obtained from the membranes at 50° C under a nitrogen stream and re-extracting the residue with chloroform/methanol (2 : 1). Usually none, or a negligible amount, remained undissolved.

The isolated rat liver was perfused as already described[2] with heparinized rat blood containing 20 μc. of algal protein-^{14}C hydrolysate; at intervals of 3–12 min the experiment was stopped and the liver rapidly perfused with cold physiological saline. The liver was then homogenized with cold bicarbonate solution (0·001 M) brought to pH 7·4 and centrifuged 10 min in the cold at 1,500 × g. The membranes were then separated from the sediment[4]. Thereafter, 10 per cent trichloroacetic acid (TCA) was added to both the membranes and the 1,500 × g supernatant and the precipitates centrifuged and treated as previously described[3] for the separation of lipid fractions and proteins and the determination of their radioactivity.

It was thus observed that the radioactivity of the membrane phosphatido-peptide rose very rapidly, reaching a maximum within 3 min, but thereafter diminished; however, the proteins both of the 1,500 × g supernatant and of the membrane gradually took up the labelled amino-acids (Fig. 1). The total radioactivity taken up by the liver rose sharply at the beginning of the experiment and thereafter rose at a reduced rate. The values obtained after 3, 6 and 12 min were respectively 82,000, 119,000 and 143,000 c.p.m. for the sum of radioactivity of the TCA-soluble and TCA-insoluble fraction.

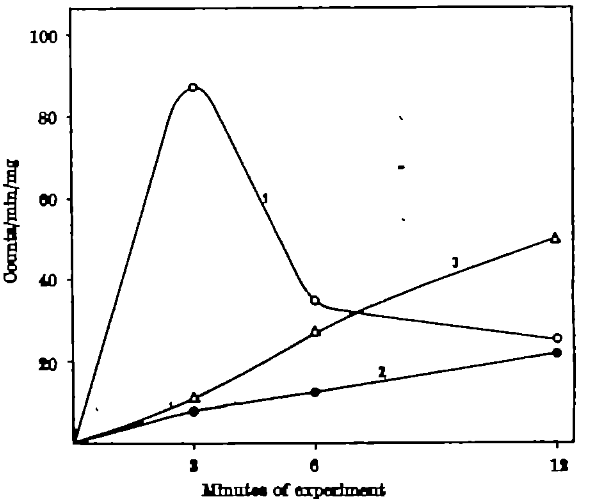

Fig. 1. Time-course of the incorporation of labelled amino-acids (algal protein-^{14}C hydrolysate) into the phosphatido-peptide fraction of cell membrane (curve 1), into the proteins of cell membrane (curve 2) and into the proteins of 1,500 × g supernatant (curve 3)

The curve in Fig. 1 relative to the membrane phosphatido-peptide is closely similar to that obtained by Hunter and Goodsall[7], when studying the incorporation of labelled amino-acids into the lipids of protoplasts of *B. megatherium*.

Such a behaviour of the membrane phosphatido-peptide seems to support its possible role in the active transport of labelled amino-acids in liver cells. The second assumption of our hypothesis, the role of cathepsin, is under investigation; the presence of these enzymes in cell membrane has been known since 1953[8]. We believe at present that the phosphatido-peptide fraction fulfils at least many of the criteria listed by Heald[9] for a substance which takes part in the active transport of a molecule.

Very recently Hendler[10] suggested that lipid–amino-acid complexes are involved both in the transport of amino-acids and in the synthesis of proteins. Although our results are not sufficient to support the last proposal, we have found that the radioactivity bound to the phosphatido-peptide fraction is easily incorporated into the proteins of isolated rat liver mitochondria. Obviously, further experimentation is necessary to demonstrate a direct utilization of the peptide moiety of our lipid fraction for the synthesis of proteins.

Effect of Adrenalectomy on Histamine Metabolism in the Rat

THE effect of adrenalectomy on the metabolism of histamine in the rat has been investigated by several workers, but with conflicting results. Though it has been established that after adrenalectomy the histamine contents of some rat tissues are raised[1–4], there is considerable discrepancy regarding how the rise is brought about and the conditions under which it occurs. For example, increased levels of tissue histamine in adrenalectomized rats have been attributed by different workers to: (1) increased uptake of histamine from the gut[2]; (2) increased rate of tissue histamine formation[3]; (3) increased ability of tissues to bind histamine[4]; (4) decreased activity of histaminase[1]. Some workers have reported that the increases in histamine-levels after adrenalectomy are greater if the animals are given water to drink than if they are given saline[1], while others have found that in animals given saline increases in the tissue levels of this amine do not occur[3].

The present experiments were performed in the hope of clarifying these discrepancies. Groups of 6 female rats of Wistar strain (120–180 g) were bilaterally adrenalectomized under ether anæsthesia. The animals received their normal food and either 0·9 per cent saline or drinking water, and were killed 4, 14 or 49 days after the operation. The histamine contents of various tissues were determined by the method of Parratt and West[6]. The results, each of which is the mean of the values from at least 3 experiments, are presented in Table 1.

Table 1. EFFECT OF ADRENALECTOMY ON THE HISTAMINE CONTENT OF RAT TISSUES

Tissue	Water 4 days	Saline 4 days	Saline 14 days	Saline 49 days
Abdominal skin	256	158	238	147
Skin of the feet	281	173	205	128
Ears	278	139	251	114
Fundic stomach	249	180	200	144
Pyloric stomach	333	229	320	120
Jejunum	220	156	201	121
Ileum	267	136	202	127
Colon	275	182	229	98
Liver	340	260	240	94
Kidney	406	271	325	113
Lung	285	162	300	100

The animals received their normal food and either saline or drinking water, and were killed 4, 14 or 49 days after the operation. All values are expressed as percentages of the control values obtained using unoperated or mock-adrenalectomized rats.

The results demonstrate two points. First, the increases in tissue histamine after adrenalectomy are as great in the skin and some other tissues as in the alimentary canal; the findings of some authors that major increases in histamine-levels are confined to the gastro-intestinal tract could not be confirmed[1,2,4]. Secondly, the increases are of similar magnitude in rats maintained on water and in rats maintained on saline. In rats maintained on water, the histamine contents of the tissues reach their highest values 4 days after the operation; in rats maintained on saline the values are highest 10–15 days after the operation and do not return to pre-adrenalectomy levels until 5–6 weeks later.

In a further series of experiments, the daily urinary excretion of histamine (μg free histamine/100 g body-weight/18 h) was followed before and after removal of the adrenals. No significant changes were noted, either in animals drinking water or in animals drinking saline. This result is in contrast with that of Bjurö and Westling, who have reported a two-fold increase in the excretion of histamine in adrenalectomized rats maintained on saline[5]. In the present work, however, the rats did not receive aminoguanidine to inhibit histaminase. The excretion of histamine was also measured in non-operated rats receiving cortisone, prednisolone or deoxycortone acetate (10 mg/kg daily for 9 days), and again no changes were noted.

Injections of glucocorticoids reduce the histamine content of the skin and small intestine, but increase the content of this amine in the pyloric stomach[7]. As is shown in Table 1, adrenalectomy likewise increases the histamine content of the pyloric stomach. While the changes in histamine-levels after glucocorticoids are probably due to changes in the rate of histamine formation[8], little or no alterations occur in the histamine-forming capacities of rat tissues after adrenalectomy. Thus, the histidine decarboxylase activities of the liver and pyloric stomach, the two major sources of this enzyme in the adult rat[9], are unaffected by adrenalectomy[9,10]. Schayer *et al.* have reported increases in the histidine decarboxylase activity of the skin and lung of adrenalectomized rats[11], but such increases are unlikely to account for the major and rapid changes in histamine-levels since these tissues contain only minute amounts of the enzyme, and are capable of forming only very small quantities of histamine.

It is more probable that the levels of tissue histamine are raised in the absence of the adrenals because of increased firmness in the binding of the amine to tissue components, coupled with a reduction in histaminase activity. It is known that after adrenalectomy the activity of this enzyme in the rat is reduced[9,12]. A final series of experiments showed that inhibition of histaminase activity is greater when the rats are maintained on water than when they are maintained on saline; it is possible that this latter finding accounts for the increases in the levels of tissue histamine occurring more rapidly in rats maintained on water.

Influence of Pregnancy and an Oxidized Lipid Diet on the Fatty Acid Composition of Blood and Tissues

RECENTLY it has been shown that a diet which is low in vitamin E and which contains 5 per cent of oxidized lipid is capable of producing the generalized Shwartzman reaction in pregnant rats[1,2]. This reaction is characterized by an episode of disseminated intravascular coagulation and, in the past, has only been produced experimentally by intravenous injection of bacterial endotoxin. The fact that the only variant in the diet which was responsible for its lethal effect was the oxidized lipid plus the fact that an increase in stainable lipid could be demonstrated in the kidney, liver, and placentas of some animals led to an investigation of the distribution of fatty acids in the blood and tissues of these animals. It seemed appropriate to compare the fatty acid compositions of tissue lipids of pregnant and non-pregnant female rats fed the oxidized lipid diet (20 per cent casein, 61 per cent corn starch, 10 per cent brewers' yeast, 4 per cent salt mixture, and 5 per cent of the ethyl esters of a molecularly distilled fraction of oxidized cod liver oil) with those of similar rats fed a pellet stock diet containing approximately 5 per cent fat.

The rats were killed on the last day of pregnancy (or 21st day of experiment for the non-pregnant controls), and lipids were extracted from serum, perirenal fat, liver,

Table 1. PERCENTAGES OF PALMITATE AND LINOLEATE IN ORGAN LIPIDS OF NON-PREGNANT AND PREGNANT RATS

The rats were fed a stock ration (Rockland rat diet) or a vitamin E-low diet containing the esters of a fraction of oxidized cod liver oil. 'Pregnant, sick' denotes rats with the generalized Shwartzman reaction. Standard deviations are given for averages of at least three values; individual values are given when there were only two samples

kidneys, and placentas with a mixture of 3 : 1 ethanol/ethyl ether. Fatty acid analyses were carried out on the methyl esters of these extracts on a Perkin-Elmer model 154C vapour fractometer having a 2 meter polydiethylene glycol succinate column at 220° C.

Palmitate- and linoleate-levels in these lipids are given in Table 1; the remaining data have been omitted because of limitations of space and because there were few significant differences. The linoleate-levels of all rats fed the fraction of oxidized cod liver oil were significantly lower than those of the rats fed the stock diet. In one series in which only the serum was examined, feeding of α-tocopherol to rats fed this diet did not raise the linoleate-level. It seems likely that the presence of oxidized fat, *per se*, is responsible for the lower levels.

Pregnancy brought about significantly higher levels of palmitate in serum and livers and also in the kidneys and placentas of the rats having the generalized Shwartzman reaction. This elevation in tissue palmitate-levels was more marked in the rats fed the oxidized cod liver oil diet.

Further control experiments were carried out on 3 non-pregnant and 2 pregnant rabbits fed a pelleted rabbit ration. The average palmitate values were: in the serum, 28·2 per cent in non-pregnant and 38·5 per cent in pregnant; in the fat, 27·5 per cent in non-pregnant and 36·7 per cent in pregnant; in the liver, 27·4 per cent in non-pregnant and 43·3 per cent in pregnant; kidneys, 24·3 per cent in non-pregnant and 27·2 per cent in pregnant. There was no overlapping of values except for one kidney value. The average palmitate-level in the placentas of these normal rabbits was 34·3 per cent. A rabbit given the generalized Shwartzman reaction by means of endotoxin had a serum palmitate-level of 45·7 per cent.

The variability of individual fatty acid-levels in rats can be seen in Table 2, which represents a compilation from many experiments of different kinds. The range of such levels are given for each sex without regard to tissue source and diet of the animals. The palmitate-levels of males and females are similar, and the coefficients of variation are the lowest of all acids.

Palmitate synthesis and tissue-levels would seem to be controlled within narrow limits but would appear to be mobilized under the stimulation of pregnancy, perhaps by hormones. The fact that, in most naturally occurring fats, palmitate in non-randomly distributed in the more labile 1,3 positions of the triglyceride molecule would suggest one reason why palmitate-levels increase as lipids are mobilized. That this may be a more generalized effect is suggested by studies in which X-irradiated rats had higher liver palmitate-levels than their non-irradiated controls.

HÆMATOLOGY

In vitro Abnormality of the Blood in Von Willebrand's Disease correctable by Normal Plasma

VON WILLEBRAND'S disease is a familial hæmorrhagic disorder affecting both sexes and characterized by a prolonged bleeding time and a low level of antihæmophilic factor (AHF, factor VIII). The prolonged bleeding time is associated with abnormal *in vivo* platelet adhesiveness[1]. However, no *in vitro* abnormality has been detected in the factors believed to be essential for hæmostasis, such as platelet viscous metamorphosis[2] and aggregation of platelets by adenosine diphosphate (unpublished observation) and by collagen[3]. The platelet-aggregating ability of the patient's connective tissue is also unimpaired[3]. Recent reports have indicated that the abnormal bleeding time can be corrected by transfusion of fresh plasma or a plasma fraction[4–6]. This effect can only be tested in patients. Identification of an *in vitro* abnormality in von Willebrand's disease would facilitate purification of this plasma factor; it would also help to elucidate both the

pathological physiology of the disease and the normal physiology of hæmostasis.

During an examination of platelet adhesiveness by Hellem's method[7], it was found that the platelets of a subject with von Willebrand's disease did not adhere when fresh citrated blood was passed through a column of glass beads. The beads (Propper Co., Long Island City, New York), were soaked in 2 per cent sodium carbonate and then in sodium chromate–sulphuric acid cleaning solution before use. Columns were made of vinyl tubing (Becton, Dickinson and Co., Rutherford, New Jersey). After glueing with vinyl cement (Schwartz Chemical Co., Long Island City), air was drawn through the columns to remove any traces of cement solvent. In mixing experiments, 1 ml. citrated plasma, separated after 10 min centrifugation at 15,000*g*, was added to 3 ml. citrated blood.

Initial results were striking (Table 1). In three subjects with von Willebrand's disease, platelets did not adhere to the beads. Fresh normal plasma restored adhesiveness, whereas the patient's plasma was ineffective. By the end of October, all this batch of beads had been used once. A second batch was obtained from the same company but had almost certainly been manufactured at a different time from the first. The new batch, as well as beads obtained from Hellem's source, demonstrated only minor and inconstant differences between subjects *A* and *B* and normal individuals. Consequently, investigations were resumed on December 4 with the original beads which had been used and then washed again as before. The number of washings is not known, but increased as the beads were used again and again. On December 18 a trip was made to another city to examine the mother and sister of subject *A*, and an unrelated family (subjects *G*, *H*, *I*) in whom three generations could be tested. Only the mother of subject *A* demonstrated abnormal platelet adhesiveness. Afterwards, the beads no longer distinguished patients *A*, *B* and *D* from normal individuals. This is in accord with the results of O'Brien[8] and Cornu and Larrieu (unpublished observations).

Recent use of columns made of unwashed soft glass beads (Minnesota Mining Co., St. Paul, Minnesota) on subjects *A*, *B*, *E* and four additional patients with von Willebrand's disease gave an average platelet adhesiveness of 26·9 per cent ± *S.D.* 11·0, whereas in 11 normal subjects, adhesiveness averaged 39·2 per cent ± *S.D.* 7·5. The probability that this difference would occur by chance is 0·02. Data in Hellem's original work actually suggest that the adhesiveness of platelets is subnormal in von Willebrand's disease since adhesiveness was below 35 per cent in 11 of 15 patients with this disease, but it was below 35 per cent in only 22 of 104 observations on normal subjects. Hellem failed to comment on this difference, and attributed some of the adhesiveness values below the lower level of normal to subnormal hæmatocrits. Further study, I hope, will eliminate the unpredictability of the method and permit consistent demonstration of an *in vitro* abnormality in von Willebrand's disease correctable by normal plasma.

* All subjects had histories of excessive bleeding and normal platelet counts and hæmatocrits. All patients except *C* and *J* had prolonged Ivy bleeding times and AHF levels below 60 per cent of average normal. Normal range of AHF was 60–200 per cent.

† This patient had a long bleeding time but normal AHF and thromboplastin generation test on several occasions.

‡ Patient *A* is blood type O; patient *B*, type AB; normal *M*, type A. In subsequent mixing tests, both patient and normal subject were of same blood type.

§ This patient had true hæmophilia. His AHF level was about 4 per cent of normal, which is lower than any of our subjects with von Willebrand's disease. He was bleeding and probably had a low hæmatocrit. This may account for the low adhesiveness when the hæmatocrit was lowered still further by adding his plasma to his blood.

Immunoelectrophoretic Studies of the β_1-Hæm-binding Globulin (Hæmopexin) in Hereditary Hæmolytic Disorders

NEALE *et al.*[1] have demonstrated by paper electrophoresis a hæm-binding globulin in the β-globulin fraction of human serum. Since then, several investigators examined this protein[2-6], which was identified by immunoelectrophoresis with β_1-*B*-globulin and called hæmopexin[7]. On starch-gel electrophoresis the hæm-binding protein was found to migrate with the fast α_2-globulins[8,9]. Hæmopexin is present in the perchloric acid-soluble fraction of serum[7,10] from which Schultze *et al.*[11] obtained a highly purified preparation by combined ammonium sulphate precipitation and zone electrophoresis. Hæmopexin is a glycoprotein containing approximately 20 per cent carbohydrate and has a sedimentation rate of 4·8*S* corresponding to a molecular weight of approximately 80,000. The purified protein has a binding capacity of 15–20 mols hæmin per mol hæmopexin; evidence for binding of hæmoglobin or cytochrome *c* could not be obtained. The hæmin binding capacity of normal human serum is approximately 10 mg/100 ml. (refs. 2 and 9).

Information on the biological significance of this protein is limited. In the sera of several patients with hæmolytic disorders, ahaptoglobinæmia was associated with deficiency or absence of hæmopexin[1,9].

In the work reported here the sera of 38 children with hereditary hæmolytic disorders were examined. The material comprised 36 samples from 11 patients with hereditary spherocytosis, 35 samples from 19 patients with thalassæmia major, 11 samples from 8 patients with sickle-cell anæmia, and included 4 samples from 4 individuals with thalassæmia minor. Sera were obtained during periods of active hæmolysis; in 13 patients sera were studied before and at various times after splenectomy. In patients with spherocytosis, splenectomy results in almost complete cessation of hæmolysis, while in thalassæmia major the effect is incomplete and transient.

Vertical starch-gel electrophoresis was performed at *p*H 8·6 in borate buffer with a voltage gradient of 5 V/cm

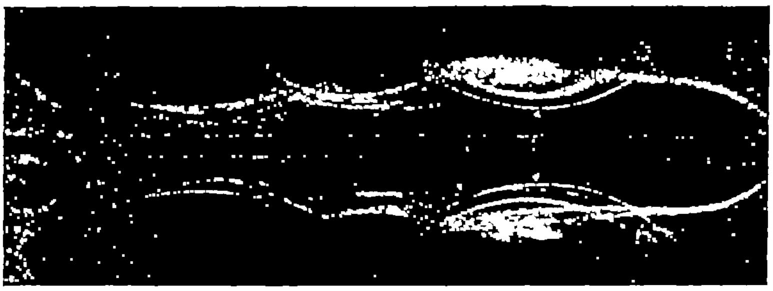

Fig. 1 Deficiency of hæmopexin ($\beta_1 - B$) in serum from a patient with thalassæmia major (upper part) is demonstrated by immunoelectrophoretic analysis. Normal serum is illustrated for comparison (lower part). The precipitation lines of hæmopexin ($\beta_1 - B$) and transferrin (Tf) are designated by arrows

for 16–18 h at room temperature[12]. Prior to electrophoresis, hæmolysate from normal individuals was added to the sera in amounts sufficient to saturate haptoglobin. The gels were sliced into two layers and stained for protein with amido black and for haptoglobin by the benzidine reagent. Sera which demonstrated a complete absence of peroxidase-positive haptoglobin bands were classified as ahaptoglobinæmic. Immunoelectrophoresis on agar gel was carried out on microscopic slides according to Scheidegger[13] in *p*H 8·2 barbital buffer and a voltage gradient of approximately 7 V/cm was applied for 80–100 min. Horse anti-serum against normal human serum No. 13411 from the Institut Pasteur, Paris, was used for the development of the precipitation lines. Samples were tested before and after addition of hæmolysates prepared from individuals with hæmoglobin A; they were stained for protein with azocarmine and examined for peroxidase activity with the benzidine reagent.

Fig. 1 illustrates the comparative immunoelectrophoretic analysis of sera from a patient with thalassæmia major and from a normal individual. In the patient's serum the precipitation line of hæmopexin ($\beta_1 B$) is absent. Experiments in which varying concentrations of serum and antiserum were used demonstrated that the absence of the precipitation line was due to a decrease of hæmopexin below the sensitivity of the method.

Table 1. HÆMOGLOBIN- AND HÆM-BINDING GLOBULINS IN HÆMOLYTIC ANÆMIAS. EFFECT OF SPLENECTOMY (SPL.)

Studied before and after spl.	5	2/5	0/5	5/5	4/5
Studied only after spl.	9	—	2/9	—	9/9
Thalassæmia minor					
Cases without spl.	4	0/4	—	0/4	—
Sickle-cell anæmia					
Cases without spl.	7	7/7	—	6/7	—
Studied only after spl.	1	—	1/1	—	0/1

The results obtained from 42 patients are summarized in Table 1. In all patients with spherocytic anæmia active hæmolysis was associated with ahaptoglobinæmia; a deficiency of hæmopexin was found in 4 of 8 patients studied before splenectomy. Decreased hæmolysis following splenectomy was associated with the reappearance of haptoglobin in some patients, and of hæmopexin in all patients studied. In thalassæmia major ahaptoglobinæmia was found only in 5 of 10 patients and hæmopexin deficiency in all patients examined. Following splenectomy haptoglobin reappeared in all cases. In contrast, the deficiency of hæmopexin persisted in 4 out of 5 patients studied, although in one individual a faint β_1-B-precipitate indicated the presence of small amounts of hæmopexin. A deficiency of hæmopexin was observed in 9 additional cases studied at various time-intervals after splenectomy, and was usually not associated with ahaptoglobinæmia. No abnormalities of the hæmoglobin and hæm-binding globulins were disclosed in thalassæmia minor. In sickle-cell anæmia all sera studied were ahaptoglobinæmic and 6 out of 8 cases were also deficient in hæmopexin.

Deficiency of β_1-hæm-binding globulin in hæmolytic disorders associated with ahaptoglobinæmia has previously led to the conclusion that β_1-hæm-binding globulin might represent an additional mechanism capable of eliminating hæmoglobin from the circulation. Although the possibility of hæmoglobin-binding to hæmopexin after complete saturation of haptoglobin has not been excluded, and indeed may explain the findings in spherocytosis and sickle-cell anæmia, binding of hæm appears to be the major function of hæmopexin[3,6,11]. The absence of detectable amounts of hæmopexin in the presence of haptoglobin as observed in thalassæmia major indicates that these two proteins have distinctive functions. Although it cannot be excluded that impaired synthesis of hæmopexin is responsible for the deficiency of this protein in thalassæmia, the observation that in one case of thalassæmia major the protein was present in decreased amounts suggests that this explanation is unlikely. Moreover, heterozygous individuals revealed no detectable abnormalities of hæmopexin. It is more probable that the deficiency of hæmopexin in hæmolytic disorders can be ascribed to the formation of a complex of hæmopexin with hæm or related protoporphyrins which is rapidly eliminated from the circulation. The deficiency of β_1-hæm-binding globulin in patients with thalassæmia major suggests that increased concentrations of a hæm compound may be present in this disorder. Further investigations are required to determine whether this compound is a normal or abnormal product of porphyrin metabolism.

This investigation was supported in part by U.S. Public Health Service grant No. 2A-5204.

Determination of Haptoglobin-groups Frequencies by Starch-gel and Agar-gel Electrophoresis : Application to Belgian and Barundi Populations

IT has been frequently stated that the determination of the haptoglobin groups of some subjects may be difficult, even by the Galatius-Jensen[1] method for detecting hæmoglobin–haptoglobin complexes with benzidine. Some 2–2 subjects with a low haptoglobin blood concentration may erroneously be considered as ahaptoglobinæmic[2]. It may also be hazardous to distinguish a subject lacking haptoglobin from one belonging to the 1–1 group, when Smithies's standard technique of starch-gel electrophoresis with borate buffer at pH 8·4 is used[3], since with this method the mobility of the hæmoglobin is nearly the same as that of the hæmoglobin–haptoglobin complex of the 1–1 pattern[4–6].

We have found that these difficulties can be overcome by using high-voltage electrophoresis in agar-gel according to Wieme's method[7,8].

The method was as follows: 1-mm thick agar-gels prepared with a barbital buffer (μ 0·05; pH 8·4), poured on 0·8 mm thick microscopic slides; identical buffer in tanks; 20 V/cm for 25 min; gel immersed in petroleum ether as sealer and refrigerant; detection of the hæmoglobin-containing fractions with a benzidine solution. This method is very different from Hirschfeld's method[9], who demonstrated the possibility of determining the haptoglobin groups by agar-gel electrophoresis; our technique will be described in detail elsewhere[10].

Fig. 1 shows typical results obtained in each of the haptoglobin groups.

Two fractions migrating towards the anode and one towards the cathode are detected: first, a fast-moving fraction of low concentration, likely to be hæmoglobin bound with methæmalbumin[11,12], which shows an albumin mobility by naphthalene black staining; secondly, a fraction corresponding to the hæmoglobin–haptoglobin complex; its mobility is different in each group, being the fastest in the 1–1 and the slowest in the 2–2 group; this fraction is lacking in ahaptoglobinæmic subjects; thirdly, migrating towards the cathode, a fraction with the same mobility in all the groups and representing free hæmoglobin.

Therefore this technique makes it possible: (1) to recognize with certainty the difference between 1–1 and ahaptoglobinæmic subjects, since free hæmoglobin is not superposed on the 1–1 haptoglobin fraction; (2) to distinguish 2–1 and 2–2 phenotypes of subjects with a low blood haptoglobin concentration because the hæmoglobin–haptoglobin complex is not spread out over several bands as it is on a starch-gel medium; (3) to recognize the haptoglobin type in 1–1, 2–1 and 2–2 subjects. Yet, for routine analysis, starch-gel electrophoresis seems the procedure of choice, since the electrophoretic mobilities of 2–1 and 2–2 hæmoglobin–haptoglobin complexes are very similar in agar-gel (Fig. 1).

With the combined techniques of starch-gel and agar-gel electrophoresis we have determined the haptoglobin groups frequencies in several populations:

(1) *Belgian population*. Blood specimens of 416 healthy Belgian adults, 141 of them living in Antwerp, were investigated. Table 1 gives the results and compares them with some data from the literature.

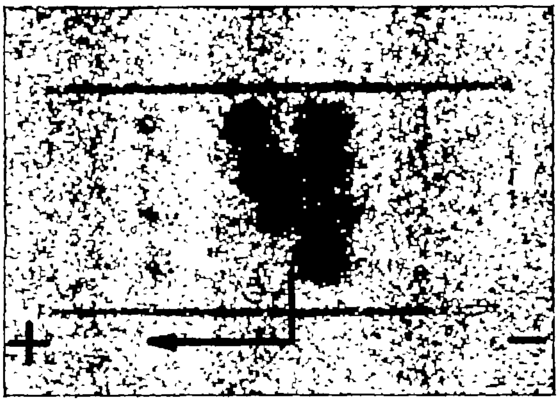

Fig. 1. Haptoglobin group patterns by agar-gel electrophoresis on microscopic slide (benzidine staining reaction). From above to below: 1–1, 2–1, 2–2 and 0–0 groups

Table 1

Populations	No. of subjects	Phenotypes (%) 1–1	2–1	2–2	0–0	Hp^1 gene frequencies[5]
Antwerp	141	17·0	47·5	35·5	—	0·407
Belgium	416	19·0	47·6	33·4	—	0·428
Sweden (ref. 11)	275	15 0	47·0	38·0	—	0·385
France (Paris) (ref. 13)	406	15 27	49·75	34·98	—	0·4015
Austria (Vienna) (ref. 14)	621	16·1	48·2	35·7	—	0·402
England (Oxford) (ref. 15)	218	10·1	55·5	31·7	2·7	0·406
Germany (Westphalia) (ref. 14)	201	19·9	46·8	33·3	—	0·433
Germany (Bavaria) (ref. 14)	273	19·4	54·2	26·4	—	0·465

The haptoglobin gene frequencies in the Belgian population are similar to those in other populations of Western Europe and more especially to the English and German ones, the German population showing the highest Hp^1 frequency ascertained in Europe[14]. No ahaptoglobinæmic subject was found among our samples of Belgian origin and the χ^2 test shows that the theory of two autosomal allelic genes[16] applies to these populations: Antwerp inhabitants: $\chi^2 = 0{\cdot}0420$, or $0{\cdot}90 > P > 0{\cdot}80$; Belgians: $\chi^2 = 0{\cdot}3241$ or $0{\cdot}70 > P > 0{\cdot}50$ for one degree of freedom.

(2) *Negro population of Burundi*. A sample of 182 healthy Burundi soldiers was examined; among them 86 had two Tutsi parents and 96 had two Hutu parents. Bahutu and Batutsi are the two most important ethnic groups of Burundi. Table 2 summarizes the results.

Table 2

	No. of subjects	Phenotypes (%) 1–1	2–1	2–2	0–0	2–1 *M*	Hp^1 gene frequencies[5]
Burundi	182	28·0	47·8	20·9	3 3	—	0·52
Tutsi	86	27·9	47·7	22·1	2·3	—	0·52
Hutu	96	28·2	47·9	19·8	4·1	—	0·52

From these results the following conclusions may be drawn: (1) The Hp^1 gene frequencies are not so high in Burundi populations as they are in Bantus living in West Africa ($Hp^1 = 0{\cdot}70$)[17] and in Western Congo ($Hp^1 = 0{\cdot}77$)[18]. (2) There is a low percentage of ahaptoglobinæmic subjects (0–0 group) in Burundi, with a frequency similar to that found in Senegalese (4·0 per cent)[1] and in American Negroes (4·2 per cent)[19]. The frequency is yet much inferior to that found in two Nigerian populations (Fulani: 50·0 per cent[20] – Noluba: 32·2 per cent[15]). (3) There is no significant difference in haptoglobin groups frequencies between Tutsi, who are of Hamitic origin, and Hutu, who are Bantus. (4) No 2–1 *M* pattern was found in our Burundi samples.

A Simple Screening Test for Waldenström's Macroglobulinæmia

THE most important characteristic which the pathological proteins in Waldenström's macroglobulinæmia have in common is the molecular weight defined by a sedimentation ratio within the range S 18–20.

The final diagnosis of Waldenström's macroglobulinæmia is therefore based on the demonstration of such a paraprotein by ultracentrifugation of the serum.

Immuno-electrophoresis with demonstration of a β 2M bow, hypo-β-2A- and hypo-γ-globulinæmia is a useful diagnostic aid. However, in routine laboratory work a screening test is needed. The Sia test is commonly used as such. In this test a drop of serum is added to a large amount of demineralized water. If cloudy precipitation occurs, the test is positive. However, the Sia test often gives a positive reaction in cases in which subsequent ultracentrifugation fails to reveal macroglobulins of the type characteristic of Waldenström's macroglobulinæmia. In rare cases, no precipitate is obtained although the serum does contain macroglobulins.

By the simple test described here it seems to be possible with greater probability to decide whether a given serum contains the proteins characteristic of Waldenström's macroglobulinæmia.

A slip of filter paper (Schleicher and Schull, 'Selecta' No. 2043, 39 mm × 310 mm) is moistened by dipping it into demineralized water. Excess water is allowed to drip off. The paper is placed on a plastic ladder (Fig. 1). The ladder with the paper is placed in the horizontal position and 10 µl. serum is applied as a streak across the paper, 8 cm from one end of the paper. That part of the paper to which the serum is applied is placed between two rungs of the ladder. After 1 min, the paper is removed to a glass plate, so that 5 cm of the paper at the end to which the serum was applied lies on the glass plate, while the rest is freely suspended. The glass plate is then placed in a jar containing demineralized water, so that the paper dips about 2 cm into the water (Fig. 2). The free end of the paper hangs down vertically into another jar with demineralized water, so that about 2 cm of it is immersed in the water. Water will then migrate (from the upper jar) through the paper past the serum streak. For this reason I have coined the term 'hydrophoresis' for the method. After 75 min, the paper is removed. It is stained with bromophenol blue in absolute alcohol for 20 min, after which excessive dye is removed by 2 per cent acetic acid. An intense blue stain is obtained by exposing the paper to strong ammonia.

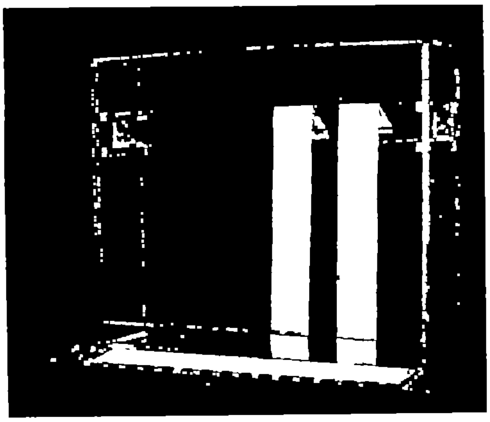

Fig. 1

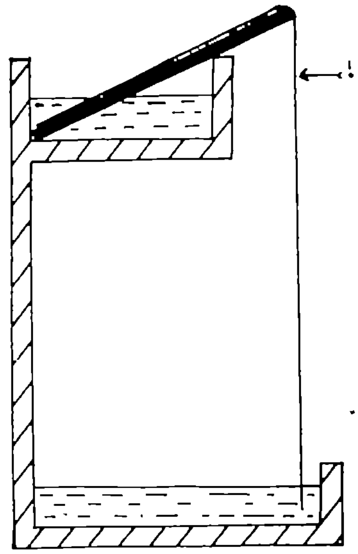

Fig. 2. Schematic drawing of the apparatus. The arrow indicates the side of the serum streak

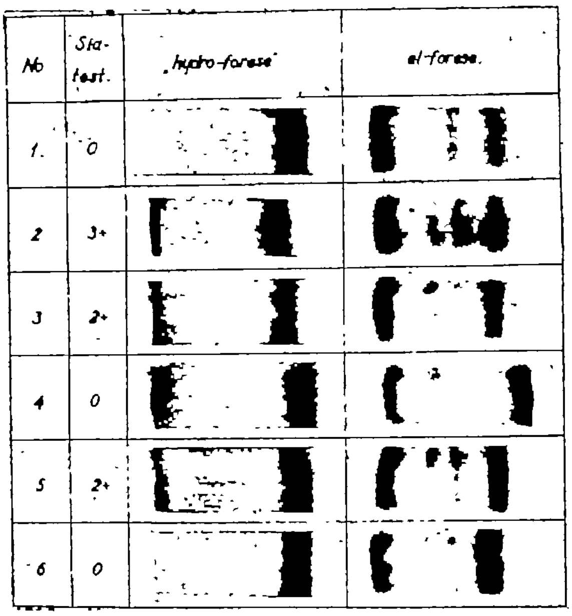

Fig. 3. The results of the Sia test are indicated by 0, 2+ and 3+

Sera from a number of healthy individuals were examined by this method. Uniform 'hydrophoretic' patterns with only slight variations were obtained. A pattern typical of a normal individual is shown in Fig. 3. No. 1. As a control measure, electrophoresis was also performed.

Two patients with Waldenström's macroglobulinæmia were studied. The diagnosis has been made after repeated demonstration of characteristic paraproteins by ultracentrifugation. In both cases, electrophoresis revealed an intensely stained band in the γ-fraction. The Sia test was strongly positive for both sera.

'Hydrophoresis' yielded identical results in these two patients (Fig. 3, Nos. 2 and 3), namely, a well-defined, densely stained, narrow band at the site of application, followed by a weakly stained area and, finally, a wide, diffusely defined band at the front.

If the paper is moistened with a 0·2 per cent aqueous solution of cysteine hydrochloride instead of demineralized water, the sharply defined band fails to appear at the site of application of serum. The Waldenstrom's macroglobulinæmia paraprotein is depolymerized by certain sulphydryl-rich compounds, for example, cysteine, to more low-molecular proteins, which are not precipitated in water at low ionic strength. The absence of precipitation after addition of cysteine is thus in support of the assumption that the proteins precipitated in the sharply defined band are 'Waldenström's macroglobulinæmia proteins'.

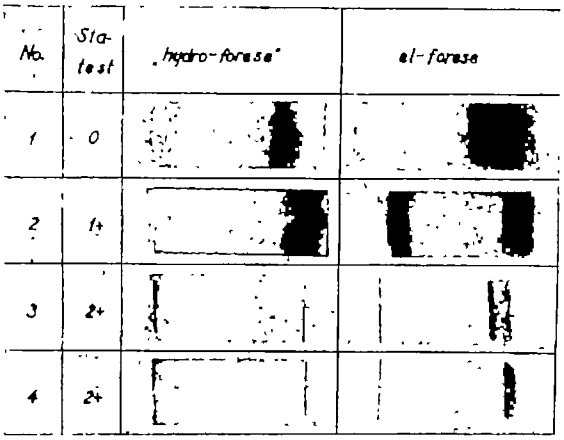

Fig. 4. The results of the Sia test are indicated by 0, 1^+ and 2^+

The sharply defined band which seems to be typical of Waldenström's macroglobulinæmia is not seen in myelomatosis. There is often relatively intense staining at the site of application, but it decreases over a wider area. In addition, distinct longitudinal stripes are often seen on the paper, and the wide band at the front may split up into two narrower bands (Fig. 3, Nos. 4, 5 and 6).

In hydrophoresis of a 10 per cent aqueous solution of human γ-globulin, moderate staining at the site of application occurs. The intensity of the staining decreases gradually along the paper, and a wide, diffusely defined band is seen at the front (Fig. 4, No. 1). In a patient with a large content of normal immune γ-globulin in the serum, a similar, but less pronounced, pattern was obtained (Fig. 4, No. 2). The serum from this patient was examined by ultracentrifugation, which failed to reveal an increase in the amount of macroglobulin. On the other hand, the Sia test was strongly positive.

Hydrophoresis was performed on sera from 50 patients with neoplastic disease. In none of these cases could the results obtained be mistaken for those typical of Waldenstrom's macroglobulinæmia.

In order to throw light on the characteristics of the precipitate obtained by the Sia test the following experiment was performed. To each of four centrifuge tubes with tapered bottoms containing about 10 ml. of demineralized water were added three drops of serum. After centrifugation and decanting of the supernatant the precipitate was re-dissolved in a small amount of physiological saline. Electrophoresis and hydrophoresis were then performed on this solution. In a patient with Waldenstrom's macroglobulinæmia (Fig. 3, No. 2), hydrophoresis now again revealed a sharply defined narrow band at the site of application, but otherwise no staining of the paper (Fig. 4, No. 3). By similar treatment of serum from a patient with myelomatosis (Fig. 3, No. 5), on which the Sia test was positive, hydrophoresis yielded only moderate staining at the site of application and an even decrease in the intensity of the staining of the paper (Fig. 4, No. 4).

The test, which may be reproduced with fairly good accuracy, seems to permit a semi-quantitative measure of the amount of macroglobulin in the serum.

Moreover, we find that it is of value that the result can be filed for comparison with subsequent tests in the same patient.

PATHOLOGY

Growth of Transplantable Cancer in Rats previously injected with Placental Tissue

An antigen in malignant and embryonic tissues capable of retarding the growth of a transplantable human tumour (HS_1) in rats has recently been described by Buttle *et al.*[1]. Seven days after injecting a variety of human tumours and normal adult and fœtal human tissues into weanling rats, they challenged the animals with HS_1 and cortisone. Significant inhibition of tumour growth was produced by prior injection of homogenates of HS_1, sarcomata and a variety of normal fœtal tissues, especially spleen, whereas normal adult plasma and muscle had little if any effect. Buttle *et al.* attributed these findings to a labile antigen, destroyed by freezing and thawing, present in high concentration in embryonic and malignant tissue, and related to a high rate of cellular division in those tissues.

On the basis of its normally rapid growth, placental tissue was tested for its ability to inhibit tumour growth in rats. Interspecific differences and modifying effects of adrenal corticosteroids were eliminated by challenging the rats with a suspension of tumour obtained from other animals of the same strain, without administration of cortisone. In all cases the tumour used was the so-called chorionepithelioma induced by Stein in 1960, and still highly malignant, though considerably different histologically from the original[2].

Wistar albino rats weighing 90–150 g received injections of 0·2–0·3 ml. of a 40 per cent suspension of placental extract in saline intraperitoneally. Placental tissues from the same strain of rat were obtained from dated pregnancies of each day of gestation from the seventh to the twenty-first (term). The tissue was removed from the uterus at hysterectomy and immediately minced and passed through a gauze strainer, avoiding contamination with other fœtal tissues, blood and decidua. Two weeks after placental injection, the animals and an 'unimmunized' control received 0·2 ml. of a 40 per cent tumour suspension in saline intraperitoneally. A group of five animals and a control were used to test the effect of placental tissue of each day of gestational age.

Table 1. Effect of intraperitoneal injection of rat placenta on the growth of transplanted 'Chorionepithelioma' in the rat. Criterion for inhibition is absence of tumour masses 2 cm. or more in diameter and of metastases 14 days after transplantation

Series Albino Wistar	Immunizing injection of placental homogenate	Experimental group inhibition (per cent)	Control group inhibition (per cent)
I	40 per cent suspension, age 7–21 days, warm	4/70 = 5·7	1/15 = 6·7
II	Full-strength, age 7–21 days, warm	13/68 = 19	2/15 = 13
III	Full-strength, age 10–20 days, warm and cold (4° C)	1/80 = 1·2	1/20 = 5·0
IV	Full-strength, age 16 days, warm and cold	1/8 = 12*	1/8 = 12*
II–IV	Summary of groups receiving full-strength	15/156 = 9·6	4/43 = 9·3
I–V	Summary of entire series	19/226 = 8·4	5/58 = 8·6

* These animals were born of tumour-bearing mothers from the first series

The chorionepithelioma ordinarily causes death of the rat in 12–14 days after transplantation, autopsy revealing masses 4 cm in diameter and extensive metastases. Our criterion for inhibition of growth was survival of the host for 14 days, without evidence of a mass 2 cm or more in diameter or of metastases at the time of necropsy or laparotomy. In the initial series, only 4 of the 70 test animals and 1 of the 15 controls met the criterion of inhibition. The experiment was repeated, changing the placental preparation from a 40 per cent suspension to a full-strength homogenate. In the second series, 13 of the 68 test animals (those receiving placenta of 10, 12 and 17 days of age) showed inhibition of tumour growth. The control animals in the 12 and 17 day groups, however, also showed inhibition, implicating the tumour itself as the variable in these cases. A third series of rats received full-strength placental injections of tissues from 10 to 20 days of gestational age. Half the animals and appropriate controls were treated exactly as in the second series; the other half of the test animals received injections of placental tissue that had been stored at 4° C for 24 h after removal from the uterus. Again, except for one animal in the 17-day-old group (cold) and the control from the same group, there was no inhibition of tumour growth in the third series. A final experimental group consisted of 16 weanlings delivered by Caesarean section of mothers which were alive but bearing large tumours on the 14th day after transplantation in the initial experimental series. Four animals received 16-day placenta warm and four received the same type of preparation cold; equal numbers of test and control animals were used in this group. Here too only one test animal and one control (cold group) met the criterion of inhibition. The combined experimental results are presented in Table 1.

It appeared that prior intraperitoneal injection of placental extract into rats, whether in 40 per cent or full-strength suspension, and whether warm or cold, had no effect on the growth of transplantable rat chorion epithelioma, nor did animals born of the tumour-bearing mothers manifest resistance to that tumour. Finally, there was no critical developmental age of the placenta at which differences in its protective function against tumour growth could be demonstrated. No prediction is made, however, regarding the possible effect of human or other heterologous placental tissue on the growth of transplantable tumours in the rat.

Normal Mitotic Activity and Karyotype of Leucocytes from Pernicious Anæmia Patients cultured in Vitamin B_{12}-deficient Medium

IN vitamin B_{12}-deficiency there are profound alterations in the metabolism of the cell nuclei, as shown by the megaloblast phenomenon, the increase in the nuclear size in various tissues, and the hypersegmentation of the peripheral granulocytes. The basic cause of these phenomena appears to be blocked replication of deoxyribonucleic acid and cell division[1,2].

It occurred to us that owing to deficiency in vitamin B_{12} the peripheral leucocytes of patients with manifest pernicious anæmia might behave abnormally, for example, fail to divide, in the cell culture system used in our laboratory for cytogenetic studies, especially if the medium were made deficient in 'anti-pernicious anæmia' factors.

Another reason for performing this work was that recently doubt has been cast on the finding of Court Brown *et al.*[3] that the chromosomes of patients with untreated megaloblastic anæmia are normal. In an investigation of 100 mitotic plates from patients with pernicious anæmia, Astaldi *et al.*[4,5] found frequent deviations from the normal, both regarding chromosome number and morphology.

Four female patients with untreated pernicious anæmia were used. Peripheral blood was withdrawn into heparin and the leucocytes were separated from the erythrocytes with the aid of phytohæmagglutinin[6]. The suspension of viable leucocytes in the patient's own plasma was then used for preparing leucocyte cultures[7]. The final medium in which the leucocytes were grown consisted of: (1) 20 per cent of the patient's own plasma; (2) 80 per cent culture medium; (3) a small amount of phytohæmagglutinin; (4) some heparin. Four different culture media were used, namely: (1) Parker's solution containing minerals, amino-acids, vitamins and antibiotics; (2) a modified Parker's solution without vitamins and antibiotics; (3) Hanks's solution containing minerals and sugar; (4) Dulbecco's solution containing inorganic salts only.

The microbiological vitamin B_{12} activity was assayed with *Euglena gracilis* and found to be 12 and below 1 μμg per ml., respectively, in cases 3 and 4. Using the same method, the components other than the serum in the culture fluid were found to contain no detectable amount of vitamin B_{12} activity if media 2–4 were used. Thus, the vitamin B_{12} content of the culture fluid was about 2·4 μμg and below 0·2 μμg per ml., respectively, in cases 3 and 4 in those flasks where media 2–4 were used.

Leucocytes from case 2 were taken and cultured twice, and in the other cases cultures were made on one occasion only. Incubation at 37° C for 72 h gave excellent growth of the leucocytes and after colchicine treatment good yields of mitoses were obtained in all the cases and with all the media. The incidence of mitoses was perhaps even higher than in normal subjects. In no case was the growth less abundant in those flasks which contained minimal amounts of vitamin B_{12} activity.

We conclude that leucocytes from the peripheral blood of patients with pernicious anæmia are capable of growth and mitotic division in the presence of extremely low amounts of vitamin B_{12}. It is also remarkable that the very simple inorganic salt solutions are sufficient as culture media in short-term cultures of leucocytes. Thus it is quite unnecessary to use the very rich and more expensive media usually recommended.

Table 1 presents the incidence of different chromosome counts in the four patients. The frequency of aneuploidy is low (14 aneuploid cells among 351 examined) and tallies with the results of a similar study on 20 normal females in this laboratory[8]. Detailed analysis of altogether 28 mitotic cells of excellent quality with the modal number 46 from the four different subjects failed to display anything abnormal in their chromosome morphology. Thus, in contrast to the results of Astaldi *et al.*[4,5], the karyotypes of our four patients with pernicious anæmia were entirely normal.

Table 1. DISTRIBUTION OF CHROMOSOME COUNTS FROM FOUR PATIENTS WITH UNTREATED PERNICIOUS ANÆMIA

Case No.	No. of chromosomes							
	< 44	44	45	46	47	48	> 48	Total
1	—	1	1	98	—	—	—	100
2	—	1	2	74	—	—		77
3	—	—	2	66	—	1	—	69
4	1	1	3	99	1	—	—	105

A few erythrocytes are always present in the leucocyte suspensions separated with phytohæmagglutinin. However, erythrocytes from patients with pernicious anæmia contain less vitamin B_{12} than those of normal subjects[9]. The number of erythrocytes was very small in our cultures (macroscopically mostly not detectable), and the red cells are not destroyed during treatment and culture. Therefore, their content of vitamin B_{12} can be neglected as a source of it. Thus, the leucocytes grow and divide in a medium containing exceedingly small amounts of vitamin B_{12} as determined by microbiological assay. It has been shown that the majority of the mitoses seen after 72 h are probably primary, that is, mitoses of blood cells originally present[10]. It may be anticipated, however, that some of the mitoses at 72 h have started in daughter cells of those originally present. Long-term cultures may indicate whether these vitamin B_{12}-deficient daughter cells are then able to subdivide further.

Transfer of Stimulation of Deoxyribonucleic Acid Synthesis in Antigen-stimulated Rabbit Spleen Cell Cultures

LITTLE is known about the nature of the antigenic stimulation to antibody production or the manner in which antigen reaches the necessary site of stimulation. A recent report[1] implicates the sequential action of at least two different types of cells. One type is a mononucleated cell with phagocytic activity, and the other a non-phagocytic cell belonging to the lymphocytic series. Fishman suggests that an RNase sensitive material is transferred from one to the other, and it has been suggested[2] that complexes between antigenic fragments and RNA may play an important part in antibody formation. A physical means whereby such a transfer might occur[3,4] has been reported. This communication reports some preliminary experiments which were designed to demonstrate a transfer of antigenic stimulation from one cell culture to another.

It has been shown[5] that DNA synthesis in spleen cell preparations from previously immunized rabbits is stimulated *in vitro* by the addition of antigen. Furthermore, only brief contact with the antigen is required for stimulation[6]. After washing, less than 0·1 per cent of the added antigen remains. In contrast, 1 per cent of the original amount (or 10 times the amount remaining after washing) of the antigen added to fresh cells is too little to produce stimulation.

This system has been used here to test whether cells 'primed' by brief contact with antigen are able to transfer stimulation to fresh cells from the same spleen. In these experiments, the response of the 'primed' cells was inhibited by irradiation or freezing and thawing. The design of the experiments and results are presented in Table 1.

Table 1. TREATMENT OF CELLS

Spleen cell suspension from immunized rabbits

C	618	
C + *C*	1,144	(1,236)
CR	71	
C + *CR*	579	(689)
P	5,168	
P + *P*	10,600	(10,336)
PR	253	
C + *PR*	3,200	(871)
PF	1,503	
C + *PF*	6,143	(2,121)
CR + *PR*	621	(324)
CR + *P*	5,087	(5,239)
C + *P*	7,737	(5,786)

(*P*) 'Primed' cells. (*C*) 'Control' cells. (*PF*) 'Primed' frozen cells. (*PR*) 'Primed' irradiated cells. (*CR*) 'Control' irradiated cells.

Part of the cell suspension (3×10^8 cells) was incubated with 3 mg/ml. of human serum albumin labelled with iodine-131 for 15 min at 37° C. The cells were washed three times in 5 ml. of medium/wash. Determination of residual radioactivity showed that less than 0·2 μg labelled human serum albumin remained/cell culture. Such cells are designated 'primed' cells (*P*). 'Control' cells (*C*) were treated identically, except they were not exposed to antigen. One portion of the 'primed' cells received a dose of 300 rads, and these were called 'primed irradiated' cells (*PR*). 'Control irradiated' cells (*CR*) were similarly prepared. In addition, another portion of 'primed' cells were frozen and thawed once to give 'primed frozen' cells (*PF*).

Cultures of such cells were incubated alone or in various combinations, and the rate of DNA synthesis was measured in the second 24-h period, as previously described[5]. The figures represent the total c.p.m. incorporated/culture during 24-h incubation with ^{14}C-thymidine. The figures in parentheses in Table 1 indicate the expected results of combinations calculated from the figures for single cultures. The results which show evidence of transfer have been underlined.

A definite enhancement of DNA synthesis was observed when 'primed' cells were incubated with control cells. This was clearly shown when DNA synthesis had been inhibited in the 'primed' cells. There was no enhancement of DNA synthesis when 'control' irradiated cells were added to 'control' cells or to 'primed' cells. The enhancement of DNA synthesis obtained when 'primed' cells, which had been frozen and thawed, were added to 'control' cells demonstrated that it is the 'control' recipient cells which respond.

The results of a single experiment are presented, but identical findings were obtained in all of three other experiments using other antigens. The enhancement of DNA synthesis was only observed when the animal had been previously immunized to the antigen. The system is therefore antigen specific.

Although the results are preliminary, two positive statements can be made.

(1) The 'primed' irradiated cells contain some factor capable of stimulating DNA synthesis in control recipient cells.

(2) The presence of this factor is dependent on contact of the 'primed' cells with specific antigen.

The nature of this transfer factor, and the cells concerned, need further investigation before definite conclusions can be drawn. At least three possibilities exist: (*A*) The minute quantity of antigen taken up represents an extremely potent fraction of the original antigen preparation. (*B*) The antigen taken up has had its antigenicity enormously enhanced. (*C*) The cells taking up the antigen hand on some material, other than antigen, which is capable of stimulating cell division. Such a material need not necessarily retain the antigen specificity.

Malaria and Glucose-6-phosphate Dehydrogenase Deficiency

DRS. C. Kidson and J. G. Gorman[1] report observations on frequencies of glucose-6-phosphate dehydrogenase (G6PD) deficiency in different parts of New Guinea and New Britain, which make a welcome addition to our knowledge of the population genetics of this area. They note that low frequencies of G6PD deficiency occur in some populations living in malarious parts of New Guinea, New Britain and elsewhere. On the basis of this fact, and a report[2] suggesting that "no significant difference in *Pl. falciparum* parasite densities occurs between affected and normal children under 3 years of age in Thailand and that affected children in this age-group may have higher densities of the non-lethal *Pl. vivax*", Kidson and Gorman issue "a challenge to the concept of selection by malaria in glucose-6-phosphate dehydrogenase deficiency".

In assessing these arguments it must be recalled that there is substantial evidence that the G6PD-deficiency gene carries with it disadvantages owing to hæmolysis in the neonatal period and later life[3]. Theoretical considerations establish unequivocally that the G6PD-deficiency gene could not have become common without some advantage[4]. This conclusion is not, in fact, disputed by Kidson and Gorman: the question at issue is the nature of the advantage. As pointed out previously[3], the only convincing argument from gene distribution against the malaria protection hypothesis would be the finding of high frequencies of abnormal hæmoglobin or G6PD-deficiency genes among populations known to have lived for long periods in malaria-free environments. No such populations have yet been found to exist. The converse argument carries very little weight, since there are many reasons why the G6PD-deficiency gene might not have attained high frequencies in populations exposed to malaria, including relatively recent introduction of the gene and unusually severe selection against it. The approach to genetic equilibrium may have progressed to different stages in different populations living in New Guinea and New Britain. The remarkable thing about the distribution of G6PD deficiency is not that it should occasionally be rare among populations living in malarious regions but rather that it should so often be common in such populations. Its distribution is much more widespread, for example, than that of hæmoglobins S, C or E.

Kidson and Gorman also report figures for G6PD-deficiency in Eastern New Guinea showing an inverse relationship with altitude among all populations tested, from low frequencies in the malaria-free highlands to high frequencies at the coast. Although conceding that these observations could be explained by malarial selection, they suggest that it is "equally possible that this pattern may in fact be the result of spread from a large gene pool on the coast near the river mouth, with dilution and diminution of the gene frequency towards the highlands". However, precisely analogous clines are seen in Sardinia[5] and in several different parts of Africa[6,7], where single foci of origin are very improbable, and in every case high frequencies of the enzyme-deficiency gene are confined to the malarious regions. In both New Guinea and Africa the cline involves several different linguistic groups which have probably, as Kidson and Gorman point out, maintained their separate identity for long periods of time.

The evidence of Kruatrachue and Harinasuta from Thailand[2] is available only in abstract form. Although it does not support the malaria protection hypothesis, neither does it provide critical evidence against the concept of protection against *P. falciparum*. The numbers involved are small (it can be calculated that one group of young children with enzyme deficiency and *P. falciparum* malaria would have included about 10 subjects and the other about 7 subjects; and the numbers with *P. vivax* malaria would have been slightly lower). It is remarkable that even in such small numbers a statistically significant excess of *P. vivax* should have been found in enzyme-deficient subjects (although there was no difference in parasite counts). This parasite preferentially attacks young erythrocytes with high enzyme activities, and no protection by G6PD deficiency would be expected. Hæmolysis as a result of *P. vivax* infection might well reduce the mean erythrocyte age, and increase susceptibility to subsequent infection with *P. falciparum*, so obscuring the difference between normal and enzyme-deficient subjects which is more obvious where *P. vivax* is less frequent.

Both our own observations in East Africa[8] and those of Gilles *et al.* in West Africa[9,10] have shown a significantly lower incidence and count of *P. falciparum* parasites in young children with enzyme deficiency than in children with normal enzymes. Moreover, in Gilles's investigations the incidence of cerebral and other complicated forms of malaria was significantly lower in enzyme-deficient subjects than in those with normal enzymes, providing direct evidence that the former are protected against the potentially lethal effects of falciparum malaria.

Finally, Kidson and Gorman argue that other parasitic diseases, in addition to variable degrees of nutritional inadequacy, are associated with climatic differences and might influence G6PD-deficiency rates. The situation is certainly complex, as already emphasized[3], and many factors might produce selection against the enzyme-deficiency gene. But in searching for the compensatory advantages required by genetic theory attention is directed first to erythrocytes, where the difference in G6PD activity between normal and affected subjects is much greater than in other tissues, and where there are good reasons for supposing that G6PD deficiency would limit multiplication of malaria parasites[3,4]. That protection against *falciparum* malaria exists has been shown by carefully conducted field investigations, the results of which cannot be seriously challenged by evidence of the type presented by Kidson and Gorman. Malaria may perhaps not be the only factor favouring the enzyme-deficiency gene, but it is an important factor, and no one has yet been able to offer any specific alternative.

Skin Reactions in Neurological Patients after Intracutaneous Administration of Proteolipid A extracted from Human Brain

EXPERIMENTAL allergic encephalomyelitis as produced in monkeys, dogs, rabbits, guinea pigs and mice serves as an experimental model for the demyelinating diseases occurring in man. Such a form of encephalomyelitis can be reliably produced using either whole brain, whole white matter or diverse extracts derived from white matter. Among the latter, an especially potent effect has been ascribed to proteolipid A, which may be extracted from white matter following the procedure of Folch and Lees[1]. Kies and Alvord found this compound highly antigenic although not quite so potent as whole brain when they produced the experimental disease[2]. Åström and Waksman[3] and Waksman[4] demonstrated that experimental allergic encephalomyelitis follows the pathogenic pattern of a delayed-type hypersensitivity reaction. These authors observed a delayed reaction against myelin antigen in the diseased guinea pig, and transmitted the disease through lymphocytes from a diseased donor rabbit to a healthy recipient. So far, however, it has proved impossible to elicit a positive skin reaction against whole brain or myelin antigen in two series of human patients who were suffering from demyelinating disease of the central nervous system[5,6].

In the present investigation two different preparations of proteolipid A derived from two patients without organic brain disease were tested. The proteolipid was administered in three concentrations: (1) 0·05 mg/c.c., (2) 0·5 mg/c.c., and (3) 1 mg/c.c. The antigen was suspended in normal sterile saline and injected intracutaneously into the skin of the forearm in a final volume of 0·2 c.c. A control injection of 0·2 c.c. normal sterile saline was given simultaneously into the skin of the opposite forearm. The patients were observed up to four days after injection. The ensuing reaction was recorded as to strength and size and biopsies were taken at the height of the reaction. Twenty-four patients were tested. Twenty-one of these suffered from multiple sclerosis, one from syringomyelia and two neurotic patients without demonstrable neurological findings served as controls. The diagnosis was based in each case on careful clinical study and the result of spinal fluid electrophoresis.

As can be seen from Table 1, fifteen out of twenty-one patients with multiple sclerosis, one patient with syringomyelia and two neurotic patients gave a positive skin test. The observable reaction never fulfilled the criteria of a delayed hypersensitivity reaction. In all instances it consisted of a diffuse, poorly demarcated area of erythema without induration (Fig. 1) which appeared 3–4 h after injection and vanished again after various time intervals (54 h in two extreme cases, 36–48 h in two others). Histologically, the reaction was characterized by oedema of the sub-epidermal connective tissue and dense perivascular cellular infiltrates composed of lymphocytes interspersed with neutrophils (Fig. 2). The proteolipid preparation extracted from the brain of the second patient proved more potent than the first since it was effective in all cases tested. The fact that two patients without demyelinating disease of the central nervous system developed a positive reaction casts considerable doubt on the specific character of the phenomenon. In these control cases, however, the erythema disappeared much faster than in the cases of multiple sclerosis and the case of syringomyelia.

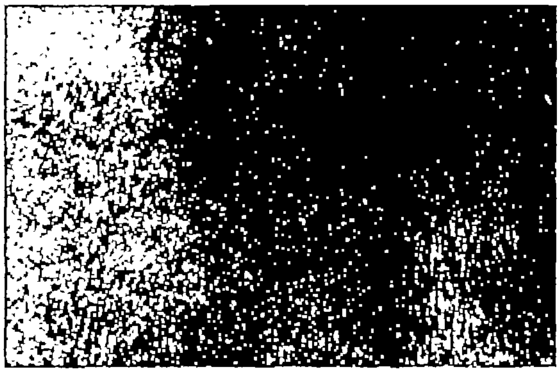

Fig. 1

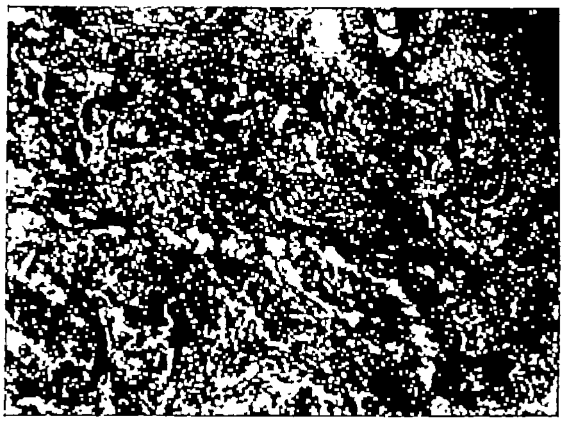

Fig. 2

While these results do not favour the view which considers multiple sclerosis a delayed-type hypersensitivity reaction against myelin antigen, some immunological process may very well be involved. Further investigations with various antigen preparations using larger numbers of patients appear to be justified.

HISTOCHEMISTRY

Serotonin in Human Mast Cells

It has been demonstrated that, besides heparin and histamine, mast cells contain serotonin (5-hydroxytryptamine, 5-HT)[1–3]. However, serotonin-containing mast cells, having been found exclusively in mice and rats, it has been held that human mast cells contain no serotonin[4]. Evidence that the mast cells in these two species contain serotonin has been obtained by parallel histological and biochemical investigations and also by serotonin assay in isolated mast cells. Yet hitherto available techniques have failed to disclose direct histochemical proof of the presence of serotonin in mast cells, mast cells in mice and rats lacking the so-called enterochromaffin reactions.

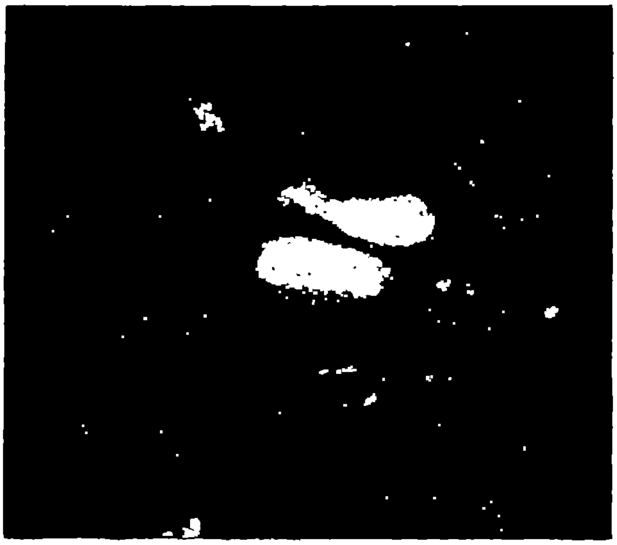

Fig. 1. (× 1,800)

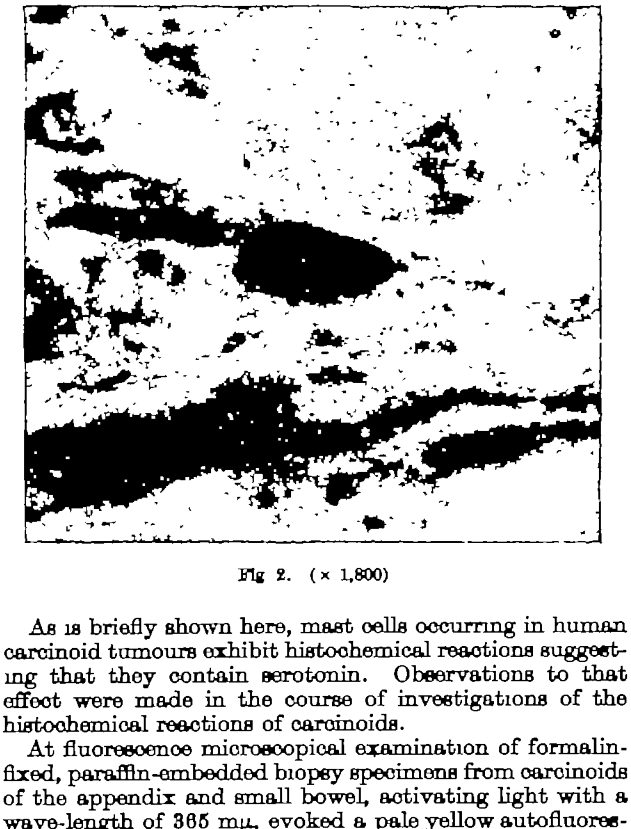

Fig 2. (× 1,800)

As is briefly shown here, mast cells occurring in human carcinoid tumours exhibit histochemical reactions suggesting that they contain serotonin. Observations to that effect were made in the course of investigations of the histochemical reactions of carcinoids.

At fluorescence microscopical examination of formalin-fixed, paraffin-embedded biopsy specimens from carcinoids of the appendix and small bowel, activating light with a wave-length of 365 mμ, evoked a pale yellow autofluorescence from the clumps of tumour cells as well as from cells situated in the interstitial connective tissue. Enterochromaffin cells in normal intestinal mucosa showed autofluorescence of similar colour. Some of the biopsy specimens included interstitial cells exhibiting positive argentaffin (hot methenamine method), alkaline diazo (fast red *B* and fast garnet *GBC*) and Schmorl's reactions. The fluorescent interstitial cells could be identified as mast cells by photographing fields containing such cells in the fluorescence microscope and then, after staining the sections with toluidine blue and May-Grünwald-Giemsa, re-photographing the same fields in regular transmitted light. In a representative pair of such photomicrographs Fig. 1 depicts a fluorescence photomicrograph displaying two fluorescent cells, one located peripherally in a cluster of tumour cells, the other in the interstitial tissue. Fig. 2 represents the same field as it appears in transmitted light after May–Grünwald–Giemsa staining. It will be seen that the cell situated just outside the tumour mass contains methachromatic granules and, accordingly, must be a mast cell. In mast cells with a few widely scattered granules, it could be perceived that the fluorescent as well as the diazo-positive substances were localized to these granules.

One of the specimens examined is especially interesting because it reveals that large numbers of mast cells with positive enterochromaffin reactions may occur even in so-called anargentaffin carcinoids. This specimen was from an appendiceal carcinoid in which the tumour cells showed a negative argentaffine reaction and a weakly positive diazo reaction. Conversely, the interstitial tissue was the site of a large number of fluorescent mast cells with positive diazo, argentaffin and Schmorl's reactions.

The so-called enterochromaffin reactions shown by enterochromaffin cells and carcinoid cells after fixation in formalin have been proved to be caused by a phenolic hydroxyl group, probably a form of tetrahydro-4-carboline[5,6]. Considerable evidence suggests that the substance that reacts with formalin is serotonin[7]. It has been assumed that mast cells in mice and rats have a serotonin content lower than the sensitivity threshold of the enterochromaffin reactions[8]. My results suggest that, under conditions of enhanced serotonin secretion, human mast cells are capable of storing histochemically demonstrable amounts of serotonin. Apparently the serotonin is localized to the granules of such mast cells rather than to the intergranular substance, as postulated in the case of mice and rats[9]. It remains to be seen whether carcinoids containing mast cells with positive enterochromaffin reactions constitute a special type of tumour or if all carcinoids normally contain such mast cells. Another interesting problem is whether the mast cells elaborate their own serotonin or merely store serotonin that has been elaborated by the tumour cells.

RADIOBIOLOGY

Quantitative Determination of Oxygen-18 by Activation Analysis

RADIOACTIVE isotopes of carbon and hydrogen are available for exchange and mechanism studies investigation in biology, but work on oxygen must use the stable isotopes oxygen-16 and -18. The ratio of these stable isotopes can be determined with mass spectrometer or density methods.

Activation analysis is a frequently used technique for the determination of trace elements in biological materials[1]. The reaction $^{16}O(T:n)^{18}F$ has been used for the analytical determination of oxygen[2]. Similar results with the $^{16}O(n:2n)^{15}O$ and the $^{16}O(n:p)^{16}N$ reactions have been reported by Meinke *et al.*[3,4], and the $^{16}O(\gamma, n)^{15}O$ reaction has been utilized by Beard *et al.*[5]. These methods, however, are only useful for the determination of gross oxygen content. Activation analysis of oxygen-18 by the reaction

$^{18}O(p,n)^{18}F$ has been reported by Fogelstrom-Fineman *et al.*[6] who used oxygen-18 as a tracer for studying photosynthesis in algae. In general, little use has been made of thermal neutrons in the reaction $^{18}O(n,\gamma)^{19}O$ for activation analysis because of the small cross-section (0·00021 barns) of oxygen-18 and the short half-life (29·5 sec) of the resulting nuclide.

Recent measurements show that the determination of ^{18}O and $^{18}O/^{16}O$ ratios by activation analysis with reactor neutrons is practical. Samples of water with oxygen-18 concentrations ranging from 0·20 atom per cent (natural abundance) to 10·79 atom per cent were irradiated for 4 min (0·9964 of saturation activity) in a thermal neutron flux of 7·2 × 10^{10} neutrons/cm^2 sec. The pneumatic 'rabbit' system in the University of Florida Training Reactor was used for the irradiations. Irradiated samples were transferred to fresh sample containers in order to avoid spurious radioactivity, and counting was started within 30–40 sec after removal from the reactor. Preliminary results, obtained with a multichannel analyser, showed only the requisite 0·20 MeV and 1·35 MeV photopeaks characteristic of oxygen-19. Actual analytical results were obtained by a different procedure. Photons were detected with a 2 × 2 in. cylindrical well-type sodium iodide (Tl) crystal, amplified by the usual photomultiplier, and fed into a single channel analyser which was set to bracket either the 0·20 MeV or the 1·35 MeV photopeak. Output data were handled in two different ways.

In the first method, the pulses were fed into an amplifier, Brush model *RD*–5621–00, followed by an oscillograph, Brush model *RD*–2321–00. The recorded results for each sample were corrected for background, fitted with an exponential decay curve by the method of least squares and extrapolated to give the activity at the time of removal from the reactor. This standard activity plotted as a function of the mass of oxygen-18 present in the sample is shown in Fig. 1. The upper detection limit was established by the size of sample which overloaded the amplifier, and the lower limit was established by insufficient activity. The mean deviation from the linear plot is 7·9 per cent.

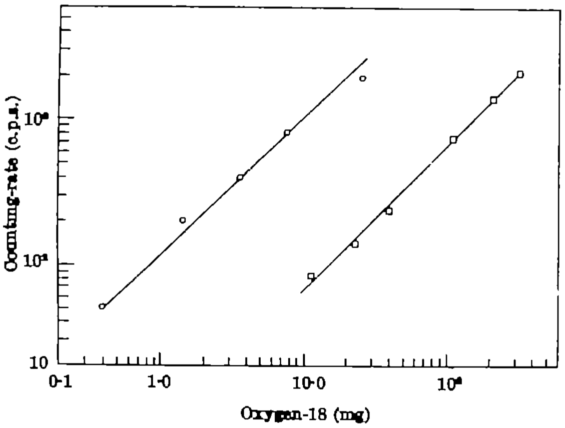

Fig. 1. Maximum activity of samples of oxygen-18. ○, 0·197 MeV photopeak; □, 1·35 MeV photopeak

In the second method, a scaler was used for obtaining the integral number of counts observed from 40 to 160 sec after the sample was removed from the reactor. Results obtained by this method are shown in Fig. 2. The mean deviation is 13·9 per cent.

The sensitivity of the method can be improved by the use of higher neutron fluxes. The minimum amount of oxygen-18 detectable with our equipment was approximately 350 µg, but a flux of 10^{14} neutrons/cm^2 sec would decrease this limit to 0·2 µg.

The thermal neutron activation of oxygen-18 can definitely be used as an analytical method for $^{18}O/^{16}O$ isotope ratio studies. This method is particularly useful for oxygen metabolism studies in living systems, and, since radioactivity is introduced after both the experiment and subsequent separations are completed, results are not obscured by possible effects of ionizing radiation on the system under investigation.

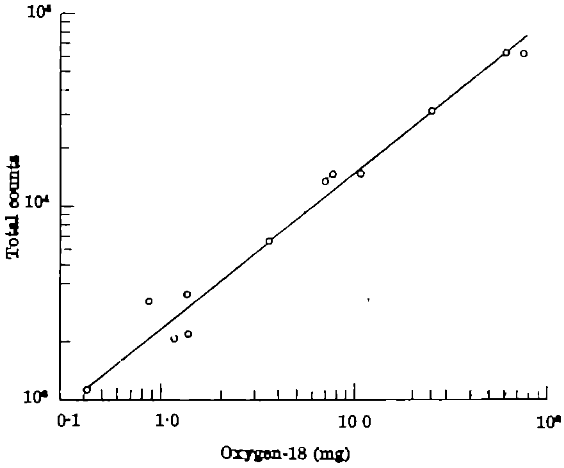

Fig. 2. Counts observed between 40 and 160 sec after removal from reactor

In collaboration with G. J. Fritz, we have obtained results on the uptake of oxygen-18 in corn seedlings exposed for varying intervals to an atmosphere containing 10 atom per cent oxygen-18. Preliminary results confirm the usefulness of the method for oxygen metabolism investigations.

Accumulation of Radium-226 by the Freshwater Gastropod *Lymnaea stagnalis* L.

DIRECT absorption of ions in solution in the environment occurs frequently in freshwater invertebrates[1-3] and could be partly responsible for radiocontamination of the freshwater fauna[4,5] by radioisotopes in solution.

If the absorbed radioactivity is firmly fixed in the animals, and eventually concentrated at a level far above that found in the surroundings, these animals could be used as indicators for the radiocontamination of their environment. The possible use of freshwater molluscs as such indicators has already been emphasized[6-8].

Exposure of the snail *Lymnaea stagnalis* L. in solutions containing 0·04 µc. radium-226 per ml. revealed, as for calcium and strontium[8], the accumulation of the radium mainly in the shell-border. Since tap-water constitutes the optimal conditions for life of *L. stagnalis* in the laboratory and approaches fairly well the natural medium, the solutions of radium-226 were made in tap-water (containing in p.p.m.: 40 Ca$^{\cdot\cdot}$, 8 Na$^{\cdot}$, 4 K$^{\cdot}$, 4 Mg$^{\cdot\cdot}$, 25 Cl$'$, 120 HCO$_3'$). The content of radium-226 of the different samples was estimated by measuring the ^{214}Bi (= Ra *C*) formed after an equilibration period of 3 weeks in hermetically closed flasks. This ^{214}Bi radioactivity was measured in a well-crystal with a single channel pulse-height analyser on the γ-peak of 609 keV. Pools of 35 mature animals in 350 ml. solution were used in five parallel experiments.

When the animals are placed for 24 h in the radium-226 solution, 70 ± 8 per cent (at 95 per cent fiducial limits) of the radium was absorbed by the animals, as appeared by measuring an aliquot of the solutions. After 7 days, 10 animals were killed, dissected and measured for their radium-226 content. At this time, more than 90 per cent of the radium originally present in the solution was absorbed by the snails.

Table 1 presents the concentration factors observed. They are expressed as:

$$\text{Concentration factor} = \frac{\text{Ra-content in the animal per unit fresh weight}}{\text{Ra-content of the solution per unit of weight}}$$

Table 1. RADIUM-226 CONCENTRATION FACTORS IN DIFFERENT PARTS OF *L. stagnalis* AFTER 7 DAYS EXPOSURE IN A SOLUTION CONTAINING ORIGINALLY 0·04 μC./ML.

Parts of the snails	Mean	*S.D.*
Newly formed (2 mm) border of shell	1,277 ± 375	135
Shell without border	376 ± 100	36
Soft parts	140 ± 26	9
Whole animals	108 ± 18	7
Blood	21 ± 4	1

Error = fiducial limit with 95 per cent probability.

To verify that the absorbed radium-226 was firmly fixed, some of the animals were returned to uncontaminated water. During the following 24 h the animals lost about 1 per cent of their radium; this quantity fell to 0·5 per cent during the third day. Further measurements were disturbed by the low level of radioactivity and problems in relation to adsorption of radium-226. The death of an animal caused a sudden increase of radioactivity lost by the soft parts in the surrounding water, contrary to the shell, which firmly retains its radioactivity even when submerged in water after removing the soft parts of the animal. This fact and the high concentration factor in the shells confirm the possibility of using this animal as an indicator for contamination by radium-226.

I observed similar results with the accumulation of calcium-45 and strontium-85 in *L. stagnalis*. The net inward movement of the radium-226, notwithstanding the fact that the concentration of radium is 20 times higher in the blood than in the surrounding medium, seems to indicate the intervention of some active transport mechanism for this accumulation of radium-226, as has already been suggested by me for calcium absorption[9].

I thank R. Kirchmann for his advice.

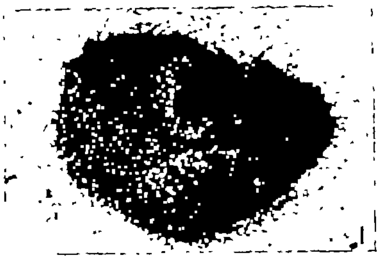
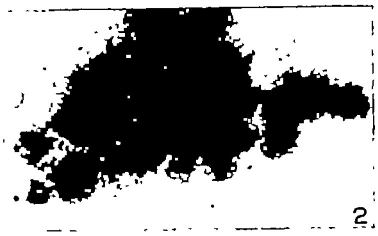
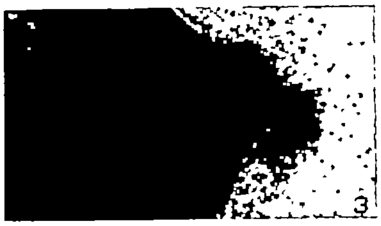
Incorporation of Iron-59 into the Cells of Different Tissues of *Chironomus plumosus*

ALTHOUGH iron plays an important part in the physiology of the living cell little is known about its localization in different parts of a cell or concerning its variation from tissue to tissue. Mammals have mainly been the object of investigations relating to the incorporation of labelled iron into the cells where the use of iron is known, such as the blood-forming cells, the liver cells, etc.[1–3]. We are not aware of the incorporation of labelled iron into the cells of other kinds of tissues and especially into the cells of invertebrates, except *Amoeba*[4].







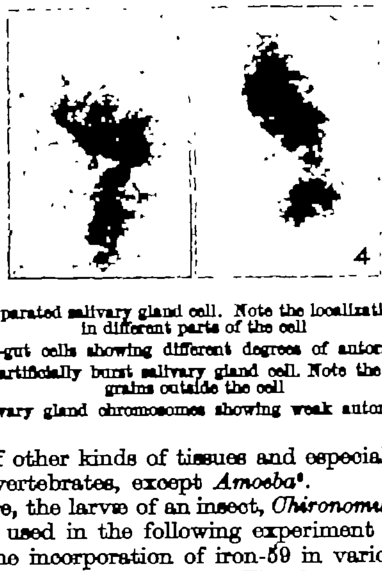


Fig. 1. A separated salivary gland cell. Note the localization of iron-59 in different parts of the cell

Fig. 2. Mid-gut cells showing different degrees of autoradiography

Fig. 3. An artificially burst salivary gland cell. Note the existence of grains outside the cell

Fig. 4. Salivary gland chromosomes showing weak autoradiography

Therefore, the larvæ of an insect, *Chironomus plumosus*, have been used in the following experiment in order to examine the incorporation of iron-59 in various parts of the cells of different tissues. The larvæ were transferred in tap-water containing $^{59}\text{FeCl}_3$ solution (sp. act. 100 mc. ^{59}Fe/g Fe). The experiment was repeated in four series, each of which involved 5 ml. of tap-water containing the following parts of $^{59}\text{FeCl}_3$: (1), 1; (2) 10; (3) 88; (4) 20. The larvæ were kept in the medium in the first and second series for 72 h, in the third for 21 h and in the fourth for 68 h. Preparations were made from salivary glands, mid-gut, Malpighian tubules and rectum according to the squash preparation technique, stained with aceto-orcein, covered with Kodak '*AR* 10' stripping films and exposed for 7–90 days.

No difference was observed resulting from the concentration of $^{59}\text{FeCl}_3$ and immersion period. In almost all the preparations cytoplasm showed autoradiography (Figs. 1 and 2). But the number of grains per mm^2 varied from larvæ to larvæ, from tissue to tissue and even from cell to cell in the same tissue (Fig. 2). Such a variation could be observed even in different parts of the same cell, but preferential localization of the label could not be detected. In some preparations the grains were also found outside the cells. This was especially the case where the cell had been burst artificially during the preparation (Fig. 3). This shows that at least some of the molecules containing iron-59 were distributed in the enchylemma of the cytoplasm and were not bound to the morphological structures of the cytoplasm.

An accumulation of grains around and on the nucleus could be seen in some autoradiographs. However, the number of the grains per mm^2 on the cytoplasm was clearly greater than those on the nucleus. The chromosomes were either unlabelled or showed very weak autoradiography. In squash preparations where the cytoplasm and the nucleus were burst artificially one could observe grains on the chromosomes, too (Fig. 4). But the number of grains seems to be less than those on the intact nucleus and varies from chromosome to chromosome. Therefore, it can be suggested that some iron-59 molecules are not bound to the chromosome, but are localized in the nucleoplasm as observed by Feldherr. No relation could be found between labelling of cytoplasm and chromosomes. For example, in some cells the cytoplasm showed a light radioactivity, whereas the chromosomes were not labelled, and vice versa. In some cases the nucleus showed stronger autoradiography than the cytoplasm.

Similar results were obtained in another experiment, when *Drosophila melanogaster* was used instead of *Chironomus plumosus*.

This study was supported in part by grants from Cento and Nato. We thank Mr. Cafer Türkman for assistance in preparation of the photomicrographs.

BIOLOGY

Glucose Utilization in Pregnant Sheep by a Continuous Infusion Isotope Dilution Method

THE importance of carbohydrate as a metabolic substrate in the ruminant has given rise to much discussion[1]. The question of the source(s) of glucose is of special interest because there is no evidence that hexose is absorbed from the ruminant alimentary tract and because acetate is the major end product of ruminal fermentation. The foetal lamb, however, has considerable hexose requirements[2], and, as a consequence, it is thought that the pregnant female sheep is normally in a precarious state of carbohydrate balance[3]. It is known that even a slight fall in food intake in the pregnant sheep may cause the accumulation of ketone bodies in the tissues and blood stream followed by clinical signs of pregnancy toxaemia.

The continuous infusion isotope dilution technique[4] has been used to study glucose utilization rates in normal pregnant sheep and those with induced pregnancy toxaemia. Four determinations on two normal Clun Forest ewes, pregnant for 130 and 142 days respectively, gave a mean utilization rate of 1·35 ± 0·18 mg/min/kg, and two ketotic ewes, pregnant for 135 and 140 days, gave a mean rate of 1·22 ± 0·13 mg/min/kg. This difference is not significant ($P > 0·5$). The opportunity was also taken to use 1-^{14}C-glucose and 6-^{14}C-glucose in the same animal on successive days and the specific activities of the expired carbon dioxide were compared. It is generally accepted that the ratio of the specific activity of expired carbon dioxide, produced when 1-^{14}C-glucose is injected, to the specific activity of expired carbon dioxide, produced when 6-^{14}C-glucose is injected, that is, the C1/C6 ratio, should be unity if the main catabolic route for glucose is the Embden–Meyerhof pathway to pyruvate, followed by conversion to carbon dioxide in the tricarboxylic acid cycle. Deviation from unity is considered to indicate the existence of another pathway which incorporates C1 of the glucose into carbon dioxide at a greater rate than C6, for example, the pentose cycle.

The C1/C6 ratios for the two normal pregnant sheep were 1·24 and 1·38, respectively, and for the two ketotic animals 1·74 and 2·05. The mean value for the ketotic sheep did not differ significantly from the mean for the normal sheep ($0·1 > P > 0·05$). The situation in ketotic pregnant sheep therefore differs from that in ketotic lactating cattle in which lower C1/C6 ratios than in normal lactating cattle were found[5].

The glucose utilization rates in the pregnant sheep are of the same order as those in non-pregnant sheep after 24 h starvation, but only about half the rates in fed non-pregnant sheep[6]. It would seem therefore that tissue glucose supply is indeed marginal in pregnant sheep, but is not significantly reduced when the animals are showing clinical signs of ketosis. The C1/C6 ratio is of special interest. The decreased ratio in ketotic cattle has been interpreted[5] as indicating a reduction of glucose metabolism by the hexose monophosphate pathway. In a detailed discussion on the use of glucose labelled with carbon-14 for evaluating glucose metabolism[7] it has been pointed out that the C1/C6 ratio may be influenced by at least four variables, that is, the activity of the pentose and of the glycolytic pathways, the use of glucose in synthetic pathways and the proportion of triose phosphate oxidized to carbon dioxide. It is therefore not possible to interpret the C1/C6 ratio in pregnant sheep in terms of percentage pentose cycle activity, but it can be concluded that 1C of glucose is incorporated into CO_2 more readily than 6C in both normal and ketotic pregnant sheep.

Effects of Lysergic Acid Diethylamide on the Nesting Behaviour of Male Pigeons

PRESENT-DAY advances in psychotherapy have added impetus to investigations into the actions of drugs which affect the central nervous system and thus cause changes in behaviour patterns. One such psychomimetic agent, lysergic acid diethylamide (LSD-25), exerts both peripheral and central actions[1]. Some of these effects in various animals and humans are nausea, vertigo, hyperhydrosis, hypersalivation, mydriasis, vasodilation or vasospasm, hypotension or hypertension, bradycardia or tachycardia, and changes in the white blood cell count[2].

The vasomotor changes are partially related to disturbances in the hypothalamic-hypophyseal-adrenal axis[2]. Rinkel *et al.*[3], studying the effects of LSD-25 on human beings, suggested that this drug stimulated the pituitary-adrenal axis yet rendered the adrenal glands unresponsive to adrenocorticotrophic hormone. It is reasonable to assume that this pituitary response may also cause a change in the blood or pituitary levels of prolactin, which has been shown to be responsible for broodiness or nesting behaviour as well as the development of the crop in pigeons[4–6].

Thus, we considered that an investigation into the effect of LSD-25 on the nesting cycle of pigeons would shed further light on the above concepts.

Eight mated male homing pigeons were removed from their respective nests in a loft between 11 a.m. and noon 3 days after their mates had laid eggs. Observations have shown that at this time the nesting behaviour becomes stabilized into a distinct cyclic pattern. The males sit on the eggs from about 10 a.m. until about 3 p.m. The females will then sit from 3 p.m. until 10 a.m. on the following day. Four of the male birds received LSD-25 in a single dose of 0·2 mg/kg (intraperitoneal). The other 4 males served as controls and received an equivalent volume of distilled water as a placebo. 0·5 h after treatment, the females were removed from the loft and all 8 males were returned. The time required for each bird to return to its own nest, after being placed back in the loft, was recorded and the data were statistically analysed. This programme was repeated until each of the 8 pigeons had received 5 doses of the drug and 5 doses of water with at least a 48-h interval between repeated administrations.

Table 1 INHIBITION OF NESTING BEHAVIOUR OF PIGEONS WITH LSD-25

Bird No.	Drug-treated*	Control*
1	62·7	0·6
2	13·0	7·4
3	73·8	0 0
4	48·4	5·5
5	87·2	0·8
6	55·0	8·6
7	18·4	13·6
8	76·2	11·4
Grand mean ± *S.D.*	57·4 ± 25·8	6·0 ± 12·2

* Average time (min) for return to nests.

The results obtained are summarized in Table 1. They represent the average time (min) required by the pigeons to return to their nests. Each value shown is based on 5 injections of the drug or distilled water. The grand mean was derived from the individual responses of each of the 8 birds. The difference between the experimental and control grand means is highly significant as determined by the standard error of the difference between the means ($P < 0.01$).

It is interesting to note that 2 pigeons (2 and 7) showed very little change in behaviour. These birds responded to the drug only during the first 3 exposures, after which they did not appear to show any reaction.

This temporary inhibition of the nesting response is not due to a peripheral motor inhibition. In view of the rapid metabolic rate of the pigeon and the fact that the peripheral symptoms wear off within 30–40 min (ref. 7) leads us to believe that the effect is due to changes within the central nervous system. It is possible that the drug, by acting on the hypothalamic centre in the brain, causes an inhibition of prolactin release from the pituitary. This lowering of the prolactin-level would decrease or inhibit the 'desire' to nest. It is also possible that the drug causes a change in the bodies' response to prolactin as it does with adrenocorticotrophic hormone. In order to substantiate these mechanisms, biochemical or bioassay studies are required.

We thank Sandoz Pharmaceuticals, New Jersey, for providing the *LSD*-25.

Effect of Reserpine on Rate of Mortality and Growth of Duck Embryos

ADAMS *et al.*[1], who injected varying doses of reserpine into the yolks of eggs of White Plymouth Rock hens during the first week of incubation, reported that in the embryos treated the mortality rate increased with increasing dosage, and that the average body-weight of the surviving embryos was lower than that of the controls. On the other hand, van Limborgh *et al.*[2] were unable to demonstrate a similar influence on the mortality rate in one-day Khaki Campbell duck embryos. Uchida[3] observed a rise of the mortality-rate with increasing dosage but no significant changes in the body-weight in eighteen-day-old White Leghorn egg embryos.

The discrepancies in these results seemed to justify a re-examination of the influence of reserpine. For this work eggs of Khaki Campbell ducks were used. Three experimental series were drafted: in series I reserpine was injected after four days of incubation, in series II after eleven days, and in series III after eighteen days. Each series consisted of 96 eggs with living embryos, and these were subdivided at random into four series of 24 eggs (sub-series *a*, *b*, *c* and *d*). Each time doses of 10, 50 and 250γ of reserpine (0·20 ml.) in the form of 'Serpasil' were injected into the yolks of the eggs of the sub-series *b*, *c* and *d*; only the solvent was injected into the eggs of sub-series *a*. Four days after injection the eggs were opened and the number of deaths determined. The surviving embryos were all fixed and weighed under standardized conditions. Statistical analysis of the results included determination of the significance of differences between percentages, Student's *t* tests on the body-weights and Terpstra's tests against progression in samples.

The results of the experiments are summarized in Table 1.

Table 1. SUMMARY OF THE RESULTS OF THE EXPERIMENTS

Series	No. of embryos treated	No. of embryos died	Mortality-rate (%)	Surviving embryos No.	Surviving embryos Mean body-weight (g)
I*a*	24	2	8·3	22	0·271
I*b*	24	3	12·5	21	0·232
I*c*	24	4	16·7	20	0·222
I*d*	24	10	41·7	14	0·214
II*a*	24	4	16·7	20	3·61
II*b*	24	6	25·0	18	3·90
II*c*	24	9	37·5	15	3·56
II*d*	24	10	41·7	14	3·62
III*a*	24	4	16·7	20	22·0
III*b*	24	8	33·3	16	21·9
III*c*	24	14	58·3	10	18·7
III*d*	24	23	95·8	1	(17·1)

With regard to the mortality-rate, Table 1 shows that, within each series, this rate rises with increasing dosage. The differences between the individual mortality percentages of the various sub-series are significant in only part of the cases, but the rise noted is highly significant in each series (series I: $P < 0.002$; series II: $P < 0.02$; series III: $P < 0.0001$). Comparison of the mortality-rates found in sub-series I*a*, II*a* and III*a*, shows that in the controls mortality does not rise with increasing age ($P > 0.20$). However, following the administration of any dose of reserpine the mortality rate rises significantly with the age of the embryos (10γ, $P < 0.05$; 50γ, $P < 0.02$; 250γ, $P < 0.002$).

With regard to the body-weights of the surviving embryos, Table 1 shows that the mean body-weight of the controls of series I is much higher than that of the reserpine-treated embryos of this series. The differences are significant ($P < 0.05$, $P < 0.001$ and $P < 0.001$ respectively). The smaller differences between the sub-series I*b*, I*c* and I*d* are not significant. Nevertheless, there is a significant correlation between increase of the dose and decrease of the body-weight ($P < 0.0003$). In series II there are neither significant differences nor a systematic rise or fall of body-weight with the dose; however, in this series the individual body-weights varied extremely. In series III the only significant difference is that between the sub-series IIIb and IIIc ($P < 0.05$), but again a significant correlation exists between increase of the dose and decrease of the body-weight ($P < 0.01$).

These findings show that reserpine has a noxious action on duck embryos, and it is of particular interest to note that older embryos are more sensitive to this action than younger ones. This indicates that reserpine acts on a factor which, with increasing age, becomes of increasing importance to life. Since the drug is known to bring about changes in metabolic processes[4,5], it might be that it acts on some enzyme system. However, further work is needed to elucidate this problem.

We thank Ciba N.V., Arnhem, for the generous supply of the solvent of 'Serpasil'.

Pogonophora from British Coastal Waters

A SUB-LITTORAL faunistic survey of the Scottish west coast has recently produced specimens of the genus *Siboglinum* from 55–62 fathoms in the North Minch about 8 miles east of Lewis. *Siboglinum* has been found in deep water in the north-east Atlantic and an undescribed species has been recorded from 80–90 fathoms off the west coast of Ireland by Southward[1], but Pogonophora were not previously known from inside British coastal waters.

The samples were collected with a 1/10 m² spring-loaded grab and the grounds surveyed included the Minches from Dubh Artach north to the Butt of Lewis, as well as all navigable mainland sea lochs and most of the Hebrides lochs. Of several hundred samples covering this area, Pogonophora were found in only four, all from the extreme north-west corner of the Minch. Details of these collections are given in Table 1.

Table 1. DISTRIBUTION OF SPECIMENS

Position	Depth (fath.)	No. of specimens per 1/10 m²
58° 24′ N., 05° 55′ W.	60	3 specimens plus several tubes
58° 27′ N., 05° 55′ W.	58	Several empty tubes
58° 31′ 48″ N., 05° 55′ W.	55	1 specimen
58° 33′ 30″ N., 05° 55′ W.	62	21 specimens plus many tubes

The bottom on which they occurred consisted of fine grey sand, and an analysis of the associated fauna is given in Table 2. At stations farther south and east where Pogonophora were not found the bottom was generally softer and more muddy and the fauna consisted either of a typical *Ditrupa* community, or of an association, common in the lochs, dominated by the polychaete *Rhodine*.

Hydrographically the distribution of the Pogonophora seems to be closely associated with a tongue of comparatively saline water from west of the Hebrides which flows round the Butt of Lewis and influences the north-west Minch. This gives bottom temperatures ranging annually from 7°–8° C in February to 11°–12° C in late September, and salinities of about 35·10 parts per thousand.

These animals thus seem to be restricted to a small part of the Minch with faunistic and hydrographic characteristics which differentiate it clearly from the rest of the area.

I thank Dr. Eve C. Southward for examining the specimens. She considers them to be identical with the species referred to from off Ireland, and is preparing a description.

Oysters killed by Trematode Parasites

DURING laboratory breeding experiments with the New Zealand mud oyster, *Ostrea lutaria* Hutton, sectioned material showed specimens with gonads containing sporocysts of a digenetic trematode parasite. The sporocysts were tubular and branched as in the family Bucephalidae, and contained rediæ, but as cercariæ were not found the trematode has not yet been identified.

Twenty-two of the oysters were fixed on arrival from Foveaux Strait, New Zealand, and showed 13·6 per cent parasitized. The remainder were kept in aquaria for 6 months and those that died were fixed and sectioned. Samples of living animals were also fixed and sectioned at intervals during the same period. The parasitization in the two groups was as follows.

	No. parasitized	No. not parasitized	Parasitization (%)
Oysters that died	35	17	67·3
Oysters that remained alive	3	17	15·0

The highly significant difference indicates that the parasites were an important cause of death.

Heavy infection causes almost complete destruction of the gonad, and later, death of the oyster. The importance of this parasite in Nature is unknown, but under laboratory conditions all the animals initially parasitized may die. Until the species is identified and the hosts are known, the probability of accidentally spreading the trematode to oysters in other countries cannot be assessed, but the danger should be recognized by anyone introducing oysters from New Zealand.

Extension and Retraction of the Tube-Feet of Ophiuroids

THE greater part of the basic anatomy of ophiuroids was worked out in the latter half of the last century and the results summarized in Bronn[1]. In the water-vascular system, the absence of tube-foot ampullæ comparable with those of asteroids or echinoids is striking. It has been generally recognized that the feet are less important in locomotion than the arms, and they are frequently attributed only sensory and adhesive functions. In several common genera the tube-feet are small and show only slight changes of shape, although protraction has been recorded[2,3]. Perhaps for these reasons there has been little discussion of possible mechanisms of protraction and it seems often to have been tacitly assumed that none is present, and that retracted feet resume the extended condition only on relaxation of their musculature (which is wholly longitudinal), by the general pressure of the coelomic fluid in the water-vascular canals or by the elasticity of the podial wall. Ludwig[4] was the first to describe the valve at the head of the podium, the lips of which prevent water from flowing back into the radial canal. The presence of this valve has been remarked upon by all subsequent reviewers of the group; but its significance, namely, that pressure is developed within the foot, has been overlooked. Comparisons between active and anaesthetized specimens of various species suggest that in a number of cases podial extension is far in excess of that which could be achieved by relaxation alone.

A number of genera have been examined histologically (*Acrocnida*, *Amphipholis*, *Amphiura*, *Ophiactis*, *Ophiocomina*, *Ophiopholis*, *Ophiopsila*, *Ophiothrix* and *Ophiura*) and in all cases the podial musculature is differentiated into two systems, one in the long stem and the other in the proximal internal end or 'head' of the foot, which is generally embedded in a cup-like expansion of the vertebral ossicle. We contend that these systems are generally antagonistic and that the head of the ophiuroid podium is the functional equivalent of the ampulla of other classes.

This arrangement is clearest in the burrowing genus *Amphiura*. The head of the podium is distinctly bulbous, and its muscle fibres are deeper and more numerous than those of the stem and quite distinct from them. In *Amphipholis squamata*, on the other hand, the two muscle systems are less differentiated; some fibres are common to both systems, but there are many more in the slightly inflated head of the podium.

When the foot retracts, the ampulla-like head of the foot cannot expand so much as the ampulla of an asteroid, because it is enclosed by ossicles and because there are no large body spaces in the arm. If the foot is to be fully retracted, a limit is set to the volume of hydraulic fluid within the podium and thus to the amount by which the foot can be protracted. The full retraction of longer feet is obtained in many species by forcing excess fluid into the radial canal. This situation can often be recognized by two structural characteristics.

First, the valve between the head of the podium and the branch from the radial canal is equipped with muscle fibres which can force the lips apart. Secondly, the radial canal is partitioned by muscular sphincters situated between each vertebra, so that each pair of tube-feet has its own elastic expansion chamber and can operate independently of its neighbours. These sphincters have been described in *Ophiactis virens* by Simroth[2] who thought they were responsible for the slight protraction of tube-feet which he observed. We have found them in *Acrocnida brachiata*, *Amphiura chiajei*, *A. filiformis*, *Ophiactis balli*, *Ophiocomina nigra*, *Ophiopholis aculeata* and *Ophiothrix fragilis*. In addition to the circular muscle fibres forming the sphincters, longitudinal fibres generally run along the floor of the radial canal and are more strongly developed in the region of the sphincters, to which they may be antagonistic.

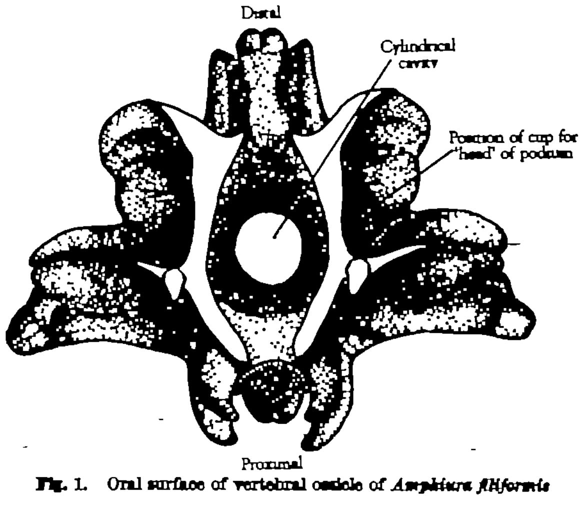

Fig. 1. Oral surface of vertebral ossicle of *Amphiura filiformis*

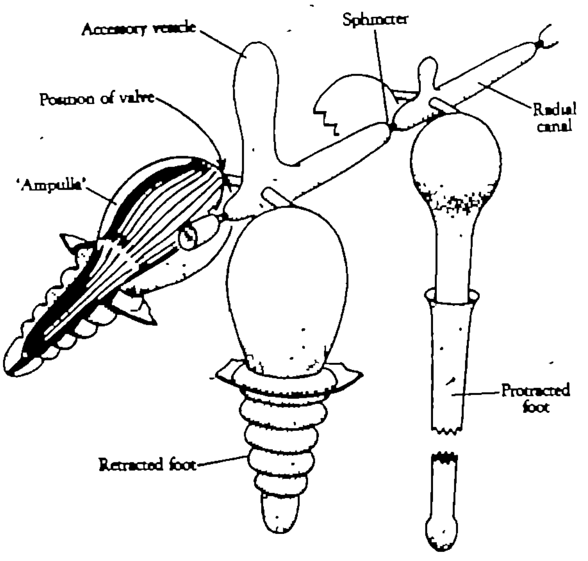

Fig. 2. Diagram of part of radial water-vascular system of *Amphiura filiformis*

Amphiura filiformis is capable of very considerable extension of the tube-feet. It possesses a series of accessory vesicles which emerge from the radial canal in each segment at the point where the lateral branches are given off to the podia. The vesicles are non-muscular, but apparently elastic, and are sometimes fixed in an expanded and sometimes in a relaxed condition. Each is suspended by connective tissue strands in a cylindrical cavity which passes completely through the middle of the vertebral ossicle (Fig. 1). This hole through the ossicle occurs in several members of the Amphiuridae[3], but not in *A. chiajei*.

Fig. 2 represents the water-vascular system of two arm segments of *A. filiformis*, and summarizes our ideas of how the system works. The right-hand pair of podia are protracted; the accessory vesicle and radial canal are relaxed, the valve is shut, the foot-head muscles are contracted and the stem of the foot is elongated. The left-hand pair are retracted; the 'ampullae' are dilated, the valves have been opened, and the accessory vesicle is expanded.

It seems possible that active protraction is general throughout the Ophiurae, because evidence for it has been found in all species examined, drawn from five families. Modification of the radial canal to permit greater extension is also widespread, but the details vary between species and much further work remains to be done. The configuration of the arm water-vascular system seems to have been similar in fossil somasteroids[6]; it will be interesting to have histological reports on *Platasterias*, the living somasteroid reported by Fell[7].

One of us (J. D. W.) is grateful for a studentship from the Department of Scientific and Industrial Research. Both of us thank Dr. D. Nichols for his useful criticism.

'Campaniform-type' Organs in Nematodes

CAMPANIFORM organs are common in insects[1], where they have been demonstrated to act as proprioceptors[2,3]. Morphologically they show considerable variation but "In vertical section the cuticular parts of the organs generally have the form of a small dome into which the sense cell process is inserted like the clapper of a bell"[1] and the structure of various types is illustrated by Snodgrass[1].

In the Nematoda lateral gland cells and pores have been known to occur in many groups for some time and are considered to be particularly obvious in species of the family Cyatholaimidae (Chromadoroidea), where they are arranged in longitudinal rows running down the lateral, dorsal and ventral surfaces of the body. I have examined these pores in species of the genera *Cyatholaimus*, *Longicyatholaimus*, *Choniolaimus* and a new genus closely related to the two latter genera (all belonging to the Cyatholaimidae) and the structures are not simple pores but complex organs very similar to the campaniform organs of insects. I have found two types of organ of which the most common and widespread is that shown in Fig. 1, 3–5. It takes the form of an elliptical cup into which projects a thin sheet of cuticle which is attached to the bottom and two sides of the cup. This Type-1 organ occurs in longitudinal rows running the full length of the body in all the genera studied and in all, except the *Longicyatholaimus* species, the sheet of cuticle runs transversely—in *Longicyatholaimus* species it runs anteroposteriorly (this may be an artefact or possibly a functional distortion). The second type of organ (Fig. 1, 1–2) is found only on the *Choniolaimus* species, where it is restricted to a short row of seven organs running posteriorly from the amphids on each lateral side of the body and two similar rows, one on each side of the body, running posteriorly from about the level of the cloacal or anal opening. This Type-2 organ is circular in plan (Fig. 1, 1) with a central dot, which is the raised central part of a domed cap which lies within the sense pore and below the surface of the cuticle (Fig. 1, 2). Each organ is supplied with a nerve and apparently with a gland cell; but the condition of my material does not allow of a more detailed study. The association of a gland cell and a sense organ is not unexpected since this condition has been found to hold in many other nematode sense organs.

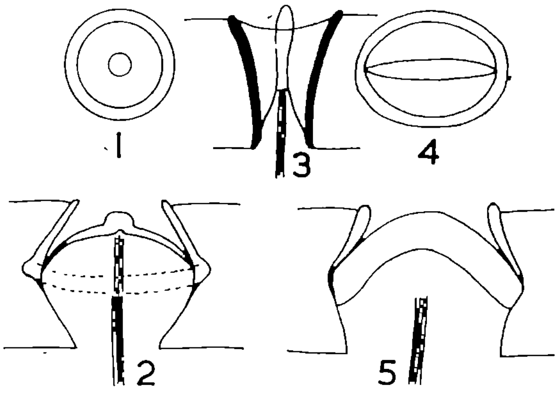

Fig. 1

It is reasonable to suppose that these organs function as mechanoreceptors in view of their morphological similarity to the campaniform receptors of insects, a suggestion supported by their distribution over the body. The distribution of Type-2 is particularly suggestive since it occurs on exactly the parts of the body which are subject to the most movement during the search for food and during copulation. The occurrence of such morphologically similar structures in both nematodes and insects does not necessarily lend weight to any idea of nematode/insect evolutionary relationships since they almost certainly represent the independent development of similar organs from similar materials to meet similar requirements and should be treated as an example of convergent evolution.

Fine Structure of *Pythium de baryanum* Hesse and its Probable Significance

ELECTRON micrographs of young hyphæ of *Pythium de baryanum* reveal some striking differences from young hyphæ of other fungi, for example, *Rhizopus* spp.[1], *Neurospora crassa*[2], and vegetative cells of yeasts[3].

The most striking difference is in the structure of the cytoplasm. Young hyphæ of *Pythium* show more numerous and more regularly distributed cisternæ and vesicles than are seen in hyphæ of *Rhizopus* and other fungi examined, suggesting a more regular endoplasmic reticulum. In older vacuolate hyphæ the endoplasm is less complex. In the young hyphæ the cisternæ may occur in layers (Fig. 1) resembling the Golgi bodies (dictyosomes) of some algae, for example *Paraphysomonas vestita*[4] and green plants, for example, *Anthoceros*[5] and maize root meristem[6]. No such distinct Golgi bodies of plant type have been demonstrated in other fungi although irregular aggregations of cisternæ were shown by Blondel and Turian[7] in *Allomyces* and by Hawker and Abbott[1] in *Rhizopus*.

The mitochondria of *Pythium* also differ from those of *Rhizopus* and certain yeasts in having shallower, undulating cristæ of irregular thickness and depth of penetration into the mitochondrial cavity. Tubules are also sometimes present in the centre of the cavity. They are closely similar

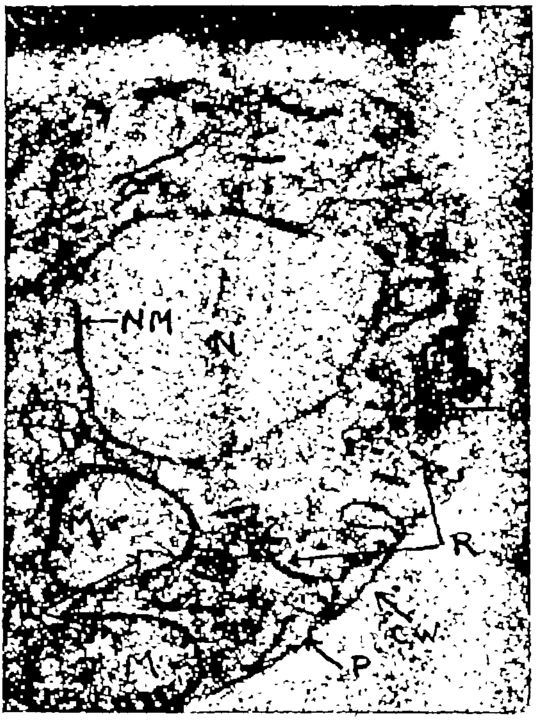

Fig. 1 Transverse section of part of a young hypha of *Pythium* (× 25,000). *CW*, Cell wall; *P*, plasmalemma; *R*, endoplasmic reticulum; *G*, Golgi body; *M*, mitochondrion; *MC*, irregular cristæ. *N*, nucleus; *NM*, nuclear membrane (note pores)

in appearance to those seen by Manton[5] in the liverwort *Anthoceros*.

The nuclear membranes are less regular in combined thickness and show more numerous pores and larger discontinuities than do those of other fungi studied.

The cell wall of *Pythium*, usually considered to consist of cellulose, is not electron dense and shows no structure in section, thus resembling the wall of *Allomyces*[7] but contrasting with that of *Rhizopus* which is electron dense and finely striate in section.

Nutritional investigations[8], the structure of the flagellæ of the zoospores[9] and the well-known morphology of the sexual reproductive organs already show that the Oomycetes differ widely from other Phycomycetes and from the higher fungi. The present study of the fine structure of *Pythium* confirms this difference and, in addition, indicates a closer affinity with certain algae and green plants than is shown by fungi in general.

Grass Tetany and Histamine

THE occurrence, distribution and ætiology of grass tetany in cattle and sheep have already been adequately described[1,2]. The most consistent symptom in all cases is a low serum magnesium-level, values below 1 mg per 100 ml. being common. The condition is sometimes accompanied by hypocalcæmia[2]. Nevertheless, severe hypomagnesæmia can be present in some cases without the appearance of clinical symptoms of tetany, which raises the question of the possible occurrence of other causative factors. The high incidence of grass tetany, for example, on young, rapidly growing pastures has given rise to views that some factor may be introduced by the herbage, and Seekles[4] has even suggested the term 'nutrition-tetany' for the condition. This factor may be independent of those which act by reducing availability of magnesium to the animal.

Death in grass tetany is usually attributed to shock. A paper by Schayer[3] would ascribe all shock phenomena to rapid histamine release into the blood. The histamine-levels in blood serum in cases of grass tetany have been shown by Seekles[4] either to be abnormally high or abnormally low. Abnormally low values were attributed to the dilating action of histamine on blood capillaries causing increased permeability of the capillary walls. Among compounds known to cause histamine release on injection both aliphatic and substituted aromatic amines and the ammonium ion have been recorded[5]. Whether dietary factors could produce similar effects is not yet known but Parrot[6] has been able to cause the death of guinea pigs by parenteral administration of histamine and has also shown that prior administration of putrescine reduces the minimum lethal dose to one-tenth of its formerly required level. The guinea pig is, however, known to be abnormally sensitive to histamine. The presence of putrescine and cadaverine in spring grass has been reported by van der Horst[7] and histamine also is present[8].

The influence of low- and high-calcium diets in guinea pigs on death from histamine has been investigated[9]; low calcium diets reduce the minimum lethal dose administered into the stomach. Similarly, diets high in potassium lead to greater susceptibility to histamine when administered intravenously to mice[10] and the influence of heavy potash fertilization in conditioning the production of tetany-prone swards has been frequently reported[1].

The treatment of grass tetany by the use of antihistaminics in conjunction with magnesium–calcium therapy has been reported by Hendriks[11] and some preliminary observations using 'Antiallergicum Vetag' (Veterinaria S.A. Zurich), both with and without magnesium–calcium injections have given results which justify further investigation.

It seems desirable, therefore, to widen the scope of investigations in grass tetany from the field of magnesium availability alone to the manner in which magnesium deficiency, either alone or with other factors, causes tetany. In this wider investigation the relationship of magnesium deficiency to histamine metabolism may play an important part and deserves closer examination.

Possible Presence of a Phytotoxin in Red-ring Infected Trees

RED-RING disease of coconuts is caused by the nematode *Rhadinaphelenchus cocophilus* (Cobb 1919) Goodey 1960, which colonizes the stem in a ring 3–5 cm inside the periphery where the fibro-vascular strands are densest, and causes the formation of a distinctive red-orange band in this zone. Characteristic symptoms are yellowing and wilting of leaves.

Although the causal agent and its method of spread have been examined[1], little or no work has been reported on the damage mechanism. The symptoms of red-ring disease are almost identical with those of bronze leaf wilt, which has been clearly shown to be due to vascular failure[2]; it is therefore possible that the damage mechanism of red-ring disease is similar in nature. This might result from blockage of vessels in the infected zone, but injection experiments using dyes into healthy and into diseased trees do not support this hypothesis, since the dye is detectable in the stem right up into the bud and out into the leaves[3]. Moreover, growing, healthy coconut trees can suffer very extensive damage to the stem and therefore to the vascular strands without obvious deleterious effects.

It is also possible, however, that wilt symptoms can arise from other causes such as the production of toxins. This may result in decreased efficiency of leaf cells with a consequent reduction in maintenance of the full transpiration stream[4–6]. Gross observations indicate that this may be the case in coconut trees infected with red-ring.

Preliminary experiments on seedlings and cuttings of tomato confirm this latter hypothesis. Hot- and cold-water extracts of red-ring infected tissue induce rapid and severe wilting of these plants, the effect being more rapid in the case of cuttings. The effect appears to be independent of the age of the extract and of the presence or absence of tissue fragments or *Rh. cocophilus* in the extract. The behaviour of tomatoes in extracts of healthy tissue is different, in that freshly prepared cell-free extracts do not produce wilting unless the extracts are allowed to stand for several hours before removal of tissue fragments. If tissue fragments be removed, it is necessary to stand the cell-free extracts overnight before they can induce wilting. There is, therefore, reason for believing that the toxin is not produced directly by the nematodes but is the product of tissue disintegration as a result of nematode invasion.

Exposure of extracts to temperatures of 100° C for 30 min does not affect their ability to induce wilting, and it is justifiable to suppose that the toxin, if present, is relatively thermostable.

Other tests have been carried out using three palms, *Ptychorapis augusta*, *Licula spinosa* and *Thrinax morissii*, as indicator plants to show the presence of a possible vivo-toxin. The results of tests with these plants are similar to those using tomato, although wilting is less pronounced. Wilting in diseased tissue extract does not occur in less than 72 h after immersion, while wilting in cell-free, healthy tissue extracts, takes far longer. These palms are far too small to observe either the external symptoms, such as yellowing, or internal symptoms, such as discoloration. In tomato plants, however, a distinct pattern of yellowing is observed. Yellowing precedes wilting in these plants. The yellowing begins along the midrib, extends along the lateral veins, then the interveinal spaces yellow and finally necrosis of the leaf occurs.

It is suggested that these observations are consistent with the production of a toxin or toxins in coconut tissues, and that the toxin or toxins are produced indirectly as a result of tissue breakdown following nematode invasion.

Effect of Treatment of Seeds with 2-Chloroethanol on the Resistance to Boron Toxicity in Wheat Seedlings

It has been shown that treatment of seeds with 2-chloroethanol increased the resistances to high salt concentration[1] and herbicide[2]. The present study is concerned with the influence of seed treatment on the boron toxicity.

Table 1. Effect of Seed Treatment with 2-Chloroethanol on the Resistance to Boron Toxicity in Wheat Seedlings

Seed treatment	Boron application (mg boron/200 g soil)	Wilted plants (per cent) h after applic. of boron 48	72	96
0·2 per cent 2-Chloroethanol (14 h)	12·5	1·9	37·5	90·3
,, ,, ,,	9	0	22·8	78·9
,, ,, ,,	5	0	4·7	23·5
Control	12·5	18·4	69·2	100·0
,,	9	4·5	43·6	92·7
,,	5	0	23·1	66·3

Wheat seeds (variety, Carstens VIII) were soaked in 0·2 per cent 2-chloroethanol for 14 h at room temperature. After that, the seeds were spread on a filter paper and dried for 4 h. The control seeds were treated in the same way using water instead of 2-chloroethanol solution. 200 g sandy soil (*p*H 5·85) was placed in a Neubauer container and moistened by 25 ml. of water. Forty seeds were placed in the soil. At 6 days after the seeding, varying amounts of boron in the form of 5,722 p.p.m. H_3BO_3 solution (1 mg boron/1 ml. solution) were applied on the surface of soil. The application of solution increased the water content of soil temporarily, and further irrigation of water was made after the moisture content of soil reduced to the original level. The first visible symptom of the toxicity was the wilting of the tips of leaf blades. The numbers of wilted seedlings were recorded. Results are shown in Table 1. Tests were replicated three times and the averages were calculated. From the results indicated in the table, I have arrived at the conclusion that the seed treatment increased the resistance.

Growth-Inhibiting Substances in Xylem Sap

A wide range of substances is already known to occur normally in xylem sap[1]. Experiments in this laboratory have now shown that growth-inhibiting substances are also present in xylem sap extracted from a range of woody plant species.

Xylem sap was collected from woody shoots using a method previously described[2], which allows quantities of up to 100 ml. to be extracted readily. To examine extracted sap for growth-inhibiting substances a volume of this material was first acidified to approximately *p*H 2·0 with dilute sulphuric acid and shaken three times with equal volumes of ether. The combined ether washings were then reduced in volume, samples placed on Whatman No. 1

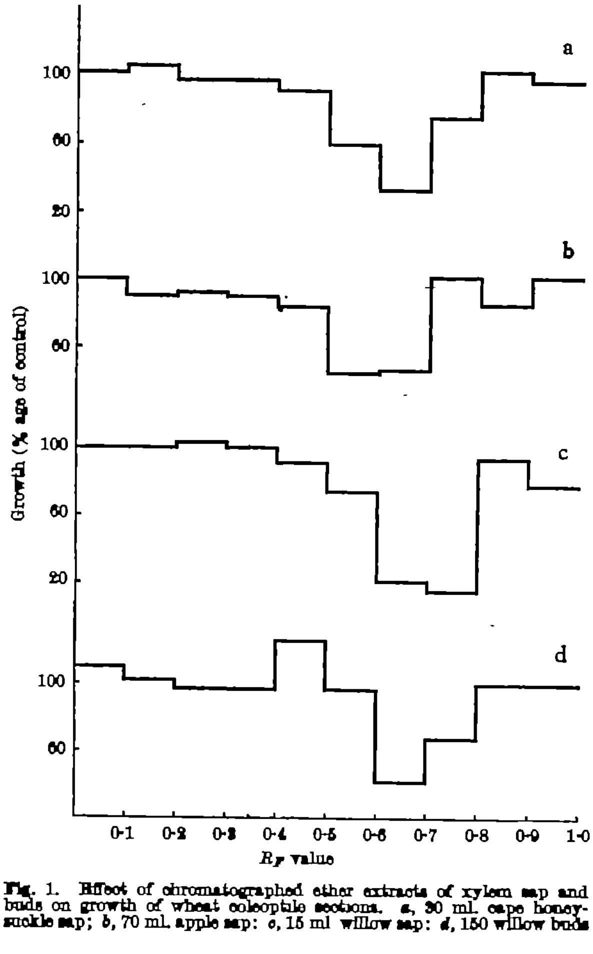

Fig. 1. Effect of chromatographed ether extracts of xylem sap and buds on growth of wheat coleoptile sections. *a*, 30 ml. cape honeysuckle sap; *b*, 70 ml. apple sap: *c*, 15 ml willow sap: *d*, 150 willow buds

chromatographic paper and chromatographed in a solvent of isopropanol/ammonia/water (10 : 1 : 1). The presence of growth-inhibiting substances on the resulting chromatogram was detected by the wheat coleoptile test using small rotating assay tubes containing 0·4 ml. of 2 per cent sucrose plus the paper section[3]. Elongation of coleoptiles was measured after 18–20 h. Fig. 1*a*–*c* show the results of tests with xylem sap of three species—Cape honeysuckle (*Tecomaria capensis* Spach), apple (*Malus sylvestris* (L) Mill. var. Sturmer pippin) and willow (*Salix fragilis* L.).

A region of marked inhibition is present on each chromatogram at an R_F value of about 0·5–0·7, suggesting the presence of similar substances in each sap.

Comparable assays of the acidic fraction of an ether extract of dormant willow buds (Fig. 1*d*) also show an inhibitory zone at approximately the same R_F values. This would suggest that the sap and leaf extracts contain similar inhibitory substances. The position of the zone of inhibition seems generally similar to that of the widely distributed 'inhibitor β'[4].

The present demonstration of such inhibitory substances within a transport stream of the plant raises the question of their possible regulatory significance in various growth phases of the plant. Such a means of free movement of inhibitors could be, for example, of importance in correlative phenomena such as control of dormancy and bud break[5–7]. Some relationship is certainly suggested because of the apparent similarity of the inhibitors present in xylem sap and in buds. Clearly, further investigations of the origin, nature and role of the inhibitors present in xylem sap are required. It is notable that no substances with growth-promoting activity could be detected in the sap extracts along with the inhibitors but this is not unexpected in view of the known strictly polar movements of naturally occurring auxins.

Embryology of the New Zealand Onchidiidae and its Bearing on the Classification of the Group

THE Onchidiidae are a group of the Gastropoda, possessing both Pulmonate and Opisthobranch characters. This fact has led them to be classified sometimes as Pulmonates and at others as Opisthobranchs. It is rather surprising to find, in a group that could throw some light on the origin of Opisthobranchs and Pulmonates, and the classification of which is debatable, that the embryology of only one species, *Onchidella celtica* Forbes and Hanley, has been examined. The two papers published on the embryonic development of this species have both resulted in important conclusions being drawn as regards the classification of the Onchidiidae.

Joyeux-Laffuie published, in 1882[1], a long paper on the organization and development of *O. celtica*. His embryonic section was based on the examination of whole mounts, and this, combined with his taxonomic conclusions some of which were erroneous, would cause the systematist to remove the family from the Pulmonata to the Nudibranchia. The second paper was that of Fretter[2] on the functional morphology and post-veliger embryology of *Onchidella celtica* and their bearing on its relationships. Fretter discusses the Opisthobranch and Pulmonate affinities of the Onchidiidae and concludes that the Opisthobranch tie is the strongest.

During 1961 I investigated the embryology of the three species of Onchidiidae found in the New Zealand region. (Six species are described in the literature, but in a paper now in preparation this number has been reduced to three.) The investigation was concentrated on *Onchidella nigricans* Quoy and Gaimard, but embryonic material pertaining to the other two species was also examined.

Onchidella nigricans breeds at Lyttelton (43° 40′ S.) during the months of December, January and February. As are all Opisthobranchs and Pulmonates, it is an hermaphrodite. Copulation takes place and this may be unidirectional, that is, one individual acts as a male and the other as a female, reciprocal or in the form of a ring. So far as is known, the last method has not been observed in any other gastropod, but a slight modification of chain copulation would produce ring copulation. About 500–11,000 eggs are deposited in each egg mass, these being of the same general type as found throughout the Opisthobranchs. The early embryonic development is very similar to that of other gastropods and results, after approximately 25 days, in the formation of a veliger. Unlike *O. celtica*, *O. nigricans* has a pelagic veliger. This has the appearance of a typical Opisthobranch veliger. The duration of its pelagic life is unknown but it is probably short, lasting about seven days. This is based on a number of facts: (1) in the laboratory the pelagic period lasted about 7 days; (2) the shell of the veliger consists of about three-quarters of a whorl, the simple outer lip of the shell is scarcely incurved and the velum is not large; (3) there was little change in size and organization of the veligers during their planktonic life. The fact that *O. nigricans* possesses an egg mass containing a large number of eggs which hatch into free-swimming veligers increases the number of points in which these molluscs agree with Opisthobranchs.

The Onchidiidae are intertidal in habitat, and so have been regarded as having re-invaded the marine zone from a terrestrial habitat. If this is the case, then *O. nigricans* has developed a free-swimming veliger which is almost identical to that of many Opisthobranchs. As Needham[3] states, evolution is reversible in the sense that structures or functions once gained can be lost, but irreversible in the sense that once lost they can never be regained. Thus, it is unlikely that a free-swimming veliger, showing the characteristic structures of an Opisthobranch larva, would reappear in evolution.

Fretter[2] has listed the Opisthobranch and Pulmonate characters possessed by the Onchidiidae. To her list of Pulmonate characters may be added another one, the spiral form of the spermatozoa. So far as is known this character is only found in Pulmonates. In view of the mixture of Pulmonate and Opisthobranch characters found in the Onchidiidae, the group must always occupy a debatable position in any clear-cut classification. It is generally considered that Pulmonates and Opisthobranchs arose either from closely related Prosobranch groups, or that the Pulmonates may have originated from an early group of the Opisthobranchs themselves. Whatever is the case, the Onchidiidae lie very close to the stem of these two groups. In agreement with Labbe and Fretter[4], it appears that the most suitable place to assign the group is with the Opisthobranchs.

The other two species, *Onchidella flavescens* Wissel and *Onchidella campbelli* Filhol, both possess direct development. Their egg masses are basically the same as those of *O. nigricans* but they are larger and contain fewer eggs. Little embryological material was available for *O. campbelli* as this species occurs only on the Sub-Antarctic islands of New Zealand. The development of *O. flavescens* and *O. celtica* is very similar.

Throughout the animal kingdom invasion of the land is usually considered to have taken place via estuaries. Various species of the Onchidiidae found in the Australasian region constitute an excellent series exemplifying this. *O. nigricans* appears to possess the strongest marine affinities, as it has a free-swimming veliger, while species such as *O. flavescens* and *O. campbelli* have taken one step towards the invasion of a terrestrial habitat, in that they possess direct development. *Onchidium damelli* forms the next link in the invasion of land, this species being restricted to estuarine waters and mangrove swamps. Finally, *Onchidina australis* can be found up to 30 ft. above high-tide mark.

MICROBIOLOGY

Sensitization of Bacterial Spores to Lysozyme and Hydrogen Peroxide with Reagents which Rupture Disuphide Bonds

VINTER[1–4] showed that the coat fractions of bacterial spores contain a high concentration of cystine disulphide bonds. Spore coats also contain a protein component[5,6] with which cystine could be associated. We have therefore subjected spores to reagents known to rupture protein disulphide bonds, and have investigated the results of these treatments.

Spores of *Bacillus cereus* NCTC 945 were incubated at 37° C with performic acid (2·5–25 per cent v/v); thioglycollic acid (1–25 per cent v/v) in the presence or absence of 8 M urea; 2-mercapto-ethanol (10 per cent v/v) at *p*H 3 in 8 M urea; sodium sulphite (12·5 per cent w/v) in the presence of 0·05 M cuprammonium ions and 8 M urea. Formic acid (2·5–25 per cent v/v) and hydrochloric acid (*p*H 3) were used as controls. None of these treatments altered the brightness of spores viewed by phase-contrast microscopy. Treated spores were washed with water and incubated with lysozyme at 37° C. Lysozyme caused phase darkening of the chemically treated spores resembling that which occurs during normal spore germination. The rate of phase darkening in lysozyme was quicker when urea was included with the disulphide bond-breaking reagents. Lysozyme did not alter the phase-contrast appearance of control or untreated spores.

Sensitization of spores to lysozyme with thioglycollic acid could be reversed by slow oxidation of the spores in aerated water. When attempts were made to reverse the effect of the thioglycollic acid treatment with hydrogen peroxide (0·04–4·0 M) it was found that the peroxide also caused phase darkening of the treated spores. Hydrogen peroxide had the same effect on spores treated with performic acid and 2-mercaptoethanol whereas up to 6 M hydrogen peroxide did not affect control spores. Phase darkening was followed by almost complete solubilization of the spores leaving only cell ghosts, presumably spore coat material, and therefore differed from the phase darkening which occurs during normal germination.

The *p*H activity curves of the lysozyme and hydrogen peroxide reactions showed important differences. The lysozyme reaction only occurred between *p*H 6·0 and 10·2 whereas the hydrogen peroxide reaction was most rapid above *p*H 10 and in the presence of metal ions and was inhibited by sequestrants. This suggested that the lysozyme reaction was physiological but the hydrogen peroxide reaction was non-physiological and depended on catalytic decomposition of the peroxide.

The reactions appeared to be general in their effects on bacterial spores. Spores of *Bacillus cereus* (three strains), *B. megaterium*, *B. polymyxa*, *B. brevis*, *B. fusiformis*, *B. mesentericus*, *B. licheniformis*, *B. subtilis*, *B. subtilis* v. *aterrimus* and *B. globigii* which were treated with performic or thioglycollic acids all became susceptible to lysozyme and to hydrogen peroxide, as also did spores of *Clostridium butyricum* (two strains), *C. saccharobutyricum*, *C. tertium*, *C. septicum* and *C. bifermentans*.

These results are compatible with: (1) Vinter's observation[1] of the high content of disulphide bonds in the coat fraction of spores; (2) chemical rupture of these bonds; (3) consequent disclosure of new substrates aided by the hydrogen bond breaking activity of urea; (4) action of lysozyme on previously protected lysozyme substrate which is present in spore mucopeptide[7]; (5) action of hydrogen peroxide on previously protected but unknown substrates. These results are also compatible with a spore structure in which the cystine disulphide-rich[1] and proteinaceous[5,6] coat surrounds the lysozyme-sensitive mucopeptide[8] and the calcium dipicolinate[8,9] of the cortex.

Normal germination of bacterial spores may involve similar reactions to those described here. Vinter[3] has suggested that spore disulphide bonds may not be solely concerned with resistance to irradiation but may also be involved in the sudden activity during germination. He demonstrated a qualitative reduction of spore disulphide bonds during germination[2]. Enzymatic rupture of spore disulphide bonds, followed by activation of a lytic system, could invoke changes in permeability[10] and swelling[11] of the spore typical of germination. For example, enzymatic rupture of disulphide bonds in yeast pseudokeratin has been described[2,12], and a spore enzyme capable of attacking spore mucopeptide was discovered by Strange and Dark[13]. Changes induced by such enzymes could parallel changes induced by disulphide bond-breakers and lysozyme. It is clearly possible that during normal spore germination endogenous enzyme systems could bring about changes similar to those induced by the exogenous systems we have described. The relevance of these reactions to normal germination is therefore now being examined.

CYTOLOGY

Chromosomal Dynamics of *Gastrimargus*

CHROMOSOME number and morphology have been regarded as most constant properties of a species both within and between different individuals. This is also[1–4] true of short-horned grasshoppers The concept of absolute karyotypic stability entails an evolutionary cul-de-sac, and therefore a relative stability alone can afford scope for further genotypic change. Though it is known that spontaneous chromosomal mutations in stable genetic systems is low[5–10], yet chromosomal variations within an organism is as common as between organisms within a population[11]. However, a re-organization of a karyotype to attain a better homeostatic stability depends not only on the incidence of structural and numerical anomalies but also on their subsequent survival[12]. Such selective incorporation of anomalies are claimed in orthopterans[13]. The incorporation of anomalies into a genetic system is as much a measure of karyotypic plasticity as it affords the starting point of further evolutionary change. Cytological examination of the two species of *Gastrimargus*, *G. transversus* and *G. africanus orientalis* (Family, Acrididae; Order, Orthoptera) collected locally (Mysore, India) has clearly shown the karyotypic dynamism.

In both species of *Gastrimargus*, the diploid chromosome number in the male is 23 ($2n = 22A + X$) as judged from chromosome counts of the gonial metaphases. Further, while a majority of spermatocytes in metaphase I show eleven bivalents and one X, a few cells distinctly show nine bivalents and an X chromosome. The latter indicates a diploid number of 19. Thus far, no gonial metaphase plates with 19-chromosomes have been found. However, the presence of cells in anaphase I with 9 and 10 chromosomes at the two poles strongly suggests the existence of cells with 19-chromosomes in the germ-line. This variation in the diploid number has to be explained in terms of karyotypic instability which might involve the presence of supernumerary chromosomes in the population. In the cells so far examined, the occurrence of sister-chromatid bridges in anaphase I is found more frequently in *G. transversus* than in *G. africanus*. Although many cells contain a single bridge, some cells with 2 or 3 bridges are also found. The frequencies are being worked out. The presence of non-staining gap in the long bivalent in the two species of *Gastrimargus* is of special interest. Most of the cells in metaphase I show 'heteromorphic' non-staining gap in *G. transversus* and 'homomorphic' non-staining gaps in *G. africanus* in the centric ends of the chromosomes. Similar non-staining gaps have been described in rye[13], *Pyrgomorpha kraussii*[14], *Mecostethus grossus*[15] and *Tetrix ceperoi*[16]. Whether these non-staining gaps are due to structural heterozygosity[15] or symptomatic of genotypic unbalance[14] or mere phenotypic expressions comparable with the starved regions of chromosomes[13] is not clear at the present moment. Specific association between autosomal bivalents and between X and autosomal bivalents in pachytene-diakinesis-metaphase I suggests the existence of translocations in *G. transversus*.

As a result of failure of cytokinesis in the last gonial division, tetraploids result which manifest as binucleate spermatocytes. There is normal consummation of meiosis in these tetraploid spermatocytes with 22 autosomal bivalents and $2X$ univalents. The resulting diploid spermatids are distinguishable from the haploid spermatids, particularly among the X-bearing ones. The size differences between $2X$- and X-bearing spermatids is significant. An occasional occurrence of two X's with eleven autosomal bivalents in metaphase I suggests the premeiotic non-disjunction of X in the last gonial division. Two of the autosomal bivalents exhibit positive heteropycnosis in zygotene-pachytene-diplotene, both in *transversus* and *africanus*. One of them always shows precocious segregation in metaphase I, though occasionally both show. The behaviour of these bivalents recalls the behaviour of supernumerary chromosomes. The formation of ring bivalents in grasshoppers has been shown to be due to the presence of two chiasmata, one in the short and other in the long arm of the chromosome. The number of ring-bivalents varies from 0 to 5 per cell between cells of the same individual and between different individuals. In *G. transversus*, though most of the cells show 2 ring-bivalents, cells with 1 or 3 are also present. Some of the cells show 4 but none showed 5 ring-bivalents. On the other hand, in *G. africanus*, cells with 1, 2, 3, 4, and 5 ring-bivalents occur but those with 3 and 4 occur more frequently than others. Details of the cytology and chromosomal dynamics of *Gastrimargus* will be published elsewhere.

VIROLOGY

Isolation of Individual Strains of Beet Yellows Virus

IN the programme of breeding for tolerance to beet yellows virus (SBYV) in sugar beet, it became desirable to obtain individual SBYV strains so that breeding material could be tested against them separately or in known combinations.

It has now proved possible to isolate single SBYV strains from plants infected with a complex of strains by a local-lesion technique. Leaves of the infected plants were ground in a mortar with 'Celite', and the sap was immediately inoculated with a very soft brush on to the upper surface of leaves of *Claytonia perfoliata* Donn. The test plants required no special treatment before or after inoculation; but best results were obtained if the temperature did not exceed 70° F between grinding and inoculation; washing the treated leaves immediately after inoculation tended to reduce mechanical damage.

Most of the inoculated leaves showed well-defined red or brown necrotic lesions about 10–14 days after treatment; uninoculated leaves and leaves inoculated with healthy sap showed no lesions. The lesions were very similar to those reported by Björling on leaves of *C. perfoliata* systemically infected with SBYV following aphid inoculation[1], but with mechanical inoculation the virus was restricted to the lesions and no systemic spread occurred. *Myzus persicae* (Sulz) did not acquire the virus from the lesions or from other parts of the plants during short or long acquisition feed times.

Single local lesions were excised with the minimum of surrounding leaf tissue, ground with 'Celite' in a drop of water and inoculated to *C. perfoliata* leaves; single lesions from these leaves were used for further inoculations. This process was repeated at least three times so that each resulting virus isolate had passed through several single-lesion transfers. Repeated passage of tobacco mosaic virus through single local lesions has usually given genetically pure strains of virus[2,3] and it seems reasonable to suppose that this technique has also given a similar separation of SBYV strains.

The final stage of obtaining sugar beet plants systemically infected with the single-lesion SBYV isolates and from which aphids could acquire the virus, was carried out using a technique based on that of Kassanis[4]. Sap from single *C. perfoliata* lesions or, preferably, from a leaf bearing many lesions derived from one original lesion, was brush-inoculated with 'Celite' on to both upper and lower surfaces of the older leaves of young sugar beet plants (4–6 leaf stage) which had been kept in the dark for

2 days previous to inoculation. The inoculated leaves of many of the sugar beet plants showed large numbers of very small brown or purple lesions about three weeks after inoculation, and some of these plants later became systemically infected. Some sugar beet breeding lines were more susceptible to systemic infection than others.

The virus strains isolated in this way from field plants infected with strain complexes were tested for virulence on *Chenopodium capitatum* Aschers, and this showed that many strains of differing virulence had been obtained. Some of these have since passed through several aphid transfers from sugar beet to sugar beet without apparently changing in virulence and they therefore appear reasonably stable *in vivo*.

Spread of Yellows Virus by *Myzus persicae* in Sugar Beet Crops

Wingless *Myzus persicae* were reared on sugar beet plants (provided by Dr. G. E. Russell, Plant Breeding Institute, Cambridge) infected with sugar beet yellows virus (SBYV), sugar beet mild yellows virus (SBMYV)[1], or both viruses. Eight widely separated plants in a 7½-acre field of sugar beet each received three adult and six young aphids from these cultures on May 31, 1962, and nearby plants were examined for aphids and virus symptoms at weekly intervals thereafter.

In this exceptional season study of the spread of the wingless aphids was not impaired by the arrival of winged aphids from elsewhere. The apterae moved readily from plant to plant, even across rows 21 in. apart when the plants were less than 9 in. diameter. During June they spread over patches of the crop more than 10 ft. in diameter, and infected them with virus. Although heavily attacked by adult ladybirds which sometimes outnumbered them, dispersal enabled the aphids to maintain their populations. These populations (less than one aphid per plant) produced eight- to sixteen-fold increases per month in the incidence of yellows virus.

In late June 1961 populations of *M. persicae* in sugar beet seed crops averaged 600,000 per acre (15–50 aphids per plant[2]). With such populations the rate of spread of yellows virus should be much greater than the increases now found in the root crop. With such rapid spread, as yellows symptoms are not visible until three weeks after infection[3], nearly all the seed crop could be infected and infective although only 2·9–10 per cent of the sugar beet seed crop and from 7–31 per cent of the mangold seed crop shows symptoms of yellows virus in June[4]. Thus, although the measures taken in 1950[5] reduced heavy visible infection in the seed crop to these much lower levels, they may not have reduced their efficiency as sources of the disease for the root crop. This would explain why the incidence of the disease in the root crop has not decreased (mean August incidence, 1946–50 = 18·9 per cent; 1957–61 = 21·8 per cent), although there is much evidence that the seed crop is the principal source of the disease[6]. Effective control would be obtained if the seed crops were only grown in alternate years[6].

Experimentally infected plants received SBYV only, SBMYV only, or both viruses. SBMYV spread to more than twice as many plants as SBYV. The least rapid spread was from plants which received both viruses; analysis shows that either virus spread to twice as many plants when it was introduced alone as when the two viruses were introduced together. Also, there is some evidence that when both viruses were present the two infections were usually introduced into a plant at different times.

ANTHROPOLOGY

Pigmy Tools from the Andaman Islands

Relatively little is known about the archæological work in Andaman Islands except for the work of Stoliczka[1], Holland[2], Cipriani[3], and Dutta[4], and practically no information is available about any stone industry. Some small stone artefacts were recovered by excavation from a kitchen-midden site situated at the Beehive Island (between lat. 12° 24′–26′ N. and long. 92° 55′–56′ E.) in Middle Andaman. The kitchen-middens are numerous in these islands and can be found whenever the elevated ridges are near to the coast or the creek.

The aborigines of the land are considered to be the survivors of the primitive negrito race, subsisting chiefly on hunting and collecting.

The collection comprises a large number of small stone artefacts fabricated out of the siliceous rocky material. They are well preserved. The collection represents a flake and blade industry belonging to the mesolithic stage of culture (the term 'mesolithic' is used here only to indicate the cultural mode of life, and does not imply dating). The industry is primarily based on the utilization of small flakes and blades and the preponderance of primary flakes is worthy of notice. When classifying the material, it emerges that the major types that contributed towards the formation of this industry are blades, points, scrapers, flakes and numerous waste products. The blades, however, are in the majority. Besides these there are some true microliths showing steep retouching. The artefacts are rather primitive, exhibiting a crude technology. The industry is of less antiquity and of recent origin. The artefacts indicate a society based on hunting and collecting economy. From a preliminary scrutiny of the artefacts, it seems that this industry had broad similarities in character with the Toalean and allied flake and blade industries developed in the Far East Islands and South-East Asia.

MISCELLANEOUS

Possible Role of Meteorites in the Origin of Life

It has been postulated by Oparin[1] that life originated in the seas of the primitive Earth, at a time when the atmosphere was reducing. The dominant sources of free energy for biopoesis are presumed to have been lightning discharges in the atmosphere and ultra-violet radiation from the Sun[2]. However, both agents tend to deposit organic compounds relatively high in the atmosphere, rather than in the seas. Advection, convection, and diffusion must be invoked as the mechanisms depositing the reaction products in the hydrosphere. The purpose of this communication is to suggest a physical process capable of yielding organic compounds of high complexity in the primitive atmosphere and providing a relatively high efficiency of transfer to the hydrosphere.

When a large meteoroid enters the Earth's atmosphere, its minimum speed (11·3 km/sec)[3] corresponds to hypersonic conditions, and a detached shock-wave forms ahead which accompanies it in flight. The temperatures behind the shock are greatest in the stagnation region, and fall off gradually with distances behind the meteoroid and away from the roughly hyperboloidal envelope of the shock. Computations have been carried out by one of us[4] for the concentrations of atomic, molecular, and free radical species at various points behind such a shock front in a standard atmosphere. The calculated concentrations presume local thermodynamic and chemical equilibrium. As such, they cannot yield final concentrations of neutral species after passage of the shock, since these depend on the various rates of reaction involved (which are poorly known, in general).

Direct computations for an ambient reducing atmosphere have not been made. However, the results for normal air are very suggestive. So long as the velocity of a body impinging on the top of the atmosphere exceeds about 7 km/sec, the corresponding stagnation temperature at equilibrium behind the shock varies from 5,000° to 10,000° K for altitudes ranging from 100 km to sea-level, respectively. These temperatures are sufficient to yield dissociation, essentially complete for oxygen and partial for nitrogen, with some ionization of the products to O^+ and N^+. For higher velocities, double ionization and other processes occur. The equilibrium concentration of a particular species (not present in the ambient atmosphere) rises with the distance behind the meteoroid and then falls off.

Qualitative extrapolation of these results to a reducing atmosphere containing hydrogen, methane, ammonia and water is easily made. Passage of a hypersonic meteoroid should yield a wake containing the monatomic species H, C, N, and O, the diatomic species CH, CN, CO, NH, OH, and NO (charged and uncharged in these cases), triatomic species, electrons, etc. As the temperature downstream of the meteoroid drops, the original ambient composition will be approached asymptotically, with a possibly small amount of complex compounds residual in the wake, as permitted by the kinetics of the situation.

However, the process of reversion to the original composition can be arrested, at least partially, if the meteoroid (and its initial velocity) are sufficiently large for it to survive passage through the atmosphere and to impinge explosively in the sea. In this event, the phenomena occurring should be similar to those in the near-surface explosion of a nuclear bomb in water[5], as in the Baker series of tests by the Atomic Energy Commission at the atoll of Bikini[5]. A hollow column of water and spray should shoot up into the atmosphere. Afterward, a dome-shaped cloud of droplets of water (the condensation cloud) should form, and finally the characteristic mushroom-shaped cloud above the water should appear. Thus, hot water mixed with steam will engulf the hot descending remnants of the wake, preventing reversion to the original composition of the ambient atmosphere, and providing the possibility of further reactions in a gaseous and aqueous medium to form complex compounds. The fall-out of the water from these clouds should provide an efficient mechanism for direct transfer of complex organic compounds to solution in the hydrosphere. For infall on the primitive atmosphere of meteorites able to reach the terrestrial surface, the process should be operative in at least two-thirds of the cases, since this fraction represents the present ratio of sea to total surface of the Earth.

It might be argued that the complexity of the compounds involved in the origin of life would imply a concentration, after passage of the shock, so low that it would be unimportant in biopoesis. However, consider a meteorite with diameter 1 km impinging on the Earth. Viewing the wake in the atmosphere as cylindrical with a diameter at least equal to that of the meteoroid, one computes that at least 10^{10} kg of air would have passed through the wake of the shock. From results[4] for normal air, the yields of NO, O, CO_2, CO, NO_2, and N_2O in the wake where the temperature is 2,000° K correspond to approximate molar fractions 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}, and 10^{-7}, respectively; hence passage of the meteoroid creates at least 10^8 kg of NO, 10^7 kg of O, 10^6 kg of CO_2, 10^5 kg of CO, 10^4 kg of NO_2 and 10^3 kg of N_2O in the atmosphere at this temperature. These numbers hold only for air in equilibrium, but suggest strongly that formation of complex compounds by reactions following passage of the shock may be quantitatively significant. Note that the meteoroid diameter selected corresponds closely to that of the minor planet (1566) Icarus, which would have an atmospheric velocity of 32 km/sec if it encountered the Earth[3].

Two further points should be kept in mind. It is generally believed that an intermediate phase occurred in the formation of the planets from gas and dust, consisting in the condensation of solid bodies or planetesimals at low ambient temperature. The planets owe their origin to accretion of these planetesimals. It follows that the rain of meteorites must have been of much greater intensity on the primitive Earth than is observed at the present time. Further, one of us[6] has proposed that the ocean basins are merely large meteoritic craters, produced by explosive impact of large planetesimals in the presence of a hydrosphere, far back in Precambrian times. If this hypothesis emerges as true, it obviously will imply a profound importance of the effect of meteorite falls in biopoesis. Furthermore, it would make highly reasonable the presence of organic compounds on the Moon, as suggested by one of us[7], in view of the hypothesized pristine presence of an atmosphere and hydrosphere.

A direct experimental check on the production of organic compounds in this manner has been undertaken by Dr. W. J. Hooker of this laboratory, by firing a hypersonic projectile through an atmosphere into a tank of water. One might also quench in water the plasma issuing from a plasma jet. An experimental check is difficult, since it involves microanalytical chemical techniques.

Sensitive Ionization System for the Detection of Permanent Gases and Organic Vapours by Gas Chromatography

THE two most commonly used high-sensitivity detection devices for gas chromatography, the 'flame ionization'[1] and the 'argon ionization' detectors[2], are insensitive to permanent gases. During an investigation into the various mechanisms responsible for ionization phenomena within the latter class of devices it was noted that under certain conditions of field and radioactive source strength, detector geometry and operating temperature, a simple ionization system using argon as carrier gas could be utilized to detect extremely low concentrations of permanent gases. The limit of sensitivity of this new mode of detector operation is up to 1,000 times greater than that reported with an earlier device[3]. In addition to this extraordinary response to fixed gases this same detector when operated at a different potential was found to retain certain characteristics, including the high sensitivity toward organic molecules as that noted by Lovelock[2] for the conventional small 'argon detector'.

The particular ionization chamber which provided optimal results is of an annular design as shown in Fig. 1. The outer cathode is a brass cylinder the internal dimensions of which are 10 mm wide and 10 mm high. The central anode is a solid brass rod 8 mm in diameter and 10 mm high, insulated from the cathode by polytetrafluoroethylene and containing two 1/16-in. dia. orifices which serve as gas inlets. The source of radiation is provided by a 200 mc. tritiated titanium foil (28 mm long × 10 mm wide) which snugly fits against the wall of the cathode. The total volume of this particular version of detector is 280 µl.

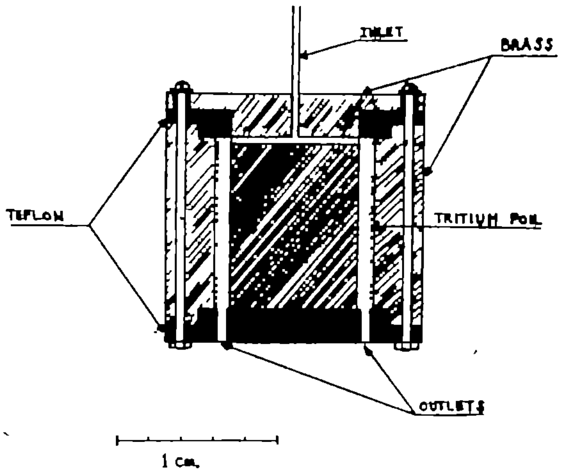

Fig. 1. A cross-section of the coaxial micro-ionization detector

While operating the device between 150° and 225° C, an investigation of the effect of variation in the applied field on the response to known volumes of permanent gases revealed an area of high sensitivity with a maximum occurring between 1–2 V (field strength = 10–20 V/cm.). At these low voltages (conveniently available from either a battery or a closely regulated power supply) all gases examined (He, Ne, CO, CO_2, H_2, O_2, N_2, CH_4, C_2H_6, C_2H_4) when passed through the detector provided an increase in current. At 165° C with an applied voltage of 1·34 V and pure argon flowing through the chamber, the standing current was $3 \cdot 7 \times 10^{-9}$ amp—about 1/2 of the saturation current obtained at 100 V. The noise-level was low at $1 \cdot 2 \times 10^{-13}$ amp. The minimum limit of detectability of these gases under the stated conditions is given in Table 1. No appreciable change in sensitivities were observed as the temperature was varied from 150° to 225° C.

Table 1. DETECTION OF PERMANENT GASES USING A CO-AXIAL MICRO-IONIZATION DETECTOR AND ARGON AS THE CARRIER GAS

Gas	µl./sec	g/sec	mole/sec
He	$7 \cdot 3 \times 10^{-3}$	$1 \cdot 3 \times 10^{-9}$	$3 \cdot 2 \times 10^{-10}$
Ne	$2 \cdot 6 \times 10^{-1}$	$2 \cdot 2 \times 10^{-7}$	$1 \cdot 1 \times 10^{-8}$
H_2	$5 \cdot 5 \times 10^{-4}$	$4 \cdot 8 \times 10^{-11}$	$2 \cdot 4 \times 10^{-11}$
CO	$4 \cdot 0 \times 10^{-4}$	$5 \cdot 0 \times 10^{-10}$	$1 \cdot 8 \times 10^{-11}$
CO_2	$1 \cdot 7 \times 10^{-4}$	$3 \cdot 3 \times 10^{-10}$	$7 \cdot 6 \times 10^{-12}$
O_2	$2 \cdot 8 \times 10^{-4}$	$3 \cdot 8 \times 10^{-11}$	$1 \cdot 2 \times 10^{-11}$
N_2	$1 \cdot 0 \times 10^{-3}$	$1 \cdot 5 \times 10^{-9}$	$5 \cdot 5 \times 10^{-11}$
CH_4	$1 \cdot 0 \times 10^{-4}$	$8 \cdot 8 \times 10^{-11}$	$5 \cdot 5 \times 10^{-12}$
C_2H_6	$3 \cdot 4 \times 10^{-4}$	$4 \cdot 8 \times 10^{-10}$	$1 \cdot 6 \times 10^{-11}$
C_2H_4	$2 \cdot 8 \times 10^{-4}$	$3 \cdot 4 \times 10^{-10}$	$1 \cdot 2 \times 10^{-11}$

The range of linearity did not substantially vary from one gas to another. For example, with methane it extended up to approximately 2 µl./sec above which the slope, although slightly decreased, continued in a linear fashion to at least 12 µl./sec. Ethane and ethylene, though included in Table 1, could have provided an additional 10-fold increase in response when analysed at normal argon detector voltages, which in the case of this detector are between 150–250 V.

The phenomenon of a maximum in sensitivity at such low applied voltages was observed to be a characteristic of small electrode separations (coaxial or parallel plate geometry) and the specific use of argon as a carrier gas.

The mechanism of ionization of permanent gases the ionization potentials of which lie above the energy of the argon metastable atoms (11·6 eV) appears to involve, in a unique manner, these neutral highly excited metastable atoms since an argon–ethylene (0·3 per cent) mixture used as a carrier gas completely quelled the excellent response.

It is believed that increased ionization in the chamber is due to the interaction of the argon excited atom (A^*) with the permanent gas molecule (M) resulting in a complex ion formation with a concomitant production of an electron, for example:

$$A^* + M \rightarrow AM^+ + e^- \qquad (1)$$

The stability of the complex ion AM^+ promotes the foregoing reaction and more than compensates for the lack of sufficient energy required for the direct ionization of the permanent gas molecules ($I.P. > 11 \cdot 6$ eV) via argon metastable atoms.

The use of the mass spectrometer and other appropriate devices has in the past established analogous reactions involving metastable atoms of the various inert gases[4–6]. In these experiments molecule ions such as A_2^+, He_2^+, $XeCH_4^+$, XeO_2^+, AN_2^+ and others have been reported. The lowering of the sensitivity observed when the applied voltage is increased is apparently due to a competition between reaction (1) and other processes which may include some form of the reverse reaction and also electron attachment for certain permanent gases. Formation of negative ions with oxygen and dissociative attachment for hydrogen are well known. Nitrogen, however, appears as an exception and will be discussed in a full report elsewhere.

Several other interesting and useful observations associated with this system were the following:

(1) This system can provide sensitivities similar to those noted in Table 1 without any potential applied to the chamber provided the cathode is suitably grounded and the device maintained at 160°–200° C. However, in these circumstances, where very small voltages generated by a thermoelectric effect are responsible for the flow of current within the chamber, the device becomes more susceptible to overload phenomena.

(2) Under comparative experimental conditions when ordinary commercial grade helium is used as a carrier gas the sensitivity of this detection system to permanent gases is reduced by at least a factor of 5.

(3) By further decreasing the internal volume of the detector, capillary columns can be readily utilized without the necessity of scavenger flow[7].

(4) When this device is operated at higher potentials (150–250 V) for the analysis of organic substances, the phenomena of electron attachment ordinarily exhibited by certain classes of compounds is minimal.

This work was supported by grants from the National Aeronautics and Space Administration (NsG 192–61) and the National Institutes of Health (H-3558).

Note added in proof. Preliminary analysis of Dr. Hooker's samples by Dr. C. A. Ponnamperuma (of the Exobiology Division, N.A.S.A., Ames Research Center, Mountain View, California) has indicated the presence of materials absorbing ultra-violet light of wave-length 260 mµ and appearing to have chromatographic characteristics similar to some of the known biological purines.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk are open to the public*)

Monday, February 11

BRITISH SOCIETY FOR THE PHILOSOPHY OF SCIENCE (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. G. Lipsey: "Problems of Scientific Discovery in Economics".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. D. R. Shearman: "Ionospheric Sounding by Incoherent Scatter at Very-High Frequencies".

UNIVERSITY OF LONDON (at Senate House, London, W.C.1), at 5.30 p.m.—Dr. M. F. Perutz, F.R.S.: "Structure of Proteins"* (John Coffin Memorial Lecture).

INSTITUTION OF MECHANICAL ENGINEERS, INTERNAL COMBUSTION ENGINES GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The High-Speed Diesel Engine—Higher Performance or Lower Cost ?"

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"North America in the Making" (programme of award-winning films).

Tuesday, February 12

SOCIETY OF CHEMICAL INDUSTRY, AGRICULTURE GROUP (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Meeting on "Carbon^{14} in Agricultural Research".

BRITISH SCHOOL OF ARCHAEOLOGY AT ATHENS (at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7), at 5 p.m.—Prof. John Evans: "Neolithic Knossos—New Facts and Problems".

ROYAL INSTITUTION OF NAVAL ARCHITECTS (at the Institute of Marine Engineers, 76 Mark Lane, London, E.C.3), at 5 p.m.—Mr. R. Cook and Mr. N. Fleming: "Aspects of Noise Reduction in Merchant Ships".

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the National College of Rubber Technology, Northern Polytechnic, Holloway Road, London, N.7), at 5.30 p.m.—Dr. W. McG. Morgan: "Chemical Promotion and Heat Treatment". 7 p.m.—Papers by members of the National College of Rubber Technology.

SOCIETY OF ENVIRONMENTAL ENGINEERS (in the Mechanical Engineering Department, Imperial College, London, S.W.7), at 6 p.m.—Lecture on "High Speed Resonance Searching with Automatic Recording".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the SIR JOHN CASS COLLEGE CHEMICAL SOCIETY, at the Sir John Cass College, Jewry Street, London, E.C.3), at 7 p.m.—Prof. H. C. Longuet-Higgins, F.R.S.: "Some Applications of Electron Spin Resonance in Chemistry".

ROYAL SOCIETY OF MEDICINE, PSYCHIATRY SECTION (at 1 Wimpole Street, London, W.1), at 8 p.m.—Dr. G. A. Foulds: "Basic Personality and the Symptom Complex in Psychiatry".

Wednesday, February 13

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Prof. J. L. Gowans: "Some Problems in Cellular Immunology".*

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. D. J. Shearman: "Recent Anhydrite, Gypsum, and Dolomite from the Trucial Coast, Persian Gulf"; Dr. D. C. Turner "Ring-Structures in the Sara-Fier Younger Granite Complex, Northern Nigeria" (to be read by Prof. W. S. Pitcher).

INSTITUTE OF FUEL (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Mr. S. L. Bragg: "Combustion Noise"; Dr. E. G. Masdin and Prof. M. W. Thring: "Combustion of Single Droplets of Liquid Fuel".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION P.G.P8 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. P. Brock and Dr. J. McKeown: "Some Improved Lead Alloys for Cable Sheathing".

UNIVERSITY OF LONDON (at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 5.30 p.m.—Dr. G. R. Wadsworth: "Dental Conditions and Nutritional Status".* (First of three lectures on "The Scientific Basis of Dentistry" organized by the British Postgraduate Medical Federation).

ROYAL SOCIETY OF ARTS (at John Adam Street, London, W.C.2), at 6 p.m.—Dr. R. G. Allen: "Water Supplies and Conservation".

UNIVERSITY OF LONDON (in the Physics Lecture Theatre, Birkbeck College, Malet Street, London, W.C.1), at 6 p.m.—Prof. D. J. Bohm: "On Problems in the Basic Concepts of Physics"* (Inaugural Lecture).

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—NUTRITION PANEL (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Miss A. M. Copping: "The Nutritional Education of the Food Technologist".

INSTITUTE OF METAL FINISHING, ORGANIC FINISHING GROUP (joint meeting with the CORROSION GROUP of the SOCIETY OF CHEMICAL INDUSTRY, at the Borough Polytechnic, Borough Road, London, S.E.1), at 7 p.m.—Mr. U. R. Evans and Mr. C. A. J. Taylor: "Metal-Pigmented Paints for the Protection of Steel".

SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. K. F. H. Murrell: "The Quality and Quantity of Information"; Mr. J. Spencer: "The Design of an Instrument Display"; Mr. A. Cowan. "Process Plant Control—Information Centre Concept".

WOMEN'S ENGINEERING SOCIETY (at "Hope House", 45 Great Peter Street, London, S.W.1), at 7.30 p.m.—Mr. M. G. Wilde: "Supersonic Airliners".

Thursday, February 14

PLASTICS INSTITUTE (at the Connaught Rooms, Great Queen Street, London, W.C.2), at 9.30 a.m.—Symposium on "Design for Profit".

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Dr. Honor B. Fell, F.R.S.: "The Role of Membrane Systems in the Response of Cells to some Chemical Agents" (Special Review Lecture).

UNIVERSITY COLLEGE, LONDON (in the Physiology Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. F. Bergel, F.R.S.: "The Therapeutic Future of Larger and Larger Molecules".*

UNIVERSITY OF LONDON (at Birkbeck College, Malet Street, London, W.C.1), at 5.30 p.m.—Prof. H. Koch (University of Louvain): "Osmotic Regulation and Salinity Preference in the Stickleback (*Gasterosteus aculeatus* (Cuv. & Val.))".* (Further lectures on February 15 and 18.)

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. Hannah Steinberg: "Measuring Effects of Drugs Upon Behaviour".* (Eleventh of twelve lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

CHEMICAL SOCIETY (at the Royal Institution, Albemarle Street, London, W.1), at 6 p.m.—Prof. R. Kuhn: "Problems of Cumulenes and Acid Hydrocarbons" (Centenary Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (at the Central Hall, Westminster, London, S.W.1), at 6 p.m.—Dr. E. Eastwood. "Electronics—The Key to Air Safety" (Faraday Lecture).

INSTITUT FRANÇAIS DU ROYAUME-UNI (at Queensberry Place, London, S.W.7), at 6.15 p.m.—M. Etienne Wolff (Professeur au Collège de France): "Les Agents Provocateurs de Malformations" (La Production Expérimentale de Monstruosites).

RADAR AND ELECTRONICS ASSOCIATION (at the Royal Society of Arts. John Adam Street, Adelphi, London, W.C.2), at 7 p.m.—Sir Bernard Lovell, O.B.E., F.R.S.: "Investigation of Space by Probes and Radio".*

Friday, February 15

PHOTOELECTRIC SPECTROMETRY GROUP (in the Physics Department, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7), at 2 p.m.—Meeting on "The Collaborative Test of Recording Ultraviolet Spectrophotometers".

BRITISH COMPUTER SOCIETY (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 2.30 p.m.—Mr. R. A. Scriven and Mr. D. Benson: "Analogue Computer Study of a Long Catenary in a High Wind".

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Ducane Doad, London, W.12), at 4 p.m.—Dr. D. R. Laurence: "The Problem of the First Clinical Trial of a Drug".*

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 5.30 p.m.—Discussion on "Why Ships Collide" lead by Captain F. J. Wylie, R.N. (Retd.) and Captain J. P. Stewart.

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION P.G.S8 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Teaching Materials Engineering". opened by Dr. T. J. Lewis and Dr. D. W. F. James.

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (joint meeting with the HEAVY ORGANIC CHEMICALS GROUP, at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. B. Sully: "Plasticisers".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Mr. Marshall Nixon: "Conservation of Water Resources".

Friday, February 15—Saturday, February 16

BIOCHEMICAL SOCIETY (at the National Institute for Medical Research, The Ridgeway, Mill Hill, London, N.W.7), at 10 a.m. on Friday—Colloquium on "The Biochemistry of Animal Viruses"; at 2 p.m. Friday and Saturday—Scientific Papers.

Saturday, February 16

SOUTH-WEST ESSEX TECHNICAL COLLEGE, with the support of the CHEMICAL SOCIETY and the BRITISH BIOPHYSICAL SOCIETY (at the South-West Essex Technical College, Walthamstow, London, E.17), at 9.45 a.m.—Symposium on "The Evaluation of the Degree of Hydrogen Bonding in Biological Molecules".

Monday, February 18

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDE GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. K. S. Hocking: "The Work of the Tropical Pesticides Research Institute, Arusha".

INSTITUTION OF MECHANICAL ENGINEERS, EDUCATION AND TRAINING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Should an Undergraduate Mechanical Engineering Course Include Production Engineering ?"

INSTITUTE OF METAL FINISHING (at the Northampton College of Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. R. W. Beattie and Mr. N. Fairweather: "Electroplating and Inspection of Electrical Contacts".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER IN PHILOSOPHY—The Registrar, The University, Sheffield (February 16).

MAP CURATOR (preferably geography graduate with an interest in maps and bibliographic work) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Leeds 2 (February 18).

LECTURER or ASSISTANT LECTURER (preferably with research interests in solid state physics, particularly the Mössbauer effect, low temperatures and N.M.R.) **in Physics**—The Registrar, The University, Manchester 13 (February 20).

Lecturer (with a degree in civil engineering and at least five years recent approved industrial experience) **in Civil Engineering** at Bendigo Technical College, Bendigo, Victoria, Australia—The Council for Technical Education and Training for Overseas Countries, 13 Lincoln's Inn Fields, London, W.C.2 (February 20).

Chair of Civil Engineering—The Secretary, The Queen's University, Belfast, Northern Ireland (February 28).

Demonstrator in Geology—The Registrar, University of New England, Armidale, New South Wales, Australia; and The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 28).

Associate Professor in Soil Mechanics in the Department of Civil Engineering, University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 1).

Browne Research Fellow in Botany or Zoology—The Provost, The Queen's College, Oxford (March 1).

Leverhulme Postgraduate Fellows (3) two in the Faculty of Science and one in the Faculty of Engineering—The Registrar, The University, Liverpool, quoting Ref. No. RV/240/N (March 1).

Research Fellow (with a good honours degree in physics or engineering) **in Textile Engineering**, to investigate problems concerned with the division of heat between two rubbing surfaces—The Registrar, The University, Leeds 2 (March 1).

Research Chemist (well-qualified organic chemist, preferably with an interest in microbiology and enzyme chemistry), for research relating to the removal of wool from sheepskins—The Director, Wool Research Organization of N.Z. (Inc.), Private Bag, Christchurch, New Zealand (March 1).

Chair of Physics in the University of Ghana—The Registrar, University of Ghana, P.O. Box 25, Legon, Accra; or The Assistant Registrar (Overseas), University of Ghana, 15 Gordon Square, London, W.C.1 (March 4).

Lecturer in Inorganic Chemistry at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 4).

Senior Lecturer (preferably with training and research experience in biochemistry and enzymology, and some teaching experience) **in Agricultural Chemistry** at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 6).

Assistant Lecturer in Biochemistry—The Registrar, University College of Wales, Aberystwyth (March 9).

Lecturer or Senior Lecturer in the Department of Physics, University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 16).

Reader in the Department of Physics, University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 18).

Lecturer in Meteorology at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 31).

Associate Professor (with strong research interests in the application of advanced analytical and synthetical techniques to machine design and the kinematics of machines) **in Theory of Machines** at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 15).

Agricultural Chemist (aged 25–45, an honours degree in chemistry with, if possible, two years postgraduate training in agricultural chemistry and soil physics) in the Ministry of Natural Resources and Surveys, Nyasaland, for duties which include analyses of soils and crops in relation to fertilizer needs, and assessing water requirements of irrigated crops—The Director of Recruitment Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting T/RC 213/110/02.

Assistant Lecturer, Grade B (with a good honours degree and an interest in developing some branch of applied physics in H.N.C. and H.N.D. courses) **in Physics**—The Principal, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex.

Biology Teacher, to deputise for one year for the Senior Biology Master—The Headmaster, Bishop's Stortford College, Bishop's Stortford, Herts.

Junior Scientific Officer (female, with an honours degree in biology, physiology or chemistry, and preferably experience of blood grouping and a knowledge of genetics), for work on blood group serology—The Director, Blood Group Reference Bureau, c/o Lister Institute, Chelsea Bridge Road, London, S.W.1.

Laboratory Technician (competent in section-cutting and staining, and in photography) **at the Marine Biological Station**, Port Erin, Isle of Man—The Registrar, The University, Liverpool 3, quoting Ref. 252.

Male Laboratory Technician (experienced), for teaching unit—The Administrator, Department of Biochemistry, South Parks Road, Oxford.

Master to teach Chemistry and some Biology—The Master, Wellington College, Crowthorne, Berkshire.

Master to teach some Sixth Form Biology and Science in the Lower and Middle School—The Headmaster, Bootham School, York.

Postdoctoral Assistant, for work on a problem in inorganic chemistry involving the use of proton magnetic resonance spectrometry—Dr. J. A. Elvidge, Organic Chemistry Research Laboratories, Imperial College of Science and Technology, London, S.W.7.

Research Assistant (preferably with experience in cytology) **in the Department of Genetics**, to take part in a programme designed to study human chromosome abnormalities and associated disorders—The Secretary, Genetics Department, The University, Sheffield 10.

Senior Technician II (male, F.I.M.L.T., or equivalent qualification in hæmatology and blood transfusion), for duties which will include the care and maintenance of scientific equipment—The Director, Blood Group Reference Laboratory, c/o Lister Institute, Chelsea Bridge Road, London, S.W.1.

Technical Officer (with either a degree in physics or engineering, Grad.I.E.E., Grad. Inst.P., or similar qualification) **in the Medical Engineering Department**, to develop electronic and other equipment for use in medical research—The Secretary, Postgraduate Medical School of London, Ducane Road, London, W.12.

Theoretical Physicist (preferably with interests in solid state or nuclear physics); and an **Experimental Physicist** (preferably with interests in radio frequency spectroscopy)—Head, Department of Physics, Assumption University of Windsor, Windsor, Ontario, Canada.

REPLANNING GOVERNMENT ORGANIZATION FOR SCIENCE

THE study of the influence of Government policy on *Science in Industry*[*], issued by the Conservative Political Centre, is the outcome of the work of a committee, with Mr. R. Carr as chairman. The committee was appointed in June 1960 to examine, in the light of the rapid scientific and technological development of other advanced countries, the role of the Government in stimulating and assisting research and development and the application of scientific methods and manpower to production in industry. Particular reference has been made in the report to scientific research and development and the application and dissemination of the results of research. It thus takes its place with such contributions as J. S. Dupré and S. A. Lakoff's recent book, *Science and the Nation: Policy and Politics*, surveying conditions in the United States, and with the report on *Industrial Research in Manufacturing Industry 1959–60* issued in 1962 by the Federation of British Industries. In fact, it was at a conference at Eastbourne in April that the last-mentioned was discussed, and at which a member of the Carr Committee, Mr. Aubrey Jones, made an important contribution. The report is the outcome of initiative by a political party and is noteworthy in the extent to which it reveals that the recommendations of the Plowden Report on the control of public expenditure and of the Gibb–Zuckerman Report on the management and control of research and development have penetrated the thinking of a major political party.

Primarily the report is concerned with the problems of Britain's industrial *future*. Indeed it is only concerned with the problems of science and Government in so far as they relate to that *future* and determine the extent to which Britain's scientific and technological effort is translated into effective action. It starts with the assumption that the solution to the problems lies in not only turning out new products, with a high technical content, beyond the competence of all except a few countries, but also in producing traditional goods at a very high level of efficiency. Above all, it is essential that these are of first-class quality and design and supported by vigorous salesmanship. No one could wish for clearer recognition of the imperative need of making the fullest possible use of modern science and technology than is to be found in this report. No less explicit is the recognition that an adequate educational programme is the vital factor.

The scientist will welcome other features of the report. For example, there is no illusion that the problems will be solved simply by spending vast sums of money on science, and it is recognized that the quality of management, old-fashioned trade union attitudes, and unwillingness to fit the products to the real requirements of the purchaser have all contributed to the difficulties. Further, it is recognized that more flexible instruments of policy can also have a specific influence on the course of research and development: it is a real advance to find in a report of this type the admission that it would be possible to modify the tax structure in such a way as to encourage inventiveness and the efficient use of labour.

True, Britain has yet to see all-party support for any concrete proposals to that end. However, the four main lines of action for Government proposed in this report and on which its attention is mainly focused are such as should command that support, whatever the differences in view as to the means by which such action should be effected. To create background conditions which can be expected both to stimulate industrial science and to make it as efficient as possible would be a reasonable remit for the Council for Scientific and Industrial Research. Add to that the responsibility for: (1) equipping the machinery of Government to fit its actions in detail to the need for proper scientific development in industry; (2) ensuring that the administration of the Government's own expenditure on science is organized to secure full value for money in the light of Britain's needs and her resources; and (3) seeing that the 'ground-level' contacts between this administration and particular parts of industry are used to the best effect, we have a reasonably comprehensive description of the functions of the Minister for Science and his Advisory Council up to the level at which they merge with the responsibilities of the Cabinet itself.

There is, in fact, a refreshing realism about this study and a freedom from preconceived ideas that may well have been fostered by some of the recent discussions in this field at the Eastbourne Conference already mentioned and at meetings of the British Association and other bodies. Questions of competition, of large- and small-scale enterprise, and of co-operative undertakings are considered with more detachment and a fuller sense of the public rather than individual interest. It is frankly admitted that a scientific policy, in the sense of a conscious effort to obtain the maximum economic advantage from scientific resources must be part of the core of the economic policy. The view of Prof. A. K. Cairncross that economic growth in a highly developed society depends more on the pace of technological development than on the actual amount of capital investment is accepted. Accordingly, the National Economic Development Council must be concerned with relating both the targets and the flow of information to scientific and technical possibilities and needs. This involves including on the Council, and in its secretariat, men who understand science and scientists who have a real knowledge of the factors which are important to research, development and innovation in industry and who can apply that knowledge continuously in the work of the Council.

One could scarcely expect to find in a survey of this type any searching review of the organization of Government and the reactions between science and public policy, but the Committee was led to conclude that a much more detailed appraisal of the industrial repercussions of policy is required than the present structure of Government can provide. Some new way must be found for bringing industrial, scientific and technical considerations into the determination of policy over a wide range of departmental activity. It recommends that every Government Department dealing with industry should have a new kind of 'scientific–economic staff' to act as a forward policy planning unit, advise the Minister on the technical and industrial implications of the Department's future policy plans, to gather economic and technical information from the relevant industries, and generally provide a technical intelligence service to the Department.

---

[*] *Science in Industry: The Influence of Government Policy.* Pp. 46. London: Conservative Political Centre, 1962.) 3s.

This is manifestly in line with the whole trend of the Plowden Report and even when a Department, like the Treasury, has no call to make specific technical judgments, the Committee believes that it would be useful for Ministers to have such a staff with a technical bias. In particular, it recommends strengthening scientific representation on both the National Economic Development Council and the secretariat and close liaison between the secretariat and the proposed staffs of the Departments. While it strongly supports the recommendations of both the Plowden Report and the Gibbs–Zuckerman Report for greater interchange of staff both in the Civil Service itself and between the Service, industry and the universities, it recommends that part of the proposed staffs should comprise scientists and economists recruited from industry and the universities on temporary contracts or secondment. It is essential that the staff should be of high quality, whether recruited from the Civil Service itself or from those with industrial experience or specialized training in science and economics, and the two-way flow of such men elsewhere in the Civil Service and in industry and in the universities is a valuable subsidiary effect of the proposal.

For the rest, Mr. Robert Carr and his Committee take a long and somewhat critical look at scientific administration generally, and while it would be unreasonable to expect the Committee's recommendations to secure extensive discussion or executive action pending the report of the Trend Committee, some of their criticism can scarcely be ignored by the Minister for Science. At the outset, it recommends the establishment at Cabinet level of a Technical Policy Committee to formulate the main lines of a scientific policy related to military and economic strategy. The membership of this Committee would include the Minister for Science, the Minister of Defence and a senior economic Minister, but no convincing evidence is advanced as to what advantage this proposal would have over making the Minister for Science a member of the Economic Policy and Defence Committees of the Cabinet, or indeed why it should prove effective in the absence of insufficient appreciation of scientific and technical factors, among others, on the part of the Cabinet generally and ultimately of the electorate.

Where the Committee appears to be most critical is in relation to defence, and here it would seem that it would prefer to strengthen the responsibilities and influence of the Minister for Science. Like the Gibb–Zuckerman Report, the Committee is critical of the functioning of the Defence Research Policy Committee, and it suggests that that Report should be followed by an investigation of the relation between the Service Departments, the Ministries of Aviation and Defence and the Treasury. It formed the impression that the Ministry of Defence required stronger powers in relation to research and development and that the Minister's Chief Scientific Adviser required a stronger staff. Although it suggests that as much defence research and development work as possible should be contracted to industry, and that improved liaison is required between the defence and civil sides, it makes no comment on the relations between the Defence Research Policy Committee and the Advisory Council on Scientific Policy either through the device of a common chairman or through the Minister for Science. Further, if the separation between defence and civil research and development is maintained, the Committee points out, care must be taken to ensure that by-products of the defence programme, once identified, are developed and exploited, and this implies that additional resources must be available for civil and industrial research generally.

The Committee's analysis in this context of the use of contracts, and especially of development contracts, which it develops later in the section of the report "Services for Industry" is sound. However, it might have gained in depth by consideration of American experience as unfolded, for example, by Prof. J. S. Dupré and S. A. Lakoff in their recent book, *Science and the Nation: Policy and Politics*†. Some of the dangers and implications of the American system indicated in the book are highly relevant even in the different conditions prevailing in Britain and underlie some of the *malaise* which, for example, has led to the appointment of the Nye Committee. The ease with which the military side can dominate an advisory scientific body, as for example in the experience of the Advanced Research Projects Agency, may afford valuable guidance when Britain's scientific organization is under reconsideration. Above all there are the apt remarks of Dr. J. R. Killian, jun., in a foreword that a technological society requires an adequate complement of scientists and engineers in the public arena if it is to deal wisely with great policy matters arising out of science and technology, and that the interface between science and political science is an area worthy of careful attention by both scientists and political scientists.

It is here, Dr. Killian considers, that the most effective bridges between science and the social sciences can be built, and while the Carr Committee does not enter into any profundities of political science its report contains enough practical suggestions to warrant serious and impartial appraisal. On balance it supports the strengthening rather than any decrease in the authority and responsibilities of the Minister for Science, and it is especially critical of the present staffing of his Office. The Committee would transfer to the Vote for that Office those for the four Research Councils—the Overseas Research Council is again not mentioned. This omission is rather curious in view of a subsequent observation on the importance of stimulating more contacts and exchanges with scientists overseas and introducing a scheme of research fellowships for young scientists from abroad. Such a project would provide his Office with a body of highly qualified scientific advisers as part of its full-time staff, including scientists temporarily seconded to Government service from industry and the universities. The Committee recognizes that finance for university research cannot be brought under the Minister for Science in the same way, but regards the absence of any formal consultation with the Minister in the process of allocating funds for scientific research at the universities as a defect in the present system. Accordingly, it emphasizes the need for effective cross-representation and consultation between the University Grants Committee and the Office of the Ministry for Science.

To a certain extent, developments in that direction have already been forced on the Advisory Council for Scientific Policy, but the Carr Committee does not appear to discount the value of that Council. It considers that full-time advisers are also required, though a group of eminent and representative scientists such as is constituted by the Council could continue to provide a stimulus and an independent judgment of great value. The Committee does not, however, appear to appreciate the difficulty of the manpower issue at that level or the co-ordinating influence which such a Council can contribute in reviewing the work of the several Research Councils, etc.

---

† *Science and the Nation: Policy and Politics*. By J. Stefan Dupré and Stanford A. Lakoff. (Spectrum Book.) Pp. x+181. (Prentice-Hall, Inc., Englewood Cliffs, N.J., and London, 1962.) 16*s*.
[See also p. 635 of this issue of *Nature*.]

Once again, strong support is forthcoming for the National Research Development Corporation, although it is admitted that its role is slighter than was at first expected. It is suggested that the basis of its finance should be reconsidered to see if better allowance could be made for the exceptionally long time likely to elapse between the provision of money for a project and the receipt of any substantial returns. The Committee also favours the establishment of an Industrial Guarantee Corporation and suggests that the Department of Scientific and Industrial Research should be provided with a specified sum for expenditure on civil development contracts over a five-year period. Both civil and defence contracts should provide the contractors with rights in exploiting the end product with the emphasis on rapid development rather than wide distribution of rights.

As might be expected, the Department of Scientific and Industrial Research receives more detailed examination, and it is recommended that the Department's research stations should, wherever possible, be progressively more closely integrated with the industries to which they are related. Welcome stress is laid on the value of greater mobility and interchange of staff, both by way of visits, exchanges and contracts between their staff and scientists in Britain and in other countries, while it is suggested that the research stations should regard the training of industrial scientists as one of their functions. This educational function has already been urged as one of the most important functions of the research associations, but its advocacy in respect of the research stations appears to be novel. Such a function, however, should become important particularly if the extent to which fundamental research is pursued in the research stations is severely limited. The Carr Committee makes no particular criticism of the research associations themselves, and although it recognizes the limitations and inherent dangers of the system, it considers that their existence could prove a valuable asset if Britain joins the European Economic Community. The educational and other advantages, particularly in the dissemination of information, outweigh the drawbacks, but the Committee would like to see the Department's grant policy towards established associations directed towards underwriting unusually interesting and adventurous projects rather than towards subsidizing routine work.

This seems rather a naïve view which ignores the inherent drawback in the finance of research from public funds, and Sir Henry Tizard's caution against the dependence of venture and enterprise on public finance may appropriately be recalled. The propping of a conservative or decadent industry, as distinct from the encouragement of a developing and enterprising industry, is as likely to be to the public disadvantage as to its advantage. Criticism of the information services of the Department of Scientific and Industrial Research is equally somewhat hesitant and overlooks the extent to which the Department fails to describe and report on such activities. On the other hand, there is a welcome emphasis on the importance of personal contact. Particularly, with the smaller firms and in encouraging firms to make full use of available facilities, such contacts are the vital factor and are the first step towards securing the benefits which mechanical developments in the handling of information have now made possible.

It is interesting to put the report alongside an address by the chairman of the Council for Scientific and Industrial Research, Sir Harold Roxbee Cox, to the Motor Industry Research Association on November 28 on taking the lead in technology. Sir Harold desiderated four great changes needed if Britain were to strengthen her dispositions for the development of invention, where the present weakness lay. First, Britain needs many more scientifically and technologically trained people. Secondly, from these Britain must encourage an increasing proportion of the best talent to adopt design and development as their professional ambition. Thirdly, more of the scientists and technologists in industry, more of the research workers, developers and designers, must become interested in administration and policy and reach positions of command. What is needed here is a different distribution of disciplines at the top, in which the applied scientist trained in management could pull his weight. Fourthly, a clearer definition of objectives is required. Too much research is carried out with no clear idea of where it may lead, and while fundamental research should always be encouraged, those objectives should be more precisely defined which are likeliest to offer technological advantage: thus it would be possible to recognize the most promising lines of applied research and development.

The resemblance between the lines of Sir Harold's address and the whole trend of the Carr Report on science in industry is remarkable. How far the analysis will commend itself to the Minister for Science is another matter. In a recent address to the National Association of British Manufacturers, Lord Hailsham claimed the achievement of two major political objectives as Minister: one was that policy had been determined by scientists on scientific grounds, and the other that he had been able to avoid building up an expensive and useless Ministry of Science. Neither objective, however, seems incompatible with the recommendations of this report, which is equally in harmony with Lord Hailsham's version of a society in which those trained minds, in science, in arts and social sciences, who put public service in front of enjoyment, profit or leisure, have a dominant part in the administration.

Apart, however, from raising, at least by implication, the question of how much should be spent on scientific research, whether pure or applied, the report is usefully considered in the context of the book by Dupré and Lakoff, which also makes incidental reference to that question. Important as is that question, however, a rather more pragmatic approach is needed, for example, than those of G. Holton in his "Notes Toward the Design of Proper Scales for Scientific Research and Scholarship" (spring 1962 issue of *Daedalus*) or of S. Dedijer in his paper on "Measuring the Growth of Science" (*Science*, 138, 781; 1962). Dupré and Lakoff, in fact, seem to give a sounder lead in their comment that a research partnership between public and private institutions does not necessarily work easily and automatically. Such a partnership, for example, is involved in the distinguishing characteristic of organized research in the United States since the Second World War—extramural Government research.

To perform its tasks effectively, the research partnership must be the object of thoughtfully constructed policies and of mutual accommodation between the partners. Dupré and Lakoff display very fairly the conflicts that arise between Government and industry, between Government and universities, the clashes of loyalty involved which are frequently independent enough of the specific characteristics of national institutions but derive from the nature of the university, or of industry, or of Government itself. Whether they are concerned with the formulation of policy or with the stuff of politics, the major challenge thrown down to organization if the relations between science and Government are to function smoothly is as manifest in this book by Dupré and Lakoff as in the Carr Report: it can neither be mistaken nor ignored by the scientist.

THE NERVOUS SYSTEM

Experimental Neurology

By Prof. Paul Glees. Pp. xii + 532. (Oxford: Clarendon Press; London: Oxford University Press, 1961.) 75s. net.

THIS book is a translation of a book published in German by the author in 1957. The lapse of time has made some amplification possible. Dr. Glees is well known for his contributions to neurohistology. The book begins with a description of the methods used to investigate the finer anatomy of the nervous system with particular reference to the tracing of the degeneration resulting from experimental lesions, and goes on to review the methods used for the study of nervous activity, including the investigation of evoked potentials by electroencephalography and the study of behaviour. Nowadays, the old distinction between anatomy and physiology has disappeared in the sense that in a large field of experimental neurology the study of the one without the other would be meaningless. Hence Dr. Glees takes the reader through the anatomo-physiology of the nervous system from the peripheral receptors by way of nervous conduction and the synapses to the spinal cord and thence to the various anatomical structures at higher levels until he reaches the cerebral cortex.

Clearly a book, even of this size, cannot hope to cover all aspects of both neuroanatomy and neurophysiology. There are therefore gaps. For example, an account of the differing rates of conduction in fibres of different sizes in the peripheral nerves does not mention the attempt to correlate these with particular forms of sensibility. It is a little difficult to know how speech comes into experimental neurology, but if it is to be included it should not be limited to a description of 'centres' for motor speech and writing even with the admission that "the word 'centre' for these areas tends to give [a] false impression".

Nevertheless this book, which is well produced, well illustrated and very well documented with references, fills a real need and will be of value to a wide range of readers who want to know what is happening in the important, but nowadays highly technical, field of experimental neurology.

LORD BRAIN

FRÉDÉRIC JOLIOT-CURIE

Frédéric Joliot-Curie et l'Energie Atomique

Par Pierre Biquard. (Savants du Monde Entier, Nr. 3.) Pp. 255. (Paris: Éditions Seghers, 1961.) n.p.

THIS is a paper-back volume, in French, in the series *Savants du Monde Entier*. The standard of the biographies which have appeared already is high and the promised volumes, which range from Aristotle to Leriche, Fermi, Cuenot and Branly, will be awaited with interest.

The author of the book is pleasantly objective and, so far as possible, allows the story to tell itself in terms of original documents. Joliot was born on March 19, 1900, entered the laboratory of Marie Curie in October 1925, married her daughter Irène a year later, was awarded the Nobel Prize in Chemistry in 1935, claimed the fission of uranium in 1938, and started up the small atomic pile *Zoé* in 1948. He died in 1958, two years after his wife.

Joliot, the son-in-law of Marie Curie, owed much to mother and daughter; but he had an original mind, great technical skill and an inventive genius. He was a man of wide attainments: he played the piano and painted effectively. He read widely and, surprisingly, was devoted to the works of Kipling, some of which had been translated by his wife. The rational, anti-clerical outlook of the Curies suited his socialism. He was 'a citizen of the world' and was active in the movements for the use of science in the cause of peace and the improvement of the lot of man. There is a danger that his activities as a communist may obscure, in the Western mind, his real achievements as a physicist. There can be no doubt of his absolute sincerity in his political ideas in relation to the catastrophic possibilities for mankind in the applications of nuclear physics.

The stories of the beryllium rays, which were an important step in Chadwick's discovery of the neutron; the production of artificial radioactivity; the sorting out of the real nature of the so-called trans-uranic elements are well told. Joliot's favourite instruments were C. T. R. Wilson's cloud-chamber, which he improved, and the Geiger counter. Unlike so many atomic scientists in other parts of the world, he always remembered with gratitude the sources of these simple and beautiful fundamental instruments of atomic research.

The documentation is excellent, and the appendixes contain lists of all Joliot-Curie's publications, jointly with his wife and separately, a list of his lecture courses, a bibliography of works devoted to him and a useful glossary, in French, of terms used in nuclear physics. The illustrations are varied and informative. Among others, these include reproductions of pages of the laboratory note-books of Joliot-Curie, a picture of him with his favourite cloud-chamber apparatus, an example of his landscape painting and a photograph of the crowd at his funeral.

W. L. SUMNER

ASPECTS OF PHYSICAL CHEMISTRY

Annual Review of Physical Chemistry

Vol. 13. Edited by H. Eyring, Associated Editors: C. J. Christensen and H. S. Johnston. Pp. vii + 528. (Palo Alto, California: Annual Reviews, Inc., 1962.) 7.00 dollars (United States); 7.50 dollars (elsewhere).

THE present volume of this highly valued review of physical chemistry contains 21 articles covering the usual proportion of old and new titles. This means that individual chapters are fairly short and when it is found that there are some 3,285 references in the bibliographies it will be appreciated that the treatment, apart from being selective, is concise. All the same, most of the authors have contrived to make their reviews interesting. A new feature, which is to be repeated, consists of a chapter of reminiscences by a veteran physical chemist. In view of the great compression of the factual articles it is questionable whether this will be welcomed by all readers.

It is obvious that not even a list of titles can be provided and only a few aspects of the volume can be mentioned. There are many useful tables of results. The discrepancy in the values of the bond length C—H found by two different groups of methods is not resolved. The chapter on cryogenics includes an interesting discussion of the Mössbauer effect, which is having an influence in various fields. In the high-temperature field, which this year is confined to moderate temperatures, it is said that the melting-point of gold is still uncertain by one or more degrees, and the accepted heat of formation of silica is apparently too low. The intervention of the solvated electron in radiolytic oxidations seems to be more probable than that of the H_2^+ ion. In water the OH' ion is probably more highly solvated than the H^+ ion, and in acid solutions the H^+ ion is more solvated than H_3O^+. The production of isotopes in meteorites by spallation reactions induced by cosmic rays is likely to throw light on the question of the constancy of cosmic rays in time and space.

The chapter on solutions of non-electrolytes seems to suggest that in this field some stagnation has set in and that what is called for is a new approach. That on electrolyte solutions repeats once more the familiar criticism of measurements with cells involving liquid contacts, without throwing much light on the validity of the thousands of measurements made daily with such cells in laboratories of all kinds; a more constructive approach would have been of more interest. In studies of gas kinetics, it is said, gas chromatography (on which some 1,500 publications appear annually) is replacing mass spectrometry. The mechanism of acid-catalysed reactions is much less simple than has been supposed.

J. R. PARTINGTON

SPECTROSCOPY IN SCIENCE AND TECHNOLOGY

Fundamentals of Infrared Technology

By Marvin R. Holter, Sol Nudelman, Gwynn H. Suits, William L. Wolfe and George J. Zissis. (Macmillan Monographs in Applied Optics.) Pp. xv + 442. (New York and London: The Macmillan Company, New York, 1962.) 79s.

Theory and Applications of Ultraviolet Spectroscopy

By Prof. H. H. Jaffé and Prof. Milton Orchin. Pp. xv + 624. (New York and London: John Wiley and Sons, Inc., 1962.) 113s.

Standardization of Spectrophotometric Data in the Near Ultraviolet, Visual and Near Infrared

By Dr. Jørgen Fog. (Institute for Medical Biochemistry and Physiology, University of Oslo.) Pp. 64. (Oslo: Johan Grundt Tanum Forlag, 1962.) n.p.

THE interaction of matter with electromagnetic radiation of all wave-lengths is assuming an ever-increasing importance in both pure and applied science. The nature of the absorption of wave-lengths 5–50 times as long as those of visible radiation has become of great industrial as well as academic interest as a result of the successful application of infra-red spectroscopy to the analysis of organic materials. The military applications of infra-red radiation, particularly its use for the guidance of missiles, are so important that the fate of a nation might well depend on the state of its infra-red technology.

The first of these books deals mainly with the latter aspect of the technology of infra-red radiation. It contains the substance of a course of lectures given at the University of Michigan by its five authors. Its first section covers basic radiation concepts, radiation measurements and transmission through various media with particular emphasis on the Earth's atmosphere. The second part is devoted to optical materials and instruments. The next section deals with the theory of detectors, noise in semiconductor detectors and detector measurements. The final chapters are concerned with typical applications, with atmospheric spectra and the major sources of infra-red information. While the growth of this subject has undoubtedly received its greatest stimulation from its use in warfare, its non-military applications such as the investigation of the radiation balance in the atmosphere are of great importance. This book will be very valuable to those who wish to profit from developments that have sprung from military requirements as well as those whose present responsibility it is to satisfy them.

The second of these books deals with the ultra-violet absorption spectra and electronic structures of molecules. It marks the enormous progress which has been made in the past thirty years in explaining chemical properties in terms of electronic structures. This achievement has resulted largely from extensive studies of the nature of the electronic spectra of a vast number of molecules. The early chapters of the book contain an excellent account of basic molecular orbital theory and the subsequent discussion of molecular spectra is developed logically within this theoretical background. Starting with the interpretation of the spectra of the simple chromophores the subject is expanded to include the whole range of organic molecules. In later chapters ligand field theory and the part played by '*d*' orbitals are discussed and applied to the spectra of inorganic complexes. Other topics treated less thoroughly in this book include fluorescence, phosphorescence and equilibrium constant determination. It is clear that the modern chemist and spectroscopist has to be steeped in quantum theory if he is to have any real understanding of his subject. At times the going is hard, but the reward is well worth the effort required for its comprehension.

The third book deals with some of the practical details of ultra-violet spectrophotometry. That its author is a professor of medical biochemistry is indicative of the way in which spectroscopic techniques have proved of great analytical value in diverse fields. The content of the book is, however, very limited, and most of what it contains can be found in the manuals issued by the instrument manufacturers.

W. C. PRICE

CHEMICAL PHYSICS

Determination of Organic Structures by Physical Methods

Vol. 2. Edited by F. C. Nachod and W. D. Phillips. Pp. xiii + 771. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.) 114s. 6d.

VOL. 1 of this work (1955) dealt with recent developments of established methods of elucidating molecular structure and the present volume supplements this by a series of 50–90 page review essays dealing with rapidly developing physical techniques of recent origin. Each writer assumes that interested readers are well acquainted with the most modern, expensive, type of American equipment that is available and that they are primarily concerned in understanding further the significance of recent precise data.

Chapter 1, on optical rotatory dispersion, will appeal most to the conventional organic chemist, for it surveys the very considerable achievement of C. Djerassi and his colleagues and can be used as a précis of his book. For the organic chemist who is interested in reaction mechanisms, Chapter 2, on mass spectrometry, collects much significant information, for mechanisms of formation of mass spectra are essentially similar to routes of unimolecular decomposition of organic molecules and give knowledge about bond strengths and of the tendencies of activated molecules to undergo molecular rearrangement. Very soon organic chemists will be demanding mass spectrometers as essential tools in studies of molecular stability and not merely as equipment for finding molecular weights.

The remaining chapters, three on optical spectroscopy and six on various aspects of magnetic resonance spectroscopy, will interest those scientists who have made 'chemical physics' their domain of interest. The individual subjects are introduced mathematically and deal mainly with refinements of knowledge of the structures of fairly simple organic or organometallic compounds. All the chapters have been well planned with data selected so as to show the importance of developments of theoretical significance, but organic chemists who wish to make but empirical use of spectroscopic or magnetic resonance data may find it difficult to glean helpful information from these pages until they have mastered older and simpler texts.

Anyone who picks up this volume can see that 'chemical physics' has now become a major science in its own right: physical chemists have had the vigour to conquer the old realm of 'properties of matter' from conventional physicists as a younger generation of the latter has emigrated to the new world of sub-atomic studies. This progressive shift of interest from pictorial organic chemistry to quantum physics should inevitably lead to major developments in physical biology as more and more natural products become amenable to exact measurement and books such as this are needed to publicize technical progress. Unfortunately, perusal of the listed references throughout the whole volume shows only too clearly that Britain is lagging in scientific repute by providing too little and too late the equipment and technical services that chemists should now be using in their laboratories.

W. A. Waters

SELF-REGULATION OF ANIMAL POPULATIONS

Animal Dispersion in Relation to Social Behaviour

By Prof. V. C. Wynne-Edwards. Pp. xi + 653 + 11 plates. (Edinburgh and London: Oliver and Boyd, Ltd., 1962.) 55s.

The author of this book has been impressed with the large number of behaviour patterns among animals, especially in the higher organized groups, that do not seem to be satisfactorily explained although their widespread occurrence indicates that they must have importance for the species. He also wished to find a satisfying theory about the natural regulation of numbers. It is certainly true that there is a very large amount of animal behaviour the ecological meaning of which has not been explored, partly because the attention of ethologists has so far been chiefly concentrated on sexual and breeding relationships, rather than on the relation of animals to the whole of their habitat and its resources. It is also the case that ecology is just now in a considerable state of confusion about the relative parts played by different processes concerned in the natural regulation of average population-levels and of population fluctuations.

The theme of this book is that over-exploitation of food resources by an animal population will lead to dissipation of the resources and deterioration of the population; that there exists an optimum level of any food resource for allowing sustained productivity; that this needs to be matched by the maintenance of an optimum level of the animal population exploiting it; and that this optimum is attained by means of the many behaviour patterns and devices (especially social ones) found among animals. The author further postulates that this end-result of evolution has been brought about in the past not by individual natural selection, but by group-selection of populations—that is, by some local populations of a species making, as it were, serious short-term mistakes in population control that were punished by starvation or other consequences of food shortage, while other populations with better fortune (and appropriate genes or traditional changes) evolved suitable behaviour 'signals' for limiting increase beyond the optimum population-level. An analogy is drawn between the position in our sea fisheries when there is overfishing, and that facing any species in Nature.

The theory is set forth with enthusiasm, often pontifically (if a bishop can wear blinkers), sometimes in a sort of Messianic exaltation which admits of no other important processes affecting population-levels. The language is usually lucid and the great array of facts that has been unearthed very interesting in itself; but the reasoning behind the language is extremely involved, and (in spite of the elaborate apparatus of decimal-numbered paragraphs) rather woolly, and the new dogma incorporated in it safeguarded by many careful side-steps that make one rather uneasy, and certainly unconvinced at present.

The incontrovertible virtue of this book is that it brings together in one place a concentration of information about the nature of social behaviour and its co-ordination by means of behaviour signals, territorial patterns and the methods by which animals determine and keep them, sexual displays, communal roosting, movements and so on. But Prof. Wynne-Edwards has not, so far as I know, ever carried out any field research on natural population control, and he therefore perhaps tends to over-simplify the way in which animals live. Thus, most species fluctuate greatly in numbers, some of them violently, a few of them with remarkable regularity, and it is difficult to imagine how there can be a set of behaviour signals elaborate enough to take care of all these different levels of numbers, or similarly of their fluctuating resources, so as to gear at all closely the populations to their supplies of food.

Moreover, what of the numerous predators that depend on scores or hundreds of different other animals for food? Or herbivores that depend on irregular and unpredictable crops of tree fruits and seeds? All we can really say is that most species do not usually starve even locally, and therefore their numbers do usually remain below danger limits. Phrases like "feed-back for the homeostatic machine" do not cover up such difficulties, which are not to be solved by any sweeping arm-chair notion. Furthermore, the author states openly that the method of group-selection in populations is an essential assumption for his theory. On p. 21 it is stated that "Group-selection is not by any means a new concept, though it has never been accorded the general recognition that its importance deserves. Particular attention has been paid to it in the present work, because it is fundamental to the dispersion hypothesis."

The enormous weakness of this enormous book, so full of fascinating information, so impregnated with one particular teleological bias, is that it gives no single case-history of group selection. I have no doubt that the process does occur and may be quite important, but this kind of selection does not only have to be related to population density and resources: it could also relate to predator pressure, disease and many other things. It is stated early in the book that predation, parasites and pathogens "will be discussed sufficiently fully". The author's views can be inferred from the fact that he devotes less than 3 out of 601 pages to these topics. In fact, this new theory, though more pleasantly clothed for display than some of the other exclusive dogmas about the natural control of populations with which the subject has been cursed during the past decade or so, cannot be a universal and exclusive explanation of such a tremendously complex phenomenon in all the animal species on Earth. Whether it occurs widely at all the courageous reader had better decide for himself. Once acclimatized to the persistent bias of the text, he will learn a great many unexpected things about animal dispersion and behaviour that certainly do require explaining as adaptations.

C. S. Elton

Science and the Nation

Policy and Politics. By J. Stefan Dupré and Sanford A. Lakoff. (Spectrum Book.) Pp. x+181. (Prentice-Hall, Inc., Englewood Cliffs, N.J., and London, 1962.) 16s.

PROF. J. S. DUPRÉ and Prof. S. A. Lakoff's readable study of the relations between science and the Government in the United States is a natural supplement or continuum of A. H. Dupré's *Science in the Federal Government*, which outlines the development of those relations up to 1940 where the present volume takes up the story. It is equally a counterpart to D. K. Price's *Government and Science*, though essentially it indicates and illustrates the problems rather than analyses them in detail or in depth. In the first part, the authors outline briefly the changes in the relations between Government and science, both in industry and in the universities, which have taken place in the United States during the past twenty years and some of the implications of those changes, notably of the development of extramural Government research. Further, the contribution which scientists have made to the formulation of policy is described in a way which assists the British reader to appreciate the significance of characteristic features of the American system, such as the position of the President's Special Assistant for Science and Technology, the President's Science Advisory Committee, or the Advanced Research Projects Agency, in a British context.

In the second part of the book the authors outline lucidly the part which scientists have played in the political scene from the general issue of defence, the development of the atomic bomb and nuclear warfare, and the issues of security, responsibility and decision which arise. The nature of politics and the process of decision could have been a little more clearly displayed. However, the book makes abundantly clear two points to which Dr. J. R. Killian, jun., refers in a foreword: the extent to which the interface between science and political science should repay study from both sides; and the imperative need for public understanding of what is to-day involved in the relations between science and Government. If such study yields constructive results in the way of new methods or institutions, if the difficult and changing problems of organization are solved, those methods and institutions will not be used, nor those solutions applied if political prejudice or dogma are allowed, in default of public understanding, to bar the way. [See also p. 629 of this issue of *Nature*.]

Progress in Inorganic Chemistry

Vol. 3. Edited by F. Albert Cotton. Pp. 551. (London and New York: Interscience Publishers, a division of John Wiley and Sons, 1962.) 113s.

THIS volume maintains the high standards of its predecessors. Hydrothermal synthesis of crystals is discussed in some detail by Laudise in an interesting article in which I was surprised to learn that sapphires may be grown hydrothermally. The degree of 'Americanization' in this particular article is unfortunate: "criteria . . . must be compromised"; "validation of . . . data"; "methods . . . categorized"; "unsystematized field", and the very prevalent "iron-containing compounds" when "compounds containing iron" would be so much clearer to anyone not familiar with the language.

There are two very long articles—one on vinyl compounds of metals by Seyferth running to nearly 500 references, and one on primary solid hydrides by Gibb. In the latter case not many conclusions were evident. Liehr has a fairly brief chapter on vibronically coupled inorganic systems, where it is clear that the author is under the impression that it is written down to the level of the average inorganic chemist. Unfortunately, this is not true. Those who struggle through may find the statement about the "rigorous crystalline field solution . . . here pictorially discussed" a little depressing. The difficulty of theoreticians to appreciate how far behind many inorganic chemists still remain does not help the keen laggards to catch up. Perhaps *Progress in Inorganic Chemistry* will be able to produce chapters on group theory and crystal field theory, for example, to lay some foundation for these chemists. The last review is on high-temperature inorganic chemistry by Searcy, who defines high temperature as "any temperature at which entropy plays a significant role in determining the reaction equilibria of interest". This is a fascinating article, particularly where dissociation energies of dimers of the elements are discussed in terms of multiple bonding and the anomalously low single bond energies for N–N and O–O. So much present-day inorganic chemistry is concerned with co-ordination compounds that this review is a refreshing change.

The general standard of presentation in this series is high, and there are few errors. J. R. BEATTIE

The Chemistry and Technology of Leather

Edited by Fred O'Flaherty, William T. Roddy and Robert M. Lollar. Vol. 3: 'Process Control of Leather Quality. (American Chemical Society Monograph Series, No. 134.) Pp. ix + 518. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1962.) 120s. net.

THIS third volume in the authoritative series on leather technology maintains the high standard of its predecessors. Full descriptions of tanner dye application, dyeing mechanism and chemistry of fat-liquoring emulsions are given as well as a discussion of the application of organic solvents for tannery practice. For the specialist there are separate sections on modern procedures for treatment of calfskin and other leathers such as industrial, glove and novelty leathers.

The text is well illustrated by photographs and the bibliography is exhaustive. It is unfortunate that in an otherwise excellent production the indexing is inadequate, but the work (which will be complete with the issue of Volume 4) is an essential part of the library of the leather technologist. A. I. SCOTT

Missile Guidance (Temple Press Monographs on Rockets and Missiles)

By J. Clemow. Pp. vii+87. (London: Temple Press Books, 1962.) 15s.

THIS book is one of a series, covering all aspects of guided weapons, intended to be a concise and authoritative introduction to the subject. The present volume discusses fundamental principles and the effects of mechanical imperfections in beam-riding, homing and command control systems; inertia navigation and other forms of long-range weapon guidance are to be treated in a later monograph. The author has been engaged in research and development of guided weapons systems for many years and has been responsible for Services text-books on this topic. It is a great pity, therefore, that the present work contains a large number of typographical errors, apparently due to too much haste in writing and in correcting proofs. These are not at all serious in themselves, but they interrupt the flow of the arguments presented.

Apart from this, the material is well arranged and a nice balance is maintained between the exposition of theory and descriptions of equipment, especially in the sections on beam-riding and homing. The particular choice of subject-matter is ideally suited to the needs of the young engineer or scientist just entered on work involving the study and analysis of guidance systems, and thus requiring a relatively brief but balanced explanation of the technology as a whole. For this reason it would probably be helpful if the bibliography were extended to include some of the text-books covering the same field. G. J. HERRING

THE IONOSPHERIC TOP-SIDE SOUNDER

THE *Alouette* satellite, containing an ionosonde capable of sounding the ionosphere from above, was launched on September 29, 1962. It was designed and built by the Canadian Defence Research Telecommunications Establishment and the satellite was put into orbit by the U.S. National Aeronautics and Space Administration. Other co-operating institutions include the U.K. Radio Research Station and the U.S. Central Radio Propagation Laboratory. The following three articles present some early results from the three co-operating institutions.

SOME PRELIMINARY RESULTS OF SOUNDING OF THE TOP SIDE OF THE IONOSPHERE BY RADIO PULSES FROM A SATELLITE

By E. S. WARREN

Defence Research Telecommunications Establishment, Defence Research Board, Ottawa, Canada

MOST of the present knowledge of the ionized upper atmosphere, the ionosphere, has been obtained by examination of radio waves reflected from the bottom of the ionization layer. Except by the incoherent scatter technique the top side of this layer is inaccessible for examination by radio waves from the ground, since the waves which penetrate to these heights are not reflected but continue outward into space. The concept of sounding the top side of the ionosphere using a sounder in a satellite was an obvious consequence of the ability to launch artificial earth satellites. As long as four years ago the idea was current among ionospheric research groups in the United States, United Kingdom, Germany and Canada. Because radio sounders, using vacuum tubes, are heavy and consume kilowatts of power, it was necessary to use solid-state devices in order to produce a sounder suitable for use in a satellite. The first top-side sounder to operate in orbit was launched at 0605 G.M.T. on September 29, 1962, as part of the *Alouette* satellite, 1962 $\beta\alpha 1$.

The *Alouette* satellite contains, in addition to the sounder, apparatus for counting cosmic-ray particles (National Research Council, Ottawa), for observing the very-low-frequency radio spectrum, and for monitoring the engineering performance. A measure of the cosmic noise-level as a function of frequency is provided by the automatic gain control voltage of the sounder receiver. The sounder data only will be discussed here.

The top-side sounder consists of a transmitter, receiver, timing circuits, antennæ, and antenna matching networks[1]. The power radiated during a pulse is of the order of 10 W. Two orthogonal antennæ are used, a 150-ft. dipole, operating at frequencies below 4·5 Mc/s, and a 75-ft. dipole for the range 4·5–11·5 Mc/s. The sounder is operated on command. Once started, it functions for 10 min, generating thirty transmissions in which the radio frequency changes linearly with time over the frequency-band 0·4–11·5 Mc/s. It then shuts off automatically until commanded on again. Nickel–cadmium batteries, recharged by solar cells, permit about 5 h of operation per day.

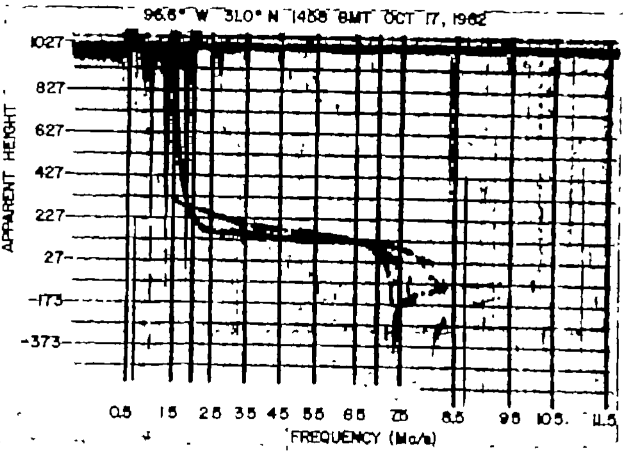

Fig. 1. A typical top-side ionogram

The *Alouette* orbital parameters as of October 17, 1962, provided by the National Aeronautics and Space Administration Computation Centre, are:

Anomalistic period		105·4137 min
Inclination		80·463 deg.
Argument of perigee		2·5649 deg.
motion	minus	49·531 deg./day
Right ascension of ascending node		158·890 deg.
motion	minus	0·984 deg./day
Semi-major axis		1·15892 Earth radii
Eccentricity		0·00225
Perigee		996·38 km
Apogee		1031·05 km
Velocity at perigee		26,498 km/h
Velocity at apogee		26,374 km/h

The height of the orbit was chosen by compromise. The lower the height, the smaller is the region explored. The greater the height, the smaller is the signal-to-noise ratio of the signals reflected near the height of the maximum ionization density. The inclination of the orbital

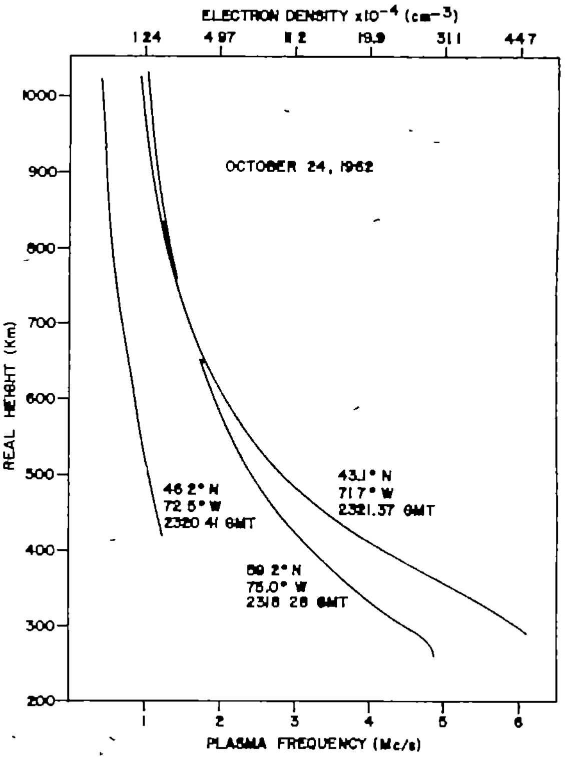

Fig. 2a. Distributions in height of free electrons showing depression of density at Ottawa latitudes

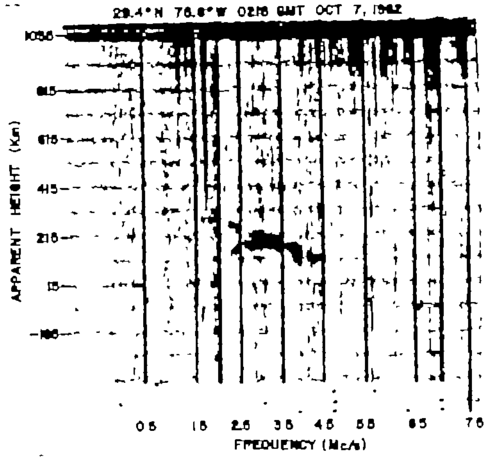

Fig. 4a. Ionogram showing cyclotron spike at 1·7 Mc/s.

plane to the equatorial plane was chosen to provide rotation of the orbital plane relative to the galaxy sufficient to distinguish diurnal variations of the ionosphere from seasonal variations, while retaining coverage of as great a range of geographic latitudes as possible.

The satellite sounder emits pulses of radio waves which travel to a reflecting surface in the ionosphere and back to the receiver in the satellite. The depth of penetration of the waves into the ionosphere and the travel time required for the return trip of the pulse is a function of the radio frequency of the wave. It is customary to express the travel time in terms of an apparent height of the reflecting surface computed using the velocity of the pulse in free space. Recordings of the apparent height as a function of frequency (ionograms) are generated from information telemetered to the ground. This information consists of the frequency calibration, of the modulation of the transmitter, and of the amplitude and time delay of the received pulses.

A top-side ionogram is shown in Fig. 1. The satellite is at a height of 1,027 km above ground. At the lowest frequencies the plasma is too dense for propagation except in the whistler mode, which is not observed on the ionograms. As the frequencies are reached for which propagation in the other modes becomes possible, vertical marks appear on the ionograms. These plasma spikes result from the generation of pulses for which the group velocity is zero. The extraordinary wave spike occurs at 1·35 Mc/s. At higher frequencies pulses reflected from below the satellite are observed. The apparent height of reflexion of the extraordinary wave falls rapidly from the satellite height at 2·0 Mc/s and penetrates the ionosphere at 8·1 Mc/s. The pulses at higher frequencies are returned from the Earth. The ordinary wave reflexion trace is similar, displaced to lower frequencies by about 0·7 Mc/s.

The apparent reflexion depths measured from the satellite sounder provide adequate data to determine the dependence of the free electron density of the ionosphere on the three spatial dimensions and time. From the distribution in height of the electrons, an effective temperature and a mean ionic mass may be deduced. A preliminary investigation of this kind has been carried out for mid-latitudes by Nelms[2]. On the assumption of an isothermal atmosphere in diffusive equilibrium, with one predominant ionic constituent, the ion mass of the constituent at 400 km is twice that of the constituent at 800 km.

A minor ionospheric storm was in progress during the first few days after launch, causing a significant change in the latitude dependence of the ionospheric electron density, as described by Hagg[3]. During this storm the electron densities were reduced at all ionospheric heights over a 25° range of latitudes centred on Ottawa. Muldrew[4] has found that the ionospheric electron density in this range of latitudes was strongly correlated with the particle counting rate in the outer Van Allen belt at latitudes between about 55° and 62° N. At 2320 G.M.T. on October 24 the ionization density of the ionosphere was again observed to have decreased dramatically over a limited range of latitudes. Fig. 2a shows the distribution in real height of the free electrons in the depressed region and at its boundaries. On the ionogram of Fig. 2b there are two reflexion traces, one each from the regions of high and low density. Their occurrence on the same record shows that

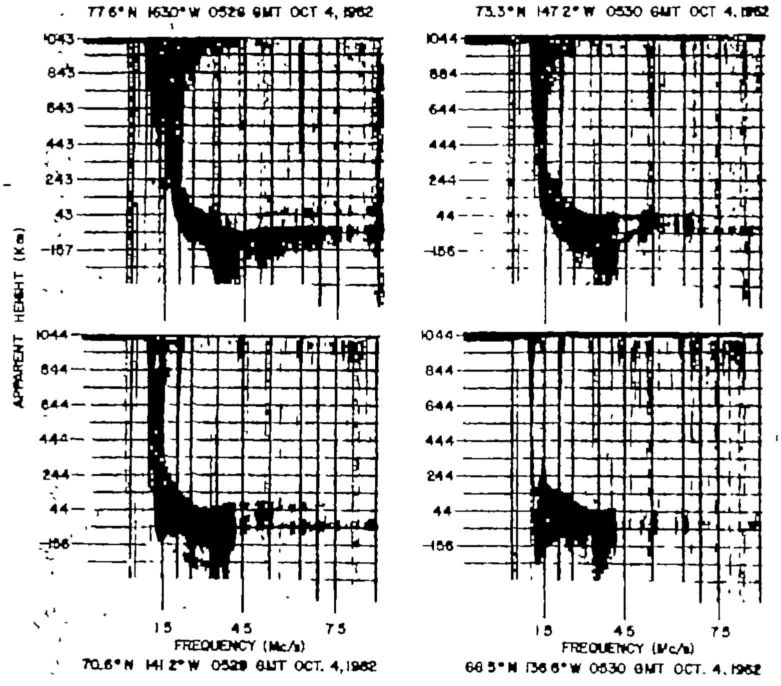

Fig. 3. Ionogram series showing spread-F and sporadic E

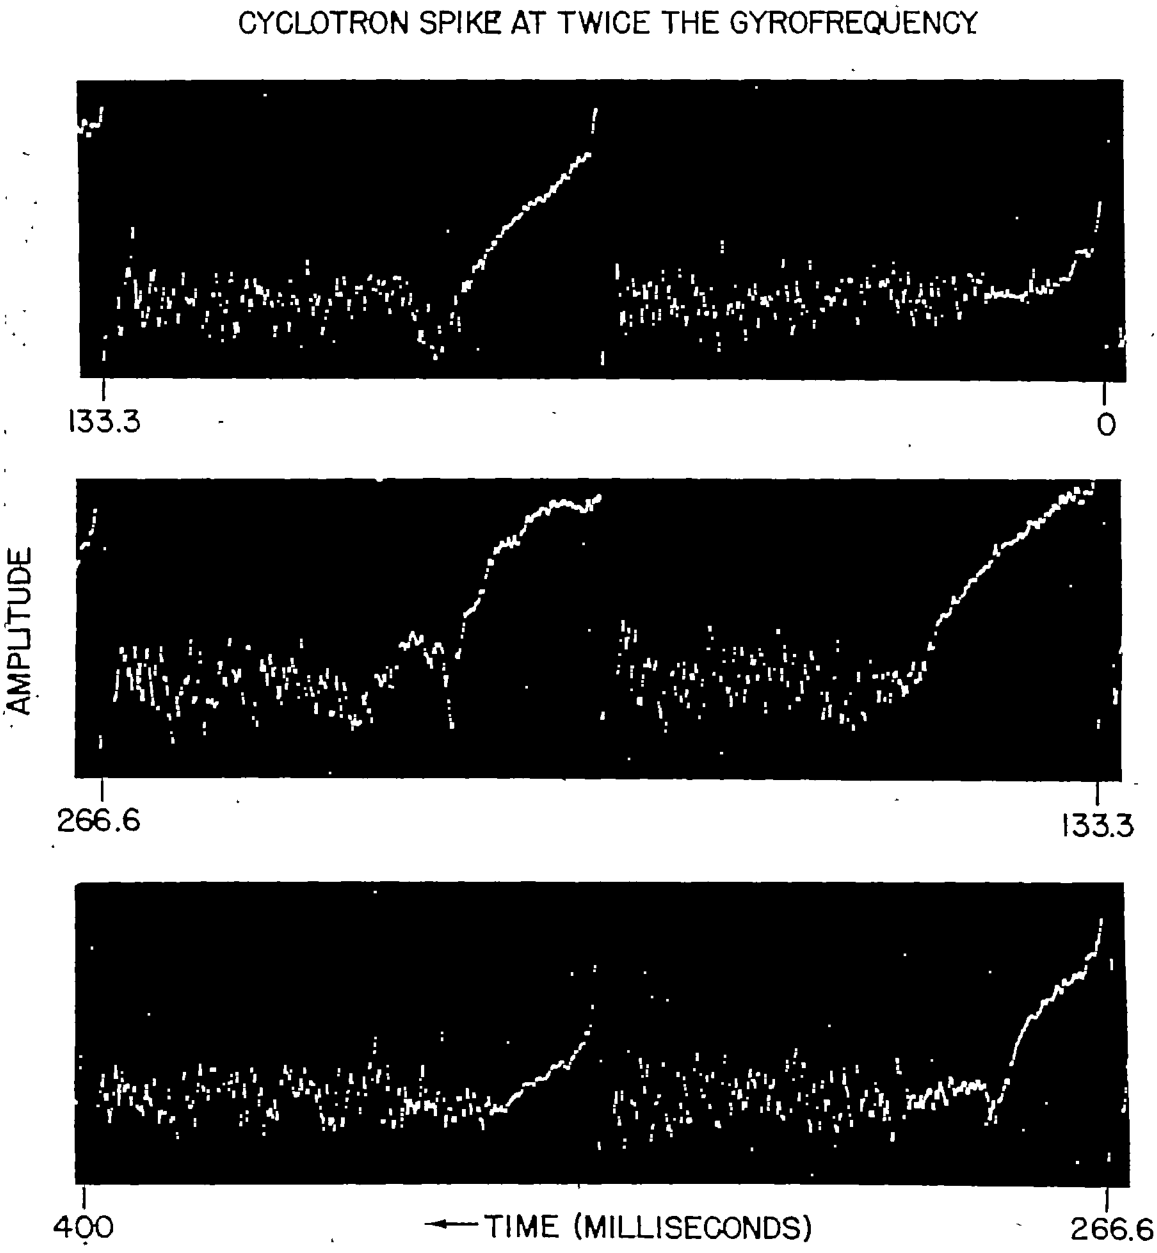

Fig. 4b. The time dependence of signal amplitudes forming a cyclotron spike

the transition from one region to the other as the latitude changes is very abrupt. This rather extreme change of the electron density was probably produced by particles ejected from the Sun with the solar flare of October 23.

At high latitudes the ionospheric reflecting surfaces are rough, producing a diffuse echo on the ionograms. The diffuseness of the echo is called spread-*F* after the same phenomenon observed on bottom-side ionograms. Fig. 3 consists of a set of night-time ionograms obtained within the auroral zone, showing, as Petrie[5] has reported, spread-*F* decreasing at lower latitudes. These ionograms show another feature that at first sight seems like a double echo from the Earth. The additional echo is reflected from a thin sporadic *E* layer about 100 km above ground. This particular patch of sporadic *E* ionization had a horizontal extent of 1,700 km. Petrie has also reported the existence in the auroral zone of diffuse clouds of ionization several hundred kilometres thick, through which the satellite passes.

The electron distributions, temperatures, and effective ion mass are parameters of great value in investigations of the ionosphere, particularly during storm times. However, some of the most interesting phenomena were unexpected. Among these are the existence of cyclotron spikes and the displacement of the plasma spikes from the associated reflexion trace.

When the transmitter is operating at multiples of the gyrofrequency of electrons about the Earth's magnetic field, cyclotron resonance occurs which causes a receiver response similar to the plasma spikes. The cyclotron spike at 1·7 Mc/s in the ionogram of Fig. 4a is that for twice the gyrofrequency. Fig. 4b shows amplitude-time curves for the signals that form this spike. These succes-

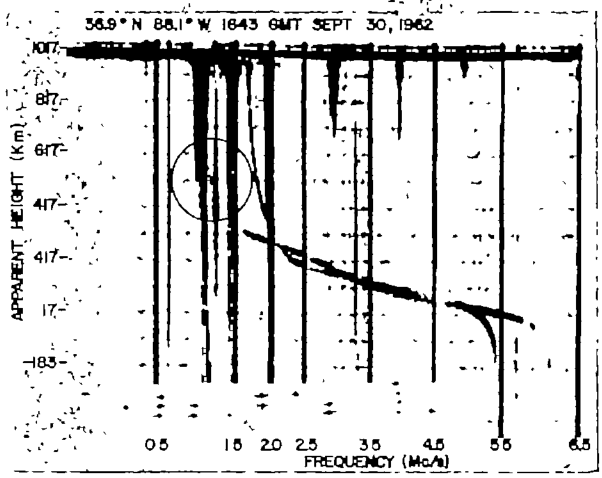

Fig. 5. Ionogram showing absence of ordinary wave reflexions between 1·25 and 1·6 Mc/s

sive pulses of the sounder transmitter are separated in frequency by 15 kc/s. Lockwood[6] has described the phenomenon and suggested that bunching of the electrons occurs when they are driven at multiples of the gyro-frequency, and that these electrons re-radiate energy to the receiver when the transmitter is shut off.

The separation of the plasma spikes from the associated reflexion traces are explicable in terms of a perturbation[7] of the ionosphere by the satellite in which the electron density behind the satellite is lowered and that ahead increased. In Fig. 5 the extraordinary wave plasma spike appears immediately to the left of the 1·5-Mc/s frequency marker. This spike forms at the lowest frequency for which pulse propagation of the extraordinary wave from the satellite can occur. This frequency is determined by the lowest density in the vicinity of the satellite. The reflexion trace commences at the lowest frequency for which the pulse can travel vertically downward from the satellite. For the extraordinary wave this is about 1·7 Mc/s. The difference in frequency between the spike and the reflexion trace is therefore a measure of the amplitude of the perturbation. The circled reflexion trace between 1·1 and 1·25 Mc/s results from coupling between the Z-wave and the ordinary wave. This identification is based on the fact that it is bounded in frequency in all the observed examples by the lowest frequency for ordinary wave reflexions and by the highest frequency for which Z-waves can propagate at the satellite. This upper limit for Z-wave propagation is indicated by the Z-plasma spike[6]. The gap in ordinary wave reflexion trace between 1·25 and 1·6 Mc/s is providing an additional means of studying the perturbation of the plasma.

In conclusion, the top-side sounding technique has been shown to be a valuable new addition to the methods available for investigation of the upper atmosphere.

The contribution of many people to the success of this experiment, particularly our colleagues at this Establishment who designed and built the spacecraft and those members of the staff of the U.S. National Aeronautics and Space Administration Goddard Space Flight Center and Marshall Space Flight Center who were responsible for placing the spacecraft in orbit, tracking the satellite, and obtaining telemetered data, is gratefully acknowledged.

INVESTIGATIONS OF THE UPPER IONOSPHERE DEDUCED FROM TOP-SIDE SOUNDER DATA

By J. W. KING
Department of Scientific and Industrial Research, Radio Research Station,
Ditton Park, Slough, England

THE Defence Research Board of Canada, the ionosphere top-side sounder of which has been described by Warren (preceding communication) has generously agreed that the Radio Research Station at Slough should record telemetry from the satellite as it passes over the Department of Scientific and Industrial Research stations at Winkfield near Slough (51° N., 1° W.), Singapore (1° N., 104° E.) and in the Falkland Islands (52° S., 58° W.), and make deductions from the recorded top-side ionograms. This article gives an account of some of the preliminary results obtained in this way. The Budden matrix method applied to a *Pegasus* computer as described by Thomas and Vickers[1] has been used to reduce the ionograms to $N(d)$ curves which show the electron concentration, N, as a function of the depth, d, below the satellite. An example is shown in Fig. 1 in which the scale of N is logarithmic. As this example shows, it is often possible to separate the log $N(d)$ curve into two parts, both of which are sometimes closely rectilinear, and to ascribe a 'scale height', H, to each part so that:

$$N \propto \exp(-h/H)$$

Up to the present, five passes over Slough and eleven passes over Singapore, each producing about 30 $N(d)$ curves, have been analysed. These data have been used to investigate the way in which the scale height varies with height above the ground and with latitude, and also the way in which the electron concentration at fixed heights varies across the equator.

Fig. 2 shows the scale heights deduced by drawing the tangents to the curve in Fig. 1 at a series of different heights. It is at once obvious that the scale height is roughly constant in each of two regions, the first extending roughly from 300 to 550 km above the ground and the second from 750 to 1,000 km, and that the scale height in the upper region is greater than that in the lower. All the log $N(d)$ curves show similar results in that the scale height is always observed to increase with height, but not all show two regions in which the scale height is constant. In order to investigate the phenomenon further it is useful to average the scale heights for all the electron density distributions occurring in a single pass and to examine the results. Some typical averaged values are

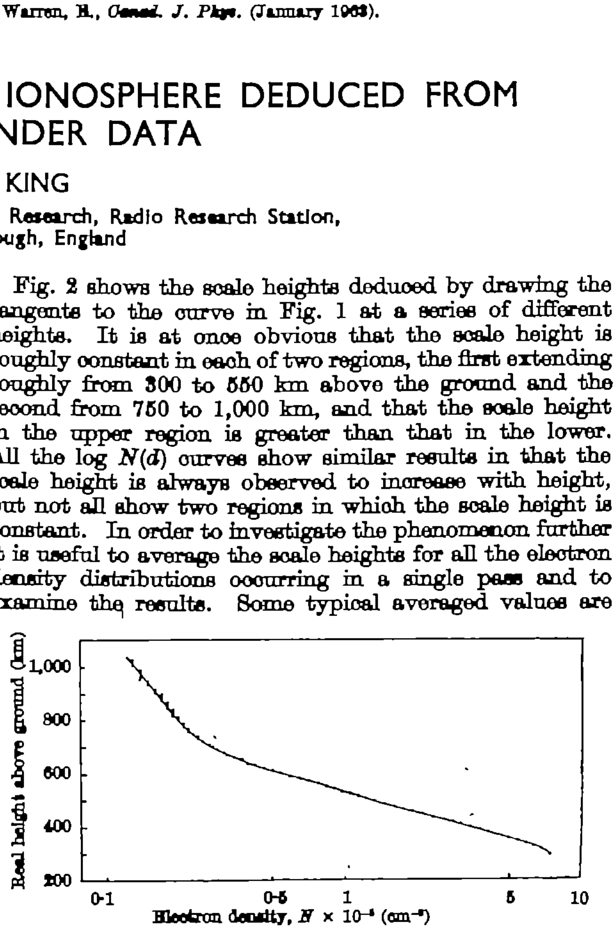

Fig. 1. Electron density distribution for a point 9° N., 88° E. recorded at Singapore at 1614 U.T. on October 1, 1962

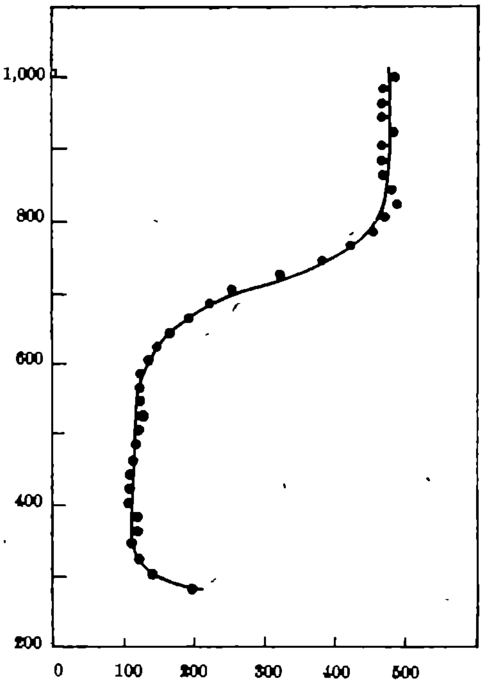

Fig. 2. Plot of scale height against real height for the distribution at a point 9° N., 88° E. recorded at Singapore at 1614 U.T. on October 1, 1962. The curved portion of the plot between 290 and 330 km represents the portion of the electron density distribution immediately above the layer maximum

listed in Table 1. It is noticeable that in the daytime the scale height in the lower region is greater at Slough than at Singapore, while that in the upper region is approximately the same. The ratio of the scale heights in the two regions is therefore smaller at Slough than at Singapore. In the light of these results it is interesting to examine the latitude variation of scale heights measured during a single pass covering a range of latitudes. Fig. 3 shows the results for such a pass extending from about 33° N. to 60° N., recorded at Slough. From Fig. 3 it is apparent that the scale height in the lower region increases as the satellite moves away from the equator, while that in the upper region remains roughly constant. These results, combined with those in Table 1, seem to indicate that the scale height near 500 km increases markedly as the distance from the equator increases, but that near 900 km does not.

The fact that the $N(d)$ curves usually indicate the presence of either one region (400–600 km above ground) or sometimes two regions in which the scale height is constant would suggest at first sight that in these regions the composition is uniform and the atmospheric gases are isothermal and in diffusive equilibrium. If these assumptions are made and if it is supposed that the electrons and ions are in thermal equilibrium and the predominant ion in the region 400–600 km is O^+, then it follows that the daytime temperature in this region over Slough is 1,530° K, a value consistent with that (1,600° K) suggested by the 1961 COSPAR atmosphere. If it is further supposed that the atmosphere at 900 km above Slough is at the same temperature, then it follows that the ions there must have a mean mass of 8 atomic units, as would be expected if they were a mixture of O^+ and He^+.

If corresponding calculations based on the same assumptions are made for the results from Singapore, they lead to a temperature of 800° K by day in the lower region, and to a mean ionic mass of 4·6 atomic units at 900 km by day. It is obvious that the higher night-time scale heights at Singapore would have to be explained by a decrease in the height of the O^+ to He^+ transition region, with consequent reductions of the mean ionic masses at 500 and 900 km, resulting from a lower night-time temperature.

Table 1. SCALE HEIGHTS OF THE ELECTRON DENSITY DISTRIBUTION

	Scale height at about 500 km above ground (km)		Scale height at about 900 km above ground (km)		Ratio	
Slough Rev 17 (day)	225	mean 190	390	mean 370	1·7	mean 2·0
Slough Rev. 30 (day)	145		370		2·5	
Slough Rev. 58 (day)	200		370		1·9	
Slough Rev. 248 (day)	190		360		1·9	
Singapore Rev. 26 (day)	100	mean 100	320	mean 350	3·2	mean 3·5
Singapore Rev. 40 (day)	100		350		3·5	
Singapore Rev. 53 (day)	100		380		3·8	
Singapore Rev. 34 (night)	120	mean 110	540	mean 600	4·5	mean 5·5
Singapore Rev. 128 (night)	100		650		6·5	

The magnitude of the daytime temperature deduced from the Singapore results scarcely seems feasible, and we must conclude that in these equatorial regions the simple assumptions made here are probably not valid. The observations outlined in the next paragraph also suggest that the simple assumption of diffusive equilibrium cannot be expected to be valid near the equator; it may

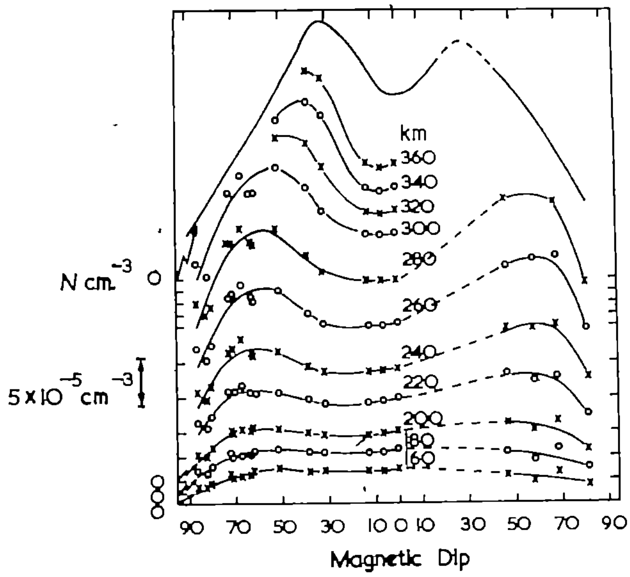

Fig. 5. Variation with magnetic dip of the mean quiet electron density *N* at a series of fixed heights at local noon in September 1957. The zero of the scale for the electron density at each height is marked. The average peak electron density *N*m *F*2 is shown as the top curve in the diagram. (After Croom, Robbins and Thomas (ref. 2))

be that the gradual decrease of scale height as the latitude decreases is a consequence of this.

The curves in Fig. 4 show how the electron density at a series of fixed heights above the ground changes with latitude during a typical pass over Singapore. These should be compared with the corresponding curves from bottom-side sounders as given, for example, by Croom *et al.*[2], whose results are reproduced in Fig. 5. The structure of the equatorial geomagnetic anomaly is clearly seen and it appears that the separation between the two peaks becomes less as the height increases until at about 700 km they merge to form a single maximum on the magnetic equator. It thus appears that the structure is such that the equatorial anomaly takes the form of an arch with its top about 700 km above the ground. Further plots such as that shown in Fig. 4 show that the top of the arch formed by the sub-equatorial peaks appears to be farthest from the ground, approximately 900 km, at about 20 h L.M.T. At this time the contours also show that the anomaly is most pronounced. During the subsequent hours the arch gradually falls until near midnight the top is only 400 km above ground and the anomaly has virtually disappeared. It should be realized that this latter representation of the diurnal variation of the anomaly is based on only the eleven Singapore passes at selected times which have so far been analysed, and extended observations might produce somewhat different results.

Another phenomenon, which is frequently observed on passes recorded at Slough, is related to sudden apparent variations in the scale height of the observed top-side electron density distributions. These usually occur, for the cases so far investigated, over a very narrow range of latitudes between 67° N. and 70° N. In this region the scale height appears to increase drastically, by as much as 50 per cent, and it is seen from Fig. 6 that the increase occurs mostly at heights greater than 700 km above the ground. It seems possible that this effect may be the result of some kind of interaction between the outer Van Allen belt and the atmosphere, but the fact that the latitude at which the phenomenon is observed is rather high may mean that the anomalous ionograms result from indirect or oblique observations of the affected region of the ionosphere.

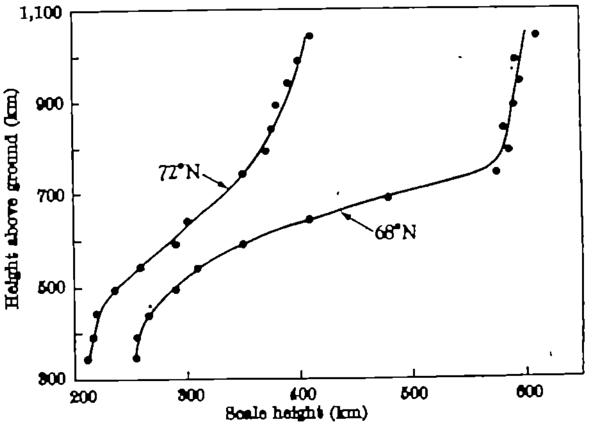

Fig. 6. Plots showing the variation of scale height with height for two electron density distributions obtained 4° apart. The first one was obtained at 72° N. and is normal and the second one was obtained in the middle of the abnormal region at 68° N. The results were recorded at Winkfield at 2227 U.T. on October 3, 1962

The satellite *Alouette* is part of the top-side sounder programme the overall management of which is the responsibility of the United States National Aeronautics and Space Administration. *Alouette* was designed and built by the Canadian Defence Research Telecommunications Establishment and was launched into orbit by the United States.

The present article represents co-ordinated effort on the part of data acquisition, processing and reduction groups at the Radio Research Station, and is published by permission of the Director of Radio Research of the Department of Scientific and Industrial Research, England.

SOME EARLY RESULTS FROM THE IONOSPHERIC TOP-SIDE SOUNDER SATELLITE

By R. W. KNECHT and T. E. VAN ZANDT
Central Radio Propagation Laboratory, Boulder, Colorado

This article presents some early results, using *Alouette* data, on the latitudinal variation of ionospheric structure and of the geographical extent of high latitude spread *F*.

Ionospheric structure. In Fig. 1 is presented a latitudinal cross-section of the top side of the ionosphere constructed from an evening pass of *Alouette* on October 1 (U.T.), 1962. This pass is mapped in Fig. 2. A moderate magnetic and ionospheric storm was in progress during this period. The 35 ionograms taken at the positions marked by open circles in Fig. 2 (and by ticks along the line showing the height of the satellite in Fig. 1) were reduced to electron density profiles using a computer programme developed by G. L. Nelms of the Canadian Defence Research Telecommunications Establishment. The accuracy of the electron density profiles is thought to to be better than ± 20 km. The contours of constant plasma frequency (isopycnic contours) were drawn through the data points with little smoothing. The contours are incomplete because of occasionally poor

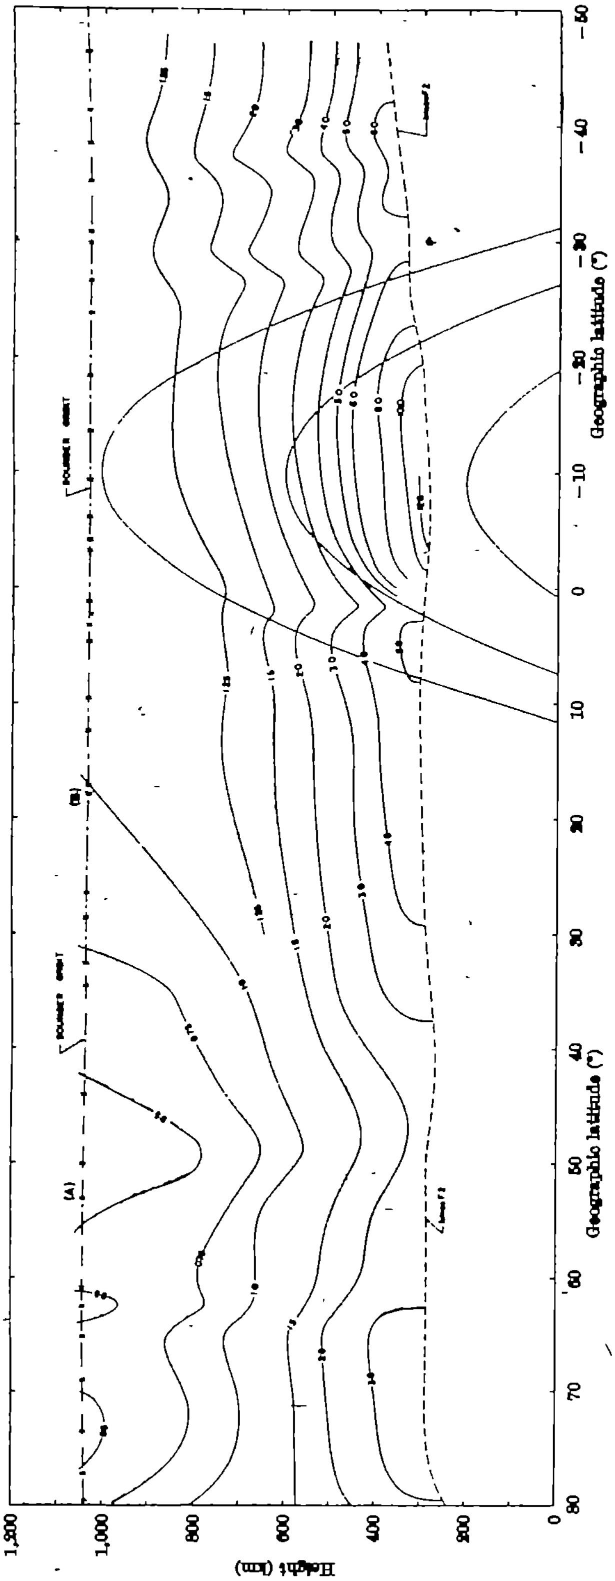

Fig. 1. A latitudinal cross-section through the ionosphere constructed from the pass mapped in Fig. 2. The contours are of constant plasma frequency in Mc/s.

ionograms, the 11·8-Mc/s upper frequency limit of the sounder, and inadequate bottom-side data.

Among the several noteworthy features along this 15,000-km cross-section are the three narrow 'troughs' in the isopycnic contours. The troughs are not magnetically conjugate, as can be seen by comparison with the lines of force also plotted in Fig. 1. (The computed lines of force all pass over 90.00° W. and 8.75° S.) Nevertheless, the two troughs at about 2° N. (+23° dip) and 27° S. (−27° dip) appear to bound different regions of the ionosphere. Poleward of these two troughs, f_oF2 (the largest plasma frequency in the $F2$ layer) is 5 or 6 Mc/s and decreases slowly with increasing latitude. Equatorward of the troughs, f_oF2 increases rapidly to at least 10 Mc/s and $h\max F2$ (the height of f_of2) decreases. The slight maxima of the isopycnic contours on the poleward sides of these two troughs extend up to at least 1,000 km, as can be seen in Fig. 3, which shows the plasma frequency at the satellite.

Although these data are equinoctial, the electron densities south of the dip equator were conspicuously larger and the structure of the ionosphere was much more complex than north of the dip equator.

The electron densities at all heights reached a minimum between 47° N. and 53° N. The electron density profiles

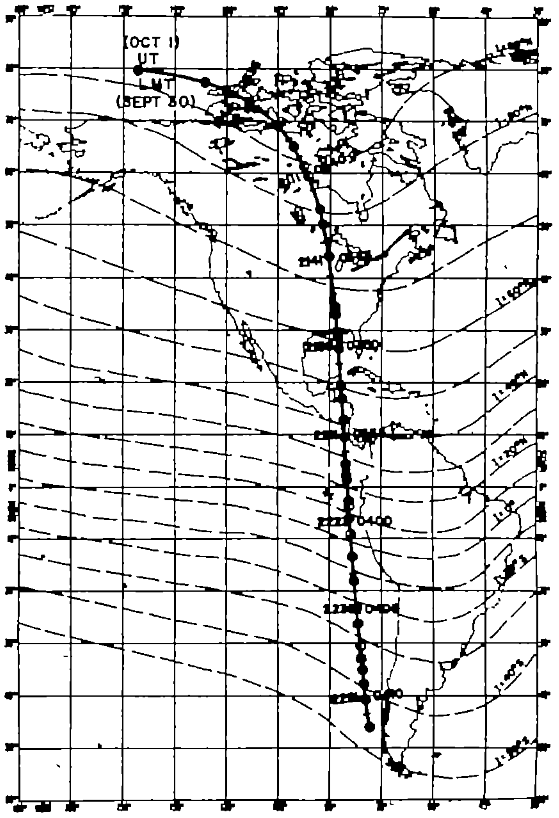

Fig. 2. Map showing the location and time of top-side soundings used to construct the ionospheric cross-section (Fig. 1). Isoclines are also shown

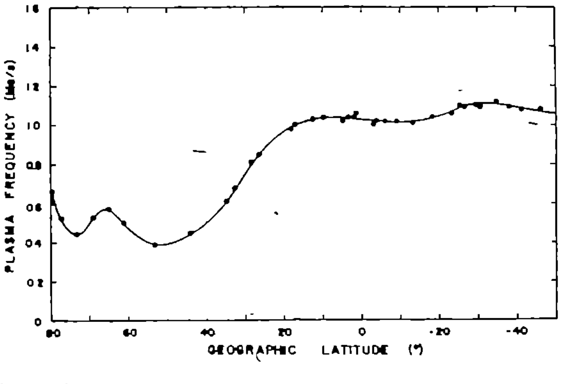

Fig. 3. Plasma frequency at the height of the satellite (1,033–1,043 km) as a function of geographical latitude

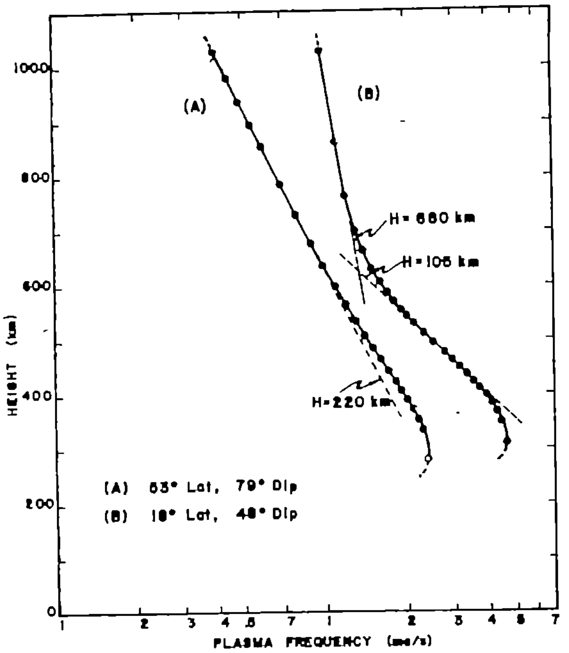

Fig. 4. Electron density profiles at points (*A*) and (*B*) on the latitudinal cross-section shown in Fig. 1

in the minimum and to the north had a markedly different shape from those to the south (Fig. 4). The profiles at latitudes higher than 45° N. (of which profile *A* is typical) consist of a long exponential region extending downward from 1,000 km, with a slight bulge just above *h*max*F*2. The scale height of the plasma, which is defined by $H = -(1/2)/(d/dh)(\ln f_N)$, where f_N is the plasma frequency, is 220 km in the exponential region. The long exponential region suggests that the ionosphere in this region is composed mostly of a single ionic species in diffusive equilibrium. Then, according to whether the species were H^+, He^+ or O^+, the temperature would have to be about 110, 440 or 1,750° K, respectively. Earlier observations show that the temperature could scarcely be as small as 440°, hence the ionosphere in this region must be composed mostly of O^+ at a temperature of about 1,750° K.

Below 45° N., the shape of the top side changes rapidly to that of profile *B*, which is typical of all latitudes below 20° N., including the region of the magnetic equator. Profile *B* contains two exponential parts, as indicated, with scale height of 105 km in the lower part and 680 km in the upper part. If these exponential parts corresponded to regions of single ionic species in diffusive equilibrium and if the ions were H^+, He^+ or O^+, the temperature would have to be 52·5, 210 or 840° K respectively, in the lower part, and 340, 1,300 or 5,440° K, respectively, in the upper part. At night at these heights the ionosphere is expected to be nearly isothermal at a temperature which could not be much smaller than 840°. Therefore, the lower part of profile *B*, which constitutes the usual *F*2 layer, must consist almost entirely of O^+ at 840°.

But the upper part must also be at a temperature of 840°, which leads to a mean ionic mass of 2·5. Therefore this region must be part of the transition toward a preponderance of H^+. Its apparent exponential form (based on only three points) is probably spurious. Comparison of these results shows two striking differences on this occasion between the ionosphere at latitudes higher and lower than 45°. First, at the higher latitudes the temperature is about twice as large as at the lower latitudes. Secondly, at the higher latitudes the ionosphere consists mostly of O^+ up to at least 1,000 km, whereas at the lower latitudes the transition to lighter ions begins at about 600 km. Since a moderate magnetic and ionospheric

storm was in progress during this period it cannot yet be said whether the structure observed on this occasion was a normal condition or a storm effect. However, the previous results are not inconsistent with previous observations.

The ion composition as a function of height and a more accurate temperature might be determined by a detailed comparison between the observed profiles and calculated profiles based on diffusive equilibrium[2]. Ion compositions determined without such detailed comparisons may be seriously in error, except where the electron density is exponential for more than a scale height.

Geographical extent of spread F. Several studies of the temporal and geographical variations of spread *F* have been made using bottom-side ionospheric sounding data[3]. Spread *F*, which is believed to be due to the presence of field-aligned irregularities in the ionosphere, manifests itself on ionograms as a spreading of the ionospheric echo over a range of delay times, in contrast with the distinct echoes in the absence of spread *F*. The studies referred to here have shown that spread *F* is most common in polar and equatorial regions. However, the boundaries of these regions of maximum occurrence have been difficult to describe owing to the sparsity of the sounding network. The *Alouette* top-side sounder, on the other hand, takes soundings approximately every 120 km along trajectories that regularly traverse the equatorial and polar zones.

The observations reported here have been taken from 27 passes of *Alouette* recorded by the U.S. National Aeronautics and Space Administration telemetry station at Blossom Point, Maryland, during the period September 30–October 12, 1962. During this period the southward passes occurred between about 1930 and 2330 h 75° W. time and the northward passes between 0830 and 1255 h 75° W. time.

Each ionogram taken during these 27 passes was put into one of three groups, according to the degree of spread *F*. The results are shown in Fig. 5. The trajectory is represented by a thin line where sharp traces were observed; filled circles represent ionograms on which a moderate degree of spread *F* was observed or which were otherwise uncertain; and trajectories represented by a thick line indicate that considerable spread *F* was present. Two top-side ionograms, taken at points (*a*) and (*b*) on the easternmost pass, shown on Fig. 5, are reproduced in Fig. 6*a* and 6*b* to illustrate considerable spread and sharp traces, respectively.

Several tentative conclusions can be drawn from this study of two weeks' data. First, in the area of observation (see Fig. 5), spread *F* was almost always present at magnetic dips greater than about 75°, and it was rarely present below about 70°. Secondly, spread *F* was equally prevalent during the mid-morning and the evening periods.

The refined description of the temporal and geographical extent of spread *F* which *Alouette* makes possible should be of considerable help both in propagation studies and in understanding the mechanism of spread *F*.

This work was supported by the National Aeronautics and Space Administration. We thank G. L. Nelms for providing us with his true height programme. The assistance of Wynne Calvert, E. E. Ferguson, G. B. Goe, D. E. McKinnis and other members of the U.S. Central Radio Propagation Laboratory staff was invaluable.

THE NATIONAL BOTANIC GARDENS OF SOUTH AFRICA, KIRSTENBOSCH

By PHILLIDA BROOKE

DURING 1963 the National Botanic Gardens of South Africa at Kirstenbosch, near Cape Town, celebrate their Golden Jubilee with a series of events which will interest and attract scientists and laymen from many parts of the world. It has long been accepted that the 30-mile long Cape Peninsula, which boasts more species of flora than the entire British Isles, is one of the richest and most interesting botanical regions in the world. Yet had it not been for the establishment of Kirstenbosch Gardens in 1913 it is likely that many rare and beautiful species of native South African plants would now be extinct.

When William J. Burchell, botanist and explorer, arrived in Table Bay in 1810 he had heard much of the botanical wonders of the Cape. "All that I had pictured to myself," he wrote soon afterwards, "was far surpassed . . . At every step a different plant appeared and it is not an exaggerated description if it be compared to a botanical garden, neglected and left to grow to a state of Nature; so great was the variety everywhere." Burchell found 105 distinct species of plants in a single mile not a stone's throw from white-washed, compact little Cape Town, though the season was late summer when, for three months, the Earth had been scorched by the Sun and seared by the south-east wind. In the wooded ravines and gorges of Table Mountain scarlet and gold disas crowded the mossy edges of late-running streams; in autumn the march lily (*Amaryllis belladonna*) appeared, deep pink and heavily scented. In winter the mountain slopes were purple with heath and carpeted with fragile oxalis which gave place, in the glory of the Cape spring, to Compositae, Iridaceae, Proteaceae and *Mesembryanthemum*, breath-taking in their vivid colours and abundance. Aware of a ready market for their wares in the streets of Cape Town and uninhibited by any legislation, flower sellers helped themselves generously to indigenous flora, tearing bulbs and roots from the ground with careless abandon. Not far away, farmers ploughed up the earth or, worse still, burnt it, so destroying the natural vegetation in favour of transient spring grazing: and all the while the city of Cape Town grew, laying down streets, building houses where once there were fields of wild flowers that could be cut down with a scythe. Well-known for their complacency, residents in Cape Town seemed little concerned when botanists deplored the situation and begged them to do something active to protect their magnificent floral heritage. True, certain necessary—if tardy—laws were passed which forbade the gathering of rarer species, but it soon became clear that this protection of what already existed was not enough; what was required was a means of bringing to cultivation and preserving for all time those plants which were facing the threat of annihilation.

No one was more keenly aware of this urgent necessity than Prof. H. H. W. Pearson, of the South African College in Cape Town. He had arrived from England in 1903 with a distinguished academic record at Cambridge and considerable practical experience both in Ceylon and at Kew, where he had been assistant to the Director. His appointment to the Harry Bolus chair of botany in the South African College brought him to the Cape for the first time at the age of thirty-three and gave him the opportunity to

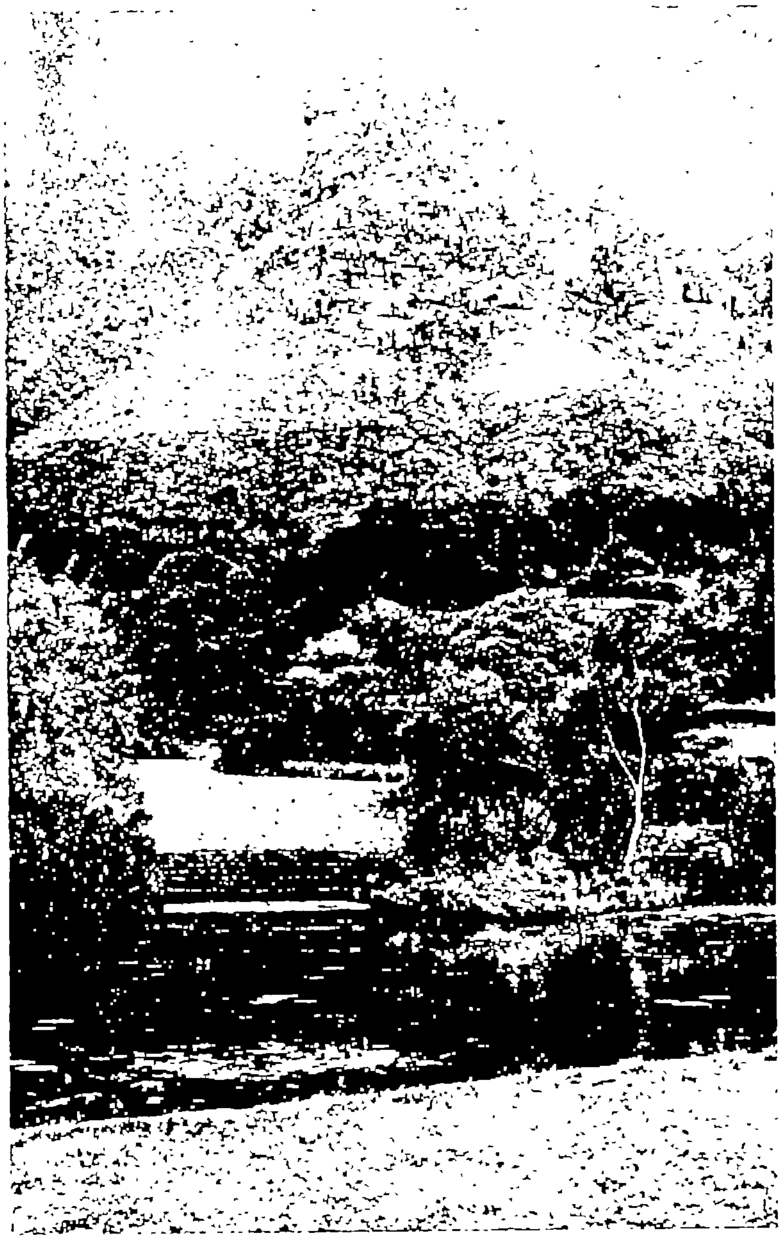

Fig 1. Castle Rock dominating the scene at Kirstenbosch (*Photo Richard Simons*)

study in the field the tremendous wealth of native flora of which he, like Burchell, had heard so much. However, disappointment awaited him. The Cape, he found, was a botanically impoverished land with a crying need for a fully equipped institution devoted to the scientific cultivation and study of indigenous plants. Ever since the Cape's earliest Commander, Jan van Riebeeck, had planted vegetables for passing seamen in the mid-seventeenth century, this had been a country renowned for its splendid gardens where *Araucaria excelsa* (Norfolk Island pine) and roses, *Magnolia*, oaks and sweet peas grew in abundance. But no one had ever troubled to create a garden solely devoted to the fascinating flora of South Africa, the ecology of which botanists had scarcely begun to explore. As he grew familiar with the country, Prof. Pearson began to foresee an establishment on the lines of the Royal Botanic Gardens, Kew, a natural garden, supported by the Government, where South African gardeners could be trained to cultivate and preserve South African plants under South African conditions. In addition, it should be an expression of the intellectual and artistic aspirations of a nation whose duty it was to appreciate the rare and the beautiful with which Nature had so lavishly endowed it.

It was not until November, 1910, that Pearson had the opportunity to offer his suggestion to the public in a concrete form. The South African Association for the Advancement of Science was to meet in Cape Town; six months earlier the four provinces of South Africa had been united under the British flag, and Pearson realized that the time was ripe to present a proposal that would appeal to the strong spirit of patriotism then prevailing and, at the same time, be of the utmost scientific interest and importance. It was in his presidential address, therefore, that he invited his associates to consider with him the establishment of a national botanic garden.

Response was immediate. A meeting was held under the presidency of Lord de Villiers, Chief Justice of South Africa, and a deputation was sympathetically received by the Prime Minister, General Louis Botha. Eventually, on May 16, 1913, a happily unanimous Parliament resolved that a national botanic garden, subsidized by the Government, should be established without delay.

Prof. Pearson had already chosen the site of his garden. Government-owned Kirstenbosch Estate lay on the eastern slopes of Table Mountain approximately seven miles from Cape Town and covered an area of some four hundred acres. Its soil was rich and varied; it was well watered by mountain streams, and indigenous plants—including seven acres of rare and beautiful silver trees (*Leucodendron argenteum*)—grew there in abundance. South and east of the estate there spread a wealth of woodland stretching towards the Cape Flats, the blue waters of the Indian Ocean and the shimmering peaks of the Hottentots' Holland mountains some forty miles away. Behind, cleft by deeply wooded ravines, towered the ramparts of Castle Rock, 2,000 ft. high, with the limitless blue of the African sky beyond. It was of this corner of the Cape Peninsula that Burchell wrote: "The view from this spot, and indeed all the scenery around, is the most picturesque of any I have seen in the vicinity of Cape Town". Without doubt Kirstenbosch, supported by the Government and developed under the expert scientific guidance of Prof. Harold Pearson, could become one of the great botanic gardens of the world.

But, according to a newspaper of the day, it had been allowed to degenerate into a "melancholy monument to neglect". Originally an outpost of van Riebeeck's seventeenth century Dutch colony at Cape Town, Kirstenbosch had been occupied by a garrison of soldiers who protected the town against the depredations of neighbouring Hottentots. A hedge of wild almond (*Brabeium stellatifolium*) was planted crescent-wise across the lower eastern slopes of Table Mountain and remnants of this one-time southernmost boundary of civilization may still be seen at Kirstenbosch, a national monument, 15 ft. high and in parts impenetrable. Later, a Government official named Kirsten owned land in the vicinity and it is thought that it was from him that the estate acquired its name. When the British occupied the Cape early in the nineteenth century Kirstenbosch was divided into two portions and allocated to Henry Alexander and Colonel Christopher Bird, both senior officials in the Colonial Service. Bird built himself a homestead high against the mountain on

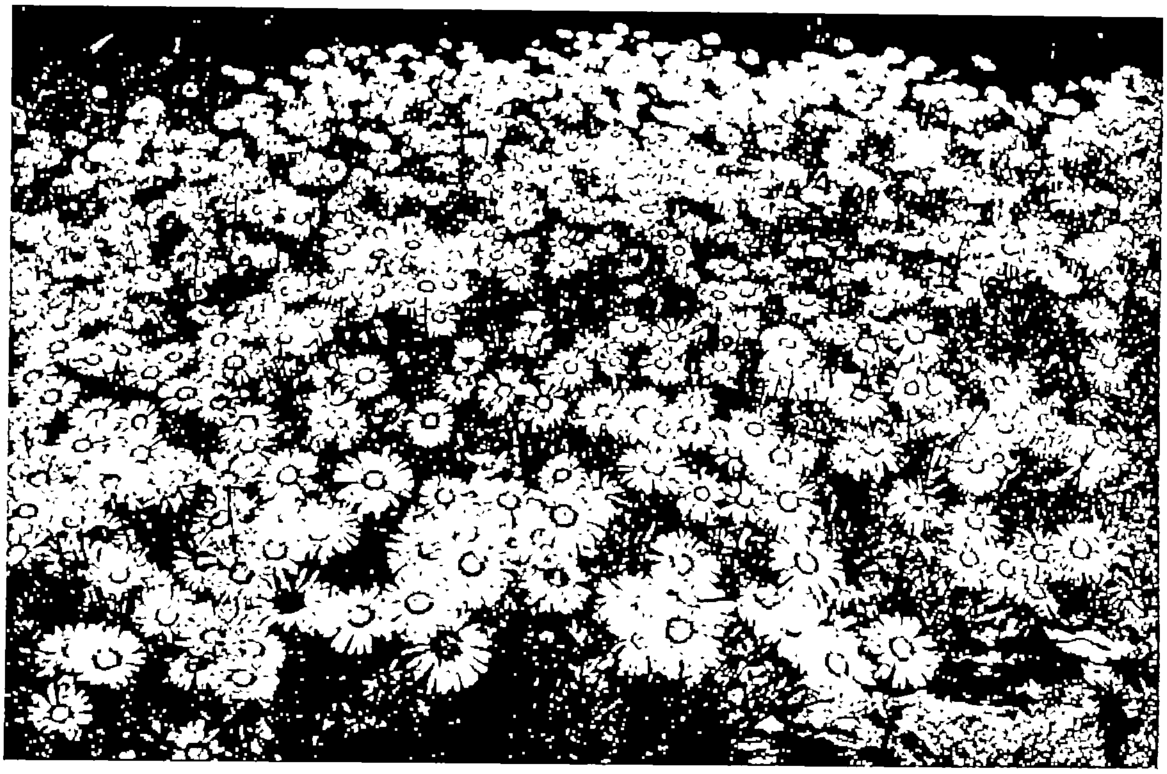

Fig. 2. A display of *Felicia tricolor*. In September the terraces at Kirstenbosch are vivid with brightly coloured spring annuals. (*Photo: Richard Simons*)

the site of the original barracks; he planted Spanish chestnuts and, it is thought, paved the beautiful little bath which now forms the heart of the Gardens and from which rises a perpetual, crystal-clear spring. Alexander built a house lower down the hillside and, according to legend, refused to put windows into the bedrooms, maintaining that where one slept there was no need to look at the view.

In time Bird returned to England, Alexander died and in 1823 his unhygienic abode was transformed by Dirk Gysbert Eksteen, member of an old Cape family, into a gracious Cape-Dutch homestead with lofty windows and wide-welcoming doors. Eksteen planted the oaks which remain to this day; he laid out vineyards and orchards and lived according to the genial, generous pattern which characterized nineteenth century Cape Town. But Eksteen died; his descendants moved away and the house became a ruin. It was at this time that Cecil John Rhodes bought Kirstenbosch Estate and, on his death in 1902, bequeathed it to the people of South Africa. At first little was done to develop it; pigs rooted among the fallen acorns, weeds grew rampant in vineyard and orchard and undergrowth obscured the dimpled beauty of the little paved bath.

When Prof. Pearson assumed honorary directorship of Kirstenbosch in August, 1913, he faced a formidable task. Despite the financial aid of the Government and the support of the newly formed Botanical Society of South Africa, funds were dangerously short. Moreover, the Professor was obliged to fulfil his duties at the College in addition to restoring an ordered garden out of a chaotic wilderness. "It will be a burden," he wrote to his friend and colleague, Prof. A. C. (later Sir Albert) Seward, "but it is worth carrying even if it never falls to me to exploit its contents."

Those were prophetic words. Scarcely three years later, after an almost incredible amount of work had been accomplished against all odds—most of it in war-time—Prof. Pearson died at the age of only forty-six. His grave lies on the hillside overlooking the Gardens and his headstone bears an inscription taken from the epitaph of Sir Christopher Wren: "If ye seek his monument, look around".

It was not until the First World War was over that Pearson's successor, Prof. R. H. Compton, was able to assume duties and in the lean years between—during which the already inadequate Government grant was reduced—Kirstenbosch Gardens were maintained by the combined efforts of the Botanical Society and of the curator, Kew-trained J. W. Mathews. Under Compton's directorship they expanded to the very summit of Table Mountain by an additional grant of 600 acres in 1922. Paths were laid, swamps were drained, hillsides were terraced and planted and the work begun by Prof. Pearson developed to maturity. In 1923 natural history classes for local school children were inaugurated, first entirely in the field then, with the completion of the thatched lecture hall, partially indoors. The Gardens' academic work extended further with the establishment, in 1938, of the Compton Herbarium, where 200,000 specimens of South African flora are preserved and where plants are brought for identification by both amateur and professional botanists. More than 30,000 packets of seed, gathered at Kirstenbosch, are despatched, free of charge, each year to the 4,000 members of the Botanical Society, while many others are sold to nurserymen all over the world. Seed collection and preparation is therefore an important part of the work carried out at Kirstenbosch, and it is largely due to the Gardens that South African flowers are now cultivated as far afield as the U.S.S.R. and New Zealand, Japan and California.

After thirty-five years at Kirstenbosch, Prof. Compton was succeeded by Prof. H. B. Rycroft under whose energetic and enthusiastic guidance the National Botanic Gardens—one of the glories of South Africa and famous throughout the world—are now entering on their Golden Jubilee Year.

A most ambitious programme of festivities, extending over ten months, has been planned. In February a garden party will be held on the lawns at Kirstenbosch and at this the State President, Mr. C. R. Swart, as patron-in-chief of the celebrations, will be guest of honour. Exhibits from America, Europe, Australia and the East will be on view at the International Flower Show planned for March, while the national spring and wild flower show in September promises to be of spectacular beauty and of great botanical and horticultural interest. Museums, libraries and art galleries throughout the country are collaborating with the Jubilee Council to organize displays of books, paintings and other exhibits, botanical in character and interest, and an international exhibition of floral stamps—"Flora 63"—has been sponsored by the Lions Club of South Africa and the Thematic Stamp Club. In the spring a week has been set aside for the young people of South Africa, who will hold their own flower show, a procession of (artificial) flower-decked floats through the streets of Cape Town and orchestral and choral concerts with "Flowers" as the theme.

Most important and serious of all the festivities will be the assembly at Kirstenbosch of fifty or more of the world's most distinguished botanists and horticulturists, including Sir George Taylor, director of the Royal Botanic Gardens at Kew; Dr. W. Domke, of the Botanical Gardens in Berlin; Prof. H. Merxmüller, director of the State Museum, Munich; Prof. H. Weimarck and Mr. Rolf Dahlgren of the Botanic Institute and Museum, Lund; Prof. W. Robyns, director of the Botanical Gardens, Brussels; Prof. Reed C. Collins of the Gray Herbarium, Harvard University; Prof. H. P. Riley of the University of Kentucky and many others.

These specially invited guests of the Jubilee Council will be entertained on day excursions to places of particular botanical interest near Cape Town and will attend lectures on South African flora arranged for their benefit. Finally, they will be taken on a tour of South Africa which will last for more than three weeks and during which they will have an opportunity to study in the field a wide variety of vegetational types, and, at the same time, to see some of the country's most splendid scenery. Headquarters of all these events will be Kirstenbosch Gardens, superbly beautiful throughout the year but at their most colourful in the southern spring months of September and October.

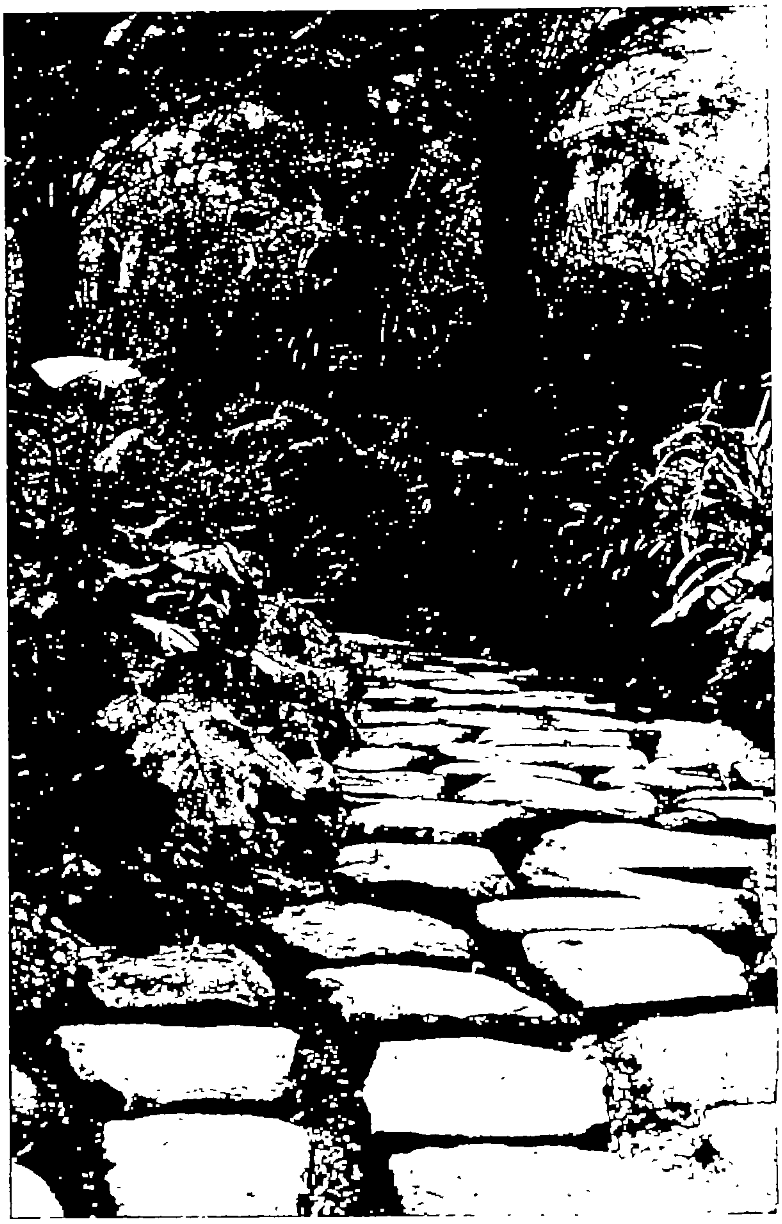

Fig. 3. A leafy dell at Kirstenbosch. Clear spring water filters through paths of stepping stones. Arum lilies grow in profusion here. (*Photo: Richard Simons*)

Primarily the purpose of these celebrations will be to make known to the world in general and to botanists and horticulturists in particular the work and functions of Kirstenbosch. At the same time it is earnestly hoped to raise funds which are urgently needed for immediate and necessary development. Since its inception fifty years ago, Kirstenbosch has struggled to establish and maintain a scientific foundation without which it could not rightly claim the title 'Botanic'. Financially, the Gardens are dependent on grants from various local authorities and funds accumulated by the Botanical Society of South Africa. But Kirstenbosch, situated as it is in the heart of a floral region second to none in scientific interest, has much to offer the world and it is for the world to make that contribution to botany a reality. When Prof. Pearson conceived the simple but magnificent idea of the National Botanic Gardens he foresaw, as its heart, a botanical research institute staffed by scientists who could set about the thorough exploration—ecological, morphological and systematic—of South African flora. In his presidential address to the South African Association for Advancement of Science on November 2, 1910, he said: "Science has not finished with a plant when it has been labelled and placed in a herbarium. . . . Research should be undertaken with the single object of discovering the truth regardless of the consequences. These may at any time assume a practical and economic importance which no one has been less inclined to expect than the investigator himself." This holds true in 1963 as it did fifty years ago and thus far, at least, Pearson's dream has not been realized for there is, as yet, no research institute at Kirstenbosch. It is estimated that the establishment and maintenance of such an institute would cost a minimum £43,000 while a further sum of £22,000 is urgently needed to enlarge the totally inadequate lecture hall where 12,000 children attend biology lessons each year. Though the extent of Kirstenbosch is more than 1,000 acres only a relatively small area is under cultivation. To develop the Gardens further would cost an estimated £9,000. It is to the public—national and international, scientific and lay—that the National Botanic Gardens of South Africa appeal for these funds.

EVIDENCE THAT THE Xg BLOOD GROUP GENES ARE ON THE SHORT ARM OF THE X CHROMOSOME

By J. LINDSTEN

DR. RUTH SANGER and DR. R. R RACE, F.R.S.
Medical Research Council Blood Group Research Unit, Lister Institute, London, S.W.1

FROM an examination of two women with ovarian dysgenesis, and of their families, evidence has emerged which suggests that the locus for Xg, the X-linked blood group system[1], is on the short arm of the X chromosome.

The two patients were consistently sex chromatin positive and each displayed, in the tissues sampled for cytological study, chromosome mosaicism of two cell lines: one, the minority, had 45 chromosomes including a single X and the other, the majority, had 46 chromosomes. In the cells of the latter line there was one normal X chromosome and a metacentric chromosome resembling No. 3 of the set; this abnormal chromosome has been interpreted[2], in these and in other patients with similar karyotype, as an isochromosome for the long arm of the X chromosome. While other interpretations are possible the suggestion that these metacentric chromosomes are isochromosomes for the long arm of the X seems likely from the combined cytological and clinical evidence. A recent observation[3] supports this interpretation: the sex chromatin masses of five such patients have a greater amount of DNA than do those of normal females. Furthermore, the presumptive isochromosomes have been shown[4,5] to be symmetrically 'hot' along their whole length when labelled with ^{3}H-thymidine late in the period of DNA synthesis.

The argument to follow concerning the site of the Xg locus hinges on this interpretation—that the structurally altered chromosome consists of two long arms of the X chromosome without a short arm.

Family J. The pedigree of this family is shown in Fig. 1. The proposita, III-3, briefly reported by Lindsten[6], is aged eighteen; she has primary amenorrhœa and the output of pituitary gonadotrophin in her urine is increased while that of œstrogens is decreased. She is of short stature (4 ft. 6 in. or 138 cm). She has neither an unusual number of pigmented nævi nor webbing of the neck. Her father was thirty-three and her mother twenty-five at the time of her birth.

Cytological investigations showed that the proposita was sex chromatin positive in cells from buccal mucosa smears, skin sections and in cells from two skin biopsies grown *in vitro*. Cells were cultured from one blood sample and from two different skin biopsies and chromosome mosaicism was observed: the majority of cells had 46 chromosomes, including an apparently normal X and a presumptive isochromosome for the long arm of the X; the minority of cells had 45 chromosomes with an XO karyotype. The parents and sibs of the proposita have sex chromatin corresponding to their phenotypic sex.

From the family history it is clear that the maternal grandfather, I-2, was colour-blind. By Ishihara and anomaloscope tests III-2 and III-5 are deuteranopic: the proposita, III-3, is deuteranopic according to Ishihara but has a normal Raleigh equation with an increased contrast. By both tests II-3 and II-4 and III-1-4-6 were normal, and by Ishihara II-1 and II-2 were normal.

The Xg groups of the family are shown in the pedigree. The proposita lacks her father's Xg^{a} antigen and this indicates that her normal X is from her mother, as does the fact that she has her mother's colour-blindness gene but not her father's gene for normal colour vision: the isochromosome would therefore have to be of paternal origin. (The family illustrates crossing-over between the loci for Xg and for deutan colour vision; this is to be expected for the cross-over rate between the two genes is known to be high[7].)

Family R. The pedigree of this family is shown in Fig. 1. The proposita, II-2, is aged twenty-two years, has primary amenorrhœa with markedly increased output of pituitary gonadotrophin, is of short stature (4 ft. 9½ in. or 146 cm) and has numerous pigmented nævi but no webbing of the neck. At the time of her birth her father was thirty-one and her mother twenty-six. She has a normal elder brother.

The patient is sex chromatin positive in cells from the oral mucosa, from skin biopsy grown *in vitro* and in the leucocytes of the blood smear; some of the sex chromatin masses in the oral mucosa cells appeared to be unusually large. The patient's chromosomes were examined in cells from two blood cultures and one skin culture and showed her to be a chromosome mosaic: the majority of her cells had 46 chromosomes, including an apparently normal X and a presumptive isochromosome for the long arm of the X, and the minority of cells had 45 chromosomes with an XO karyotype. The presumptive isochromosome in the cells with 46 chromosomes was found[5] to be symmetrically 'hot' and to label with ^{3}H-thymidine later than the other chromosomes in the course of DNA synthesis. The father and mother had a normal chromosome complement in cells from blood cultures.

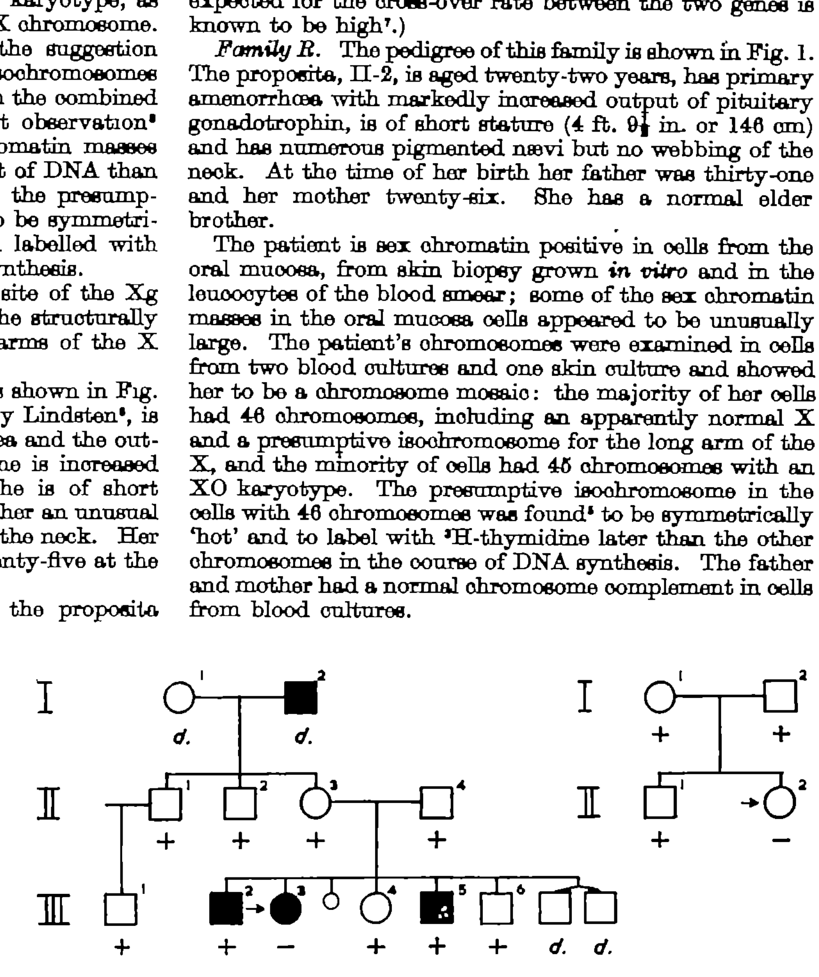

Fig. 1. The family J. (left) and the family R. (right). Arrow = proposita. Xg groups: + = Xg(a+), − = Xg(a −). Colour vision: solid black = colour-blind (deuteranopic), hollow = normal (for details see text). d. = dead and not tested for Xg or for colour vision

The proposita, her mother and father have normal colour vision; the first two were tested on the anomaloscope and the Ishihara, the father only on the latter.

The Xg groups of the family are shown in the pedigree: because the proposita is Xg(a −) while her father is Xg(a +) it must be considered that the morphologically normal X which she has in both her cell lines is from her mother (who must be heterozygous Xg^aXg). It follows that the presumptive isochromosome present in the cells with 46 chromosomes is of paternal origin—yet the patient is Xg(a −).

Other cases. The families of 12 other patients who have presumptive isochromosomes for the long arm of the X have been tested, but the Xg groups did not segregate in the informative way they did in the J. and R. families. The groups of these other families are recorded in Table 1: in four of the 12 patients the presumptive isochromosome appears to be of paternal origin (families Fra., All., And., Eri.; see discussion).

Table 1. TWELVE FAMILIES IN WHICH THE PROPOSITA HAS A PRESUMPTIVE ISOCHROMOSOME FOR THE LONG ARM OF THE X BUT IN WHICH THE Xg GROUPS ARE LESS INFORMATIVE THAN THOSE OF THE FAMILIES J. AND R.

* not found to be a mosaic (XO/X iso-X).
‡ Her mother, sister and 2 brothers are all +.

Discussion. Analysis of the two families, J. and R., indicates that the presumptive isochromosome of both patients is of paternal origin. If this abnormal chromosome found in the Xg(a −) daughters consists of two long arms of the X chromosome from the Xg(a +) father then these arms do not contain the Xg locus, which should therefore be located on the short arm. (The evidence that family J. gives for the deutan locus being on the short arm has already been discussed[2,3].)

Two possibilities could upset this argument. The hypothesis of Lyon[10], which postulates that in the mouse and possibly in all mammals only one X chromosome is 'active' in any one cell, makes it theoretically possible that the isochromosomes of our two patients are 'inactive' in all cells. If this were so the Xg(a −) reactions of the two patients could merely reflect lack of gene action and would not afford evidence of the arm on which Xg is located. The fact that the isochromosome is 'hot' when labelled with ^{3}H-thymidine late in the period of DNA synthesis[4,5] indicates that it synthesizes later than the other chromosomes: whether this means that it is also 'inactive' remains to be demonstrated.

The second possibility is that the two different cell lines found in both patients might be so distributed that those producing the Xg groups have 45 chromosomes including the single, maternal, X carrying the silent *Xg* gene. In this event again the Xg locus could be on either arm of the X chromosome. However, an identical, non-random distribution of two cell lines in two unrelated individuals seems most unlikely.

Thus, though the evidence is suggestive, definite proof that the Xg locus is on the short arm of the X chromosome must await clarification of these problems.

In some of the patients, the Xg findings can help in tracing the origin of the presumptive isochromosomes, but there are certain limitations and two sets of factors have to be taken into consideration: the 'activity' or otherwise of the presumptive isochromosomes and the situation of the Xg locus on the short or long arm of X chromosomes generally. If the presumptive isochromosomes of the patients were 'inactive' in all cells, a paternal origin could be assumed in six of the 14 patients (R., J., Fra., All., And., Eri.) irrespective of the situation of the Xg locus: on the other hand, if they were 'active', one could conclude a paternal origin for the six only on the assumption that the Xg locus is on the short arm. In the two patients J. and R., 'activity' of the isochromosomes would imply that the Xg locus is on the short arm (if we disregard mosaicism), and indeed this is the object of the present article.

We thank Dr. P. M. F. Bishop, London, who referred the proposita of family R. for investigation, Dr. M. Svenmar, Råvemåla, for help in obtaining blood samples from the family J., and Prof. I. Kugelberg, Stockholm, for the colour vision investigation of that family. We also thank Dr. W. M. Court Brown, Edinburgh, Dr. E. G. Oastler and Dr. W. G. Whyte, Glasgow, and Dr. A. Motulsky, Seattle, for samples from three of the families listed in Table 1. We thank Dr. J. D. Mann, Grand Rapids, and Dr. A. Cahan, New York, for generous supplies of the anti-Xg^a serum.

One of us (J. L.) gratefully acknowledges a grant from Nordisk Insulinfond.

NEWS and VIEWS

The Academy of Sciences of the U.S.S.R.: Academician V. A. Kirillin

ACADEMICIAN VLADIMIR A. KIRILLIN, director of the High Temperature Laboratory of the Department of Technical Sciences, has been elected a vice-president of the Academy of Sciences of the U.S.S.R. in succession to Academician A. V. Topchiev, who died in Moscow on December 27. Academician Kirillin is a graduate of the Moscow Power Institute, where he has taught for the past twenty years. Ten years ago he was elected corresponding member of the Academy, and in 1962 he became a full-member. He has been awarded a State Prize and a Lenin Prize for his participation in theoretical and experimental investigations of the thermal properties of water and steam. He is also chairman of the U.S.S.R. Co-ordinated Committee on the Properties of Steam.

Academician B. E. Paton

ACADEMICIAN BORIS PATON, director of the Electrical Welding Institute, has been elected a new member of the Presidium of the Academy. He became a full-member of the Academy in 1962. Academician Paton has been working for some twenty years in the Institute, which is named after his father, Yevgeny Paton. Last year he was elected president of the Academy of Sciences of the Ukrainian S.S.R.

Engine Research and Development at the Ministry of Aviation: Dr. John Remfry

Dr. John Remfry has been appointed director of engine research and development at the Ministry of Aviation, in succession to Dr. J. W. Drinkwater, who is now at the National Gas Turbine Establishment, Farnborough. Born in 1904, he held a Foundation Scholarship at Sir Joseph Williamson's Mathematical School, Rochester, before entering H.M. Dockyard, Devonport, as an indentured apprentice to Marine Engineering and Shipbuilding in 1919, where he gained the Admiralty Prize for first place in school subjects in all dockyards in 1923 and a Whitworth scholarship in 1924. He graduated with the degree of B.Sc.(Eng.) with honours in mechanical engineering and motive power at the City and Guilds Engineering College in the University of London in 1926 and was awarded the Diploma of the Imperial College in aeronautics in 1927 after post-graduate study at the Royal College of Science. After a year at the National Physical Laboratory, Dr. Remfry was until 1936 a research engineer with Messrs. Rowntree and Co., York. During the next year in the Chief Engineer's Department of the London County Council he was concerned with the efficient generation and utilization of steam and electrical power. In 1937 he joined the Engine Department of the Royal Aircraft Establishment, Farnborough, and worked on problems of heat interchange for aircraft engine radiators, oil coolers and charge coolers. In 1944 he was transferred to the Directorate of Engine Research and Development, which was successively under the Ministries of Aircraft Production, Supply and Aviation, where he was engaged on the performance estimation and approval of reciprocating and gas turbine engines and the supervision of research at universities and contractors' works on aerodynamics, thermodynamics, heat transfer and engine materials. He has been an assistant director for aero engine projects and performance since 1950.

International Academy of Astronautics: Honorary Members

Prince Louis de Broglie, Miss Jacqueline Cochran and Mr. Harry F. Guggenheim have been elected honorary members of the International Academy of Astronautics. The first honorary member of the Academy was the late Prof. Niels Bohr.

Prince Louis de Broglie, the well-known French physicist, has made major contributions to the development of modern physics and to the fostering of international scientific co-operation. He is a member of the French Academy of Sciences and has been its secretary since 1942. Prince Louis de Broglie has received many honours and awards, including the Nobel Prize for Physics in 1929. For his efforts to explain aspects of modern physics to the layman, he was the first recipient of the Unesco Kalinga Prize in 1953. He has been professor at the Institut Henri Poincaré in Paris since 1928, and in 1943 he founded a Centre for Studies in Applied Mathematics. In 1945 he was counsellor to the French High Commission on Atomic Energy.

Miss Jacqueline Cochran (Mrs. Floyd B. Odlum), the leading woman in American aviation, has done much to prove that women are as capable as men to achieve success in the field of practical flying. She was the first woman to fly in the Bendix transcontinental race in 1934, and has since won numerous Bendix trophies, as well as the Clifford Burke Harmon Trophy of the International League of Aviators. Miss Cochran was the first woman pilot to pierce the sonic barrier in 1953, and she holds several national and international flight records. Since 1959 she has been president of the International Aeronautical Federation, an organization the functions of which now include the verification and maintenance of manned space flight records.

Mr. Harry F. Guggenheim, American philanthropist and publisher, has played an important part in the promotion of aeronautics and astronautics both on a national scale and on an international level. His interest in aviation goes back to the 1920's. He was U.S. delegate to the International Conferences on Civil Aeronautics in Washington, D.C., in 1927 and 1928. As president of the Daniel and Florence Guggenheim Foundation, he founded the Daniel and Florence Guggenheim Jet Propulsion Centres at Princeton University and at the California Institute of Technology, where his father had previously founded the Guggenheim Aeronautical Laboratory. Mr. Guggenheim was U.S. Ambassador to Cuba during 1929–33, and he has been honoured with numerous awards and decorations.

Anglo-Belgian Company for Marine Reactor Development

The United Kingdom Atomic Energy Authority and a syndicate of Belgian industrial companies headed by Belgonucléaire have jointly formed a company to own all the results of their development programme for the *Vulcain* reactor. The formation of the Company follows an announcement in May 1962 that the Authority had signed an agreement with Belgonucléaire to undertake a joint research and development programme on a design of nuclear reactor suitable for marine propulsion—given the name of *Vulcain*—on which Belgonucléaire had already done much preliminary work. This reactor is an advanced version of the pressurized water reactor embodying the principle of variable moderation. The Authority's participation in this joint effort is part of the programme of research announced by the Minister of Transport in November 1961 to develop a reactor system economically attractive to a wide range of shipping. This research is being undertaken with the approval and support of the Working Group on Marine Reactor Research, appointed jointly by the Minister for Science and the Minister of Transport. After assessing the relative merits of a number of reactor types most suitable for further development for marine propulsion, the Working Group's recommendation was accepted in November 1962, that the programme of research be concentrated in future on two types. One of these is the *Vulcain* reactor, and the other is the Integral Boiling Reactor, which is an advanced reactor concept originating within the Authority.

Fuel Elements for *Scorpio* Reactor

The Metallurgy Division at Harwell has recently completed the production of 400 plutonium-bearing fuel elements for *Scorpio* (Sub-critical carbon-moderated reactor assembly for plutonium investigations) experiments at the Atomic Energy Establishment, Winfrith. They are being used to simulate the partially used uranium fuel elements of a power reactor, in which plutonium has been formed by neutron bombardment of uranium-238; this plutonium build-up profoundly affects the behaviour of a reactor, especially its response to temperature variations. The fuel elements take the form of cylindrical bars, 28 in. long by 1·2 in. diameter, of depleted uranium containing 0·43 per cent uranium-235 with 0·25 per cent plutonium added; they are sheathed in stainless steel 0·015 in. thick. It is hoped that the *Scorpio* experiments will not only improve the basic understanding of plutonium reactor physics but will also help to check the accuracy of theoretical calculations of the effects of plutonium build-up in power reactors. The *Scorpio*'s are sub-critical graphite-moderated reactor assemblies of widely variable lattice geometries and capable of being heated to temperatures of up to 400° C. Precise measurements of neutron flux distribution throughout such an assembly (in *Scorpio* 1), or within individual lattice cells (in *Scorpio* 2), enable the reactivity of a system to be studied at different temperatures.

Astronomy in the United States

A PANEL to estimate the probable need for major new facilities in astronomy in the United States during the next 5–10 years has been set up by the National Academy of Sciences. Dr. Albert E. Whitford, director of Lick Observatory, Mount Hamilton, California, is chairman of the panel. Chairman of the Committee on Government Relations is Dr. George B. Kistiakowsky, professor of chemistry, Harvard University, who was special assistant on science and technology to President Eisenhower.

The panel will concern itself mainly with solar and galactic astronomy, optical and radio astronomy, ground-based and space astronomy, independent research observatories and those connected with universities. The astronomer members of the panel will also discuss the needs of astronomy with respect to manpower and the use of new devices such as high-speed computers for the automation of telescopes and the processing of data, electronic-image tubes as substitutes for photographic plates, and radio-astronomy receivers. Other members of the panel are: Prof. R. N. Bracewell, Stanford University; Prof. Frederick T. Haddock, jun., University of Michigan; Dr. Frank D. Drake, National Radio Astronomy Observatory, Green Bank, West Virginia; Dr. William Liller, Harvard College Observatory; Dr. W. W. Morgan, Yerkes Observatory, University of Chicago; Mr. Bruce H. Rule, California Institute of Technology; and Dr. Allan R. Sandage, Mount Wilson and Palomar Observatories.

The Institute for Medical Research, Federation of Malaya

THE annual report of the Institute for Medical Research, Federation of Malaya, for 1960, which includes a report from the United States Army Medical Research Unit (Malaya) and statistical appendixes, as well as a list of publications and reports, includes also a report on the eighth and final year of continuous filariasis investigations (Pp. vi + 184. Kuala Lumpur: Institute for Medical Research, 1962. 2.50 Malayan dollars). This report envisages a co-ordinated campaign of control by mass treatment with diethylcarbamazine, starting in 1961, of all persons living in endemic areas, estimated at 5 per cent of the population. Research on *Salmonella typhi* phage types in Malaya continued, but routine biochemical estimations occupied most of the time of the staff of the Division of Biochemistry. The Division of Entomology finished its intensive collection of culicine mosquitoes, and in wall tests with *Aedes aegypti* a new formulation of benzene hexachloride containing a resin gave similar results to the normal wettable powder formulation. An investigation into monkey malaria in the country was commenced, and a notable advance was made in co-operation by Government agencies to improve nutrition in rural areas. A valuable development was the opening of a plant for the production of tuna fish meal by a commercial firm in Penang. Further evidence was obtained that leptospirosis is a common infection in humans in Malaya.

Salary Re-scaling for Colleges of Advanced Technology

IN replying for the Government in the House of Commons on January 23, the Parliamentary Secretary to the Ministry of Education, Mr. C. Chataway, said it was intended, as one consequence of the transfer of the colleges of advanced technology to direct grant, that salaries of the staff in the Colleges should be related to those of university staffs. By the end of summer 1962, broad agreement had been reached between the Ministry and the national teachers' bodies concerned on the main outlines of the negotiating procedure to be followed for this transition from the Burnham system to one more closely related to the university system. The Government, however, was at this time also considering the position with regard to university salary negotiations, and eventually concluded the review of university salaries was most appropriately referred to the National Incomes Commission and that college of advanced technology salaries should be simultaneously referred to the Commission. The Commission had not yet settled the procedure for the submission of evidence, but when it had done so the various bodies concerned would be fully informed. When it was decided to authorize an immediate overall increase of 10 per cent in university salaries it was also decided, in view of the very substantial increase which college of advanced technology staffs had received as a result of the last Burnham settlement in January 1962, that any adjustments in their salaries should be limited to the more senior grades. The precise adjustments will be a matter for discussion with the teachers' associations and the representatives of the chairmen and principals of the colleges as soon as it is known what increases are to be approved for the various grades of university staff. Mr. Chataway added that he fully shared the view that the colleges must be recognized as equivalent in status to universities but that decision on that must await the Robbins report.

Films on the Peaceful Uses of Atomic Energy

As part of its continuing programme to make information available in its Member States, the International Atomic Energy Agency has established a film library and has recently published a catalogue of the 167 films that are now available for loan (Film Catalogue No. 1: *Films on the Peaceful Uses of Atomic Energy available through the International Atomic Energy Agency*. Pp. v + 51. Vienna: International Atomic Energy Agency, 1962). In the catalogue, films are listed under subject headings such as geology, safety, instrumentation, space, physics, radioisotopes, reactors, waste disposal. Each film is briefly described in a few sentences of text. Indicated in tabular form are country of origin, date of production, length, languages available and whether the film is in colour or black-and-white. Although most of the films at present available are in English, about fifteen are available in French, seven in Russian, four in German and one each in Spanish, Italian and Japanese. Several films are available in more than one language. Films are loaned to organizations in the Agency's 78 Member Nations for only the cost of return shipment. Copies of the catalogue are available from the Film Library, the International Atomic Energy Agency, Kärntnerring 11, Vienna I.

Bibliography on Direction Finding and Related Ionospheric Propagation

FOLLOWING a conference held at the University of California at Los Angeles in June 1960, at which the aspects of long-range high-frequency radio propagation that affect radio-location and direction-finding, and the related problems of measurement and analysis, were discussed, it was decided to launch a *Bibliography on Direction Finding and Related Ionospheric Propagation Topics* (Edited by Olaf D. Remmler. National Bureau of Standards Technical Note 127. Pp. 115. U.S. Government Printing Office, Washington 25, D.C. 1962. 60 cents). A group of the papers presented at the conference was published in *Radio Propagation*, Section D of the *Journal of Research of the National Bureau of Standards*, May–June issue, 1961. This bibliography, though not exhaustive, includes more than 850 titles on direction finding and related topics including instrumental details, observations and data analysis, and theories of propagation. In connexion with the conference, the Numerical Analysis Research Staff of the University of California at Los Angeles prepared a bibliography of works on the conference subject published during 1955–59. This has since been edited and extended to include references to individual papers resulting in the present publication published during 1955–mid-1961. In addition, references to bibliographies, proceedings of conferences, reviews, surveys and texts as far back as 1940 have been incorporated to provide access to the earlier literature of the subject and to related fields of research.

University News :

Keele

Since its foundation in 1949 as the University College of North Staffordshire, one of the special features of the University of Keele has been the maintenance of close links between different disciplines and the avoidance of departmental specialization. Although there has been no Department of Sociology, considerable emphasis has been placed on the development of sociological studies in a number of Departments, particularly those of Economics, Geography and Political Institutions. Moreover, for some years past the University has been responsible for the running of the *Sociological Review*. The further development of sociological studies within the University will be greatly helped by a gift of £50,000 from the Nuffield Foundation to provide a permanent endowment for a Statistical Research Unit in Sociology. It is hoped that the director of the Unit will not only develop new sociological studies based on accurately recorded information, but will also forge fresh links between sociological studies already in progress in several Departments of the University.

Sussex

The third annual report of the University of Sussex, covering the year ended July 31, 1962, which includes the formal birth of the University when its Royal Charter took effect on August 16, reviews briefly the progress in buildings and administration (Pp. 22+xii. Stanmer, Brighton: The University of Sussex, 1962). Capital expenditure amounted to more than £645,000, met mostly from £629,000 in non-recurrent grants from the University Grants Committee, which also made a recurrent grant of £40,500. The recurrent grants for the quinquennium 1962–67 were announced in April 1962, but additional funds from Government sources will be required if the University's target of 1,700 students by 1966–67 is to be achieved. Further substantial donations were received during the year and amounts received and promised against the original target figure of £500,000 exceeded £650,000. During the year, addition of 23,000 volumes and pamphlets, 16,000 by purchase, brought the total in the library to 33,000. In October 1961 fifty-two undergraduates were admitted to the B.A. degree course and three part-time research students to courses leading to a higher degree. For 1962–63, 2,453 applications were received for the B.A. and 627 for the B.Sc. course, and 202 and 159 students, respectively, were accepted.

The Clough Memorial Research Fund

Part of the Clough Fund has, in former years, been used in the form of research grants for the furtherance of geological research in Scotland and Northern England. The Edinburgh Geological Society has now decided to use this money to institute the Clough award. This is to be presented, biennially, to the person or persons normally in their early thirties and of British nationality whose geological work in Scotland or Northern England (as defined in the regulations for the administration of the Clough Fund) is of outstanding merit. The first Clough Award will be made during 1963. Further information can be obtained from the Honorary Secretary, the Edinburgh Geological Society, c/o the Grant Institute of Geology, King's Buildings, West Mains Road, Edinburgh 9.

The National Institute of Sciences of India

At the twenty-eighth anniversary general meeting of the National Institute of Sciences of India, held on December 30, the following were elected officers and members of Council of the Institute for 1963: *President*, Prof. H. J. Bhabha; *Vice-Presidents*, Dr. A. C. Joshi and Prof. T. R. Seshadri; *Treasurer*, Sri S. Basu; *Foreign Secretary*, Prof. P. S. Gill; *Secretaries*, Prof. R. C. Majumdar and Prof. B. R. Seshachar; *Editor of Publications*, Prof. P. Maheshwari; *Members of Council*, Dr. Atma Ram, Prof F. C. Auluck, Prof. Ram Behari, Prof. K. A. Chowdhury, Dr. S. N. Dasgupta, Prof. A. K. Dutta, Prof. S. Gupta, Dr. B. S. Kadam, Prof. S. Kilpady, Prof. D. S. Kothari, Dr. L. S. S. Kumar, Dr. B. Mukerji, Dr. C. Radhakrishna Rao, Dr. M. L. Roonwal, Prof. M. R. Sahni, Prof. T. S. Sadasivan, Prof. N. R. Tawde and Prof. W. D. West.

Sir Lawrence Bragg, director of the Davy Faraday Laboratory, the Royal Institute, London, was elected an Honorary Fellow.

The Night Sky in March

Full moon occurs on Mar. 10d. 07h. 49m. U.T. and new moon on Mar. 25d. 12h. 10m. The following conjunctions with the Moon take place: Mar. 6d. 22h., Mars 3° N.; Mar. 22d. 10h., Saturn 1° N.; Mar. 22d. 13h., Venus 2° N. In addition to these conjunctions with the Moon, Venus is in conjunction with Saturn on Mar. 20d. 23h., Venus being 0·9° N. Mercury is too close to the Sun for observation. Venus is a morning star, rising about an hour before the Sun. Mars is above the horizon most of the night, setting shortly before sunrise. It is at a distance of 77 million miles on March 15, when its stellar magnitude is $-0{\cdot}2$ and it is in Cancer. Jupiter and Saturn are too close to the Sun for observation. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Mar. 3d. 23h. 21·6m., χ^1 Ori. (*D*); Mar. 6d. 03h. 09·0m., 85 Gem. (*D*); Mar. 7d. 00h. 46·8m., δ Cnc. (*D*); Mar. 16d. 04h. 18·5m., θ Lib. (*D*). *D* refers to disappearance. The vernal equinox occurs on Mar. 21d. 08h.

Announcements

The British Small Animals Veterinary Association and the Universities Federation for Animal Welfare are jointly sponsoring a symposium on "Small Animal Anaesthesia" at the Middlesex Hospital Medical School during July 23–24. Further information can be obtained from Mrs. J. G. Wright, 114 Maida Vale, London W.9.

A symposium on "The Natural Radiation Environment" will be held at William Marsh Rice University, Houston, during April 11–13. Subjects under discussion will include: instrumentation and techniques; cosmic radiation; terrestrial gamma radiation; natural environmental radiation studies. Further information can be obtained from Prof. J. A. S. Adams, Department of Geology, Rice University, Houston 1, Texas.

"Bird Protection in Scotland" is the title of the Acorn Lecture to be given by Mr. G. Waterston, the Scottish Centre for Ornithology and Bird Protection, at the Arthur D. Little Research Institute on February 25. Further information can be obtained from the Secretary, Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, Midlothian.

A symposium on "Cell Electrophoresis", sponsored by the British Biophysical Society, will be held at the Chester Beatty Research Institute during May 7–8. The types of cells under discussion will include those from normal tissue, cultures, blood and bone marrow, bacteria and plants. Further information can be obtained from Dr. E. J. Ambrose, Chester Beatty Research Institute, Fulham Road, London, S.W.3.

Erratum. In the article entitled "Adaptive Teaching Machines", which appeared on p. 1276 of the December 29, 1962, issue of *Nature*, the word 'minimize' in the first sentence of the penultimate paragraph should read 'maximize'.

THE ASSOCIATION OF UNIVERSITY TEACHERS

THE Association of University Teachers were the guests of the Southampton Association of University Teachers and the University of Southampton during December 17–20, and their meetings were presided over by Prof. W. W. Chambers of the University of Glasgow.

The deliberations were dominated by the effects of the Government's financial policy towards universities. The effects which were reported to the Council included losses of staff, failure to provide places for some 2,500 well-qualified candidates and postponement or changes in plans for expansion affecting every institution in the United Kingdom and Northern Ireland. Although most attention was given to problems of expansion, the long-delayed issue of salaries gave rise to heated debate when representatives learned that the claim for increases of about 30 per cent, substantially agreed with the vice-chancellors, had not been discussed with the University Grants Committee, as provided for in the procedure laid down by the Treasury. The University Grants Committee had not arranged the necessary meeting. This news, together with Press reports and rumours that the matter was to be referred to the not yet constituted National Incomes Commission, led to demands that the subject be taken up with the Chancellor of the Exchequer through Parliament. The Council in a resolution objected to the discrimination inherent in the National Incomes Commission but left the Association free to present data to the Commission if university salaries were referred to them by the Government.

The discussion of university expansion was centred on what was described as the "18+ Crisis", and the Council passed a policy resolution submitted by Liverpool:

"That the policy of the A.U.T. on expansion should be based on the following principles:

"(1) The A.U.T. recognizes and welcomes the necessity for a substantial expansion of the universities for reasons both of national need and social justice. It insists, however, that neither purpose will be served if expansion leads to deterioration in the quality of the education offered.

"(2) The special quality of university education derives from the active participation of university teachers in fundamental research and scholarship. Therefore, the A.U.T. regards the provision of adequate time and facilities for these activities to be essential to the successful fulfilment of the universities' role.

"(3) The A.U.T. considers that the maintenance of the quality of university education must have precedence over expansion if lack of money or other resources forces a choice. No lowering of essential standards can be contemplated.

"The first duty of the A.U.T. in the present situation is to intensify the campaign for an immediate and substantial increase in the resources available to the universities.

"Further, it is the duty of the A.U.T. to warn the public that grave injury to the national economy will result if university research is sacrificed in an attempt to expand undergraduate teaching without the necessary resources."

The Council then went on to discuss proposals for making the problems of university expansion widely known to the general public.

The growth of the Association to a membership of some 10,000, almost all non-medical university teachers, in universities other than Oxford and Cambridge had created problems of organization which were the subject of further discussion, and proposals were made for changing the form of one of the half-yearly meetings.

Other matters which were discussed included proposals to improve the status of university technicians, the problems of student selection and the improvement of general degrees and possible ways of raising the popular esteem of the general degree. D. CHAPMAN

ZOOLOGICAL EXPEDITIONS

THE twenty-eighth annual meeting of the Association of British Zoologists was held at the Offices of the Zoological Society of London on January 5. The president for 1963, Dr. F. Fraser Darling, was unable to attend, and the chair was taken by Prof. C. F. A. Pantin. After the business meeting several papers were read on "The Scientific Aims, Planning and Results of Zoological Expeditions".

Mr. N. A. Holme (Plymouth) outlined his present work investigating the bottom of the English Channel. Since the pioneer dredging activities of the *Porcupine* and *Challenger* expeditions the faunistic exploration of the benthos is now fairly complete, except for the deep sea. In the English Channel the present surveys are concerned with assessing biomass and productivity, dispersal and aggregation, and the factors which limit the distribution of bottom-living animals. There is no ideal sampling apparatus, either qualitative or quantitative: trawl, dredge, Petersen bottom-sampler, anchor-dredge and automatic camera all have their disadvantages. On a rapid survey only one type of gear can be used at each station, and Mr. Holme stressed the importance of careful planning to make the most of the ship's time. After dealing with the practical aspects of sorting, preserving and working-up samples of benthos, Mr. Holme made a plea for the early publication of results.

Dr. Anna Bidder (Cambridge) gave a lively account of her trip to the South Seas to study living specimens of the pearly nautilus in 1960–61. Local people in New Caledonia, the Loyalty Islands and New Britain brought her *Nautilus* caught in traps baited with putrescent fish and meat. In this way she was able to study, in the public aquarium at Nouméa or, elsewhere, in aquaria improvised from slop-basins on the foreshore, specimens of three species of this nocturnal, bottom-living mollusc. The chambered shell of the pearly nautilus has been sung by poets and worked over by every zoology student, and yet we have known scarcely more than Aristotle could tell about the habits of the animal within. Now Dr. Bidder has not only been able to confirm the Aristotelian account, but answer much which was speculative concerning one of the most bizarre forms of cephalopod radiation.

Prof. C. F. A. Pantin (Cambridge) described how, during a war-time holiday, his chance find in an English oakwood of the terrestrial nemertine worm *Geonemertes* led him in subsequent years to pursue studies on the taxonomy and world distribution of this genus, and on its anatomy, physiology and ecology, whenever opportunity could afford during visits to Europe, Africa, New Zealand and various oceanic islands. Prof. Pantin made the point, which was further emphasized in discussion by Prof. G. C. Varley (Oxford), that whereas the objectives of an expedition should be carefully defined, the members of the expedition should have a sufficiently wide background to take advantage of the unexpected opportunity or the sideline which sometimes may lead to the most rewarding results. Prof. Pantin also suggested that in all universities the young graduate proposing to undertake research should first be given the opportunity of an 'expedition year', a year in the field which would yield experience of real value irrespective of the kind of research eventually pursued.

The University of Cambridge Expedition to British Honduras in 1959–60 was a considerable enterprise where ten undergraduates worked in the field for eleven months on a comprehensive programme including archaeology, botany, zoology and physiography. Mr. P. K. Bregazzi (Cheltenham College) described the zoological work which was mostly concerned with the faunal ecology of the corals and the land ecology of the cays which lie scattered within a broad channel between the shore and a long fringing reef. Using mostly skin-diving methods the party lived much of the time in a small sailing-boat with which they managed to explore 150 miles of the channel. Interesting results were obtained on the diurnal activity of coral polyps and on the origin of 'beach-rock' formations on the islands, but Mr. Bregazzi concluded that the work was chiefly significant as the first step in a long-term programme and he noted that the area had since been visited by at least five expeditions from Britain and the United States.

An expedition with a careful programme in applied science was described by Mr. P. D. Fry (Royal Veterinary College). In 1962 eight undergraduates visited East Africa to study so far as they could the diseases which affect wild mammals and birds and domestic cattle, and to collect material which might show how these diseases affect man. Special attention was directed to game animals likely to be included in cropping programmes. Travelling in 'Land-Rovers' the party in ten weeks got through a great deal of work, mostly in Uganda, where they were able to examine more than 200 animals ranging from the spiny mouse to the elephant. Systematic autopsies yielded pathological material and parasites, and there were collections of blood-smears and blood sera for studies on protozoal disease and on immunology. Some of the collections were from game anaesthetized with the 'capchur' gun. A notable feature of this expedition, to which Prof. Varley directed attention, was its active co-operation in the field with medical and veterinary research organizations of Uganda and Kenya, and the approval and patronage it won from the World Health Organization.

Dr. Robert Clarke (National Institute of Oceanography) summarized the discussion and concluded with some general observations. He recalled that the exploratory expedition in zoology had, in the past thirty years, mostly given way to specialized objectives in evolution, physiology and especially ecology. The emphasis was now on productivity, both by land and sea, and he welcomed the kind of expedition described by Mr. Fry which had avowed economic ends in a world hungry for proteins. The planning of expeditions should take realistic account of possible hitches in the field, so that, as mentioned by Mr. Holme, any lengthy or costly expedition should have alternative programmes which (combined, as it may be, with the readiness to improvise) can in the event turn some impending failure into success. Only the enthusiast like Dr. Bidder, going out alone, could afford a single objective and be almost sure to achieve it. Working up results at home, an expedition always brings back more material than it can deal with. Great collections build up over the years, and there was an urgency in Prof. Pantin's plea for more taxonomists in professional zoology. Even an expedition with the most radical aims in applied science must know what the animals are—be they a food resource or a disease vector.

Reviewing the general trend of expedition activity, Dr. Clarke noted that the major expeditions were national undertakings until about ten years ago. Their era was one of great achievement, and by example he mentioned the work of the vessels of the *Discovery* Expedition and the National Institute of Oceanography which between 1926 and 1951 had made the remote Southern Ocean the best known scientifically of the world oceans; but he welcomed the present trend towards international co-operation in the expeditionary field. Such activity has mainly been at sea, and in its modest way a beginning was made by the *Enern*'s voyage to the Antarctic in 1953 when Norwegian, Dutch and British scientists collaborated in a whale-marking expedition. Development of the large-scale venture has been assisted by the growth of international organizations like the International Council of Scientific Unions and the specialized agencies of the United Nations which have provided the administrative machinery. The International Indian Ocean Expedition, in which ships of thirteen nations are engaged, will be especially active in 1963, and in this year also five nations will co-operate in surveying the equatorial region of the Atlantic. International relations could not but benefit from such work, and it was heartening to mention in conclusion another aspect of the co-operative expedition which he illustrated from a recent mission with the Food and Agriculture Organization to the west coast of South America. No traveller could have failed to notice that past expeditionary work in the countries of Asia, Africa and Latin America has mostly been the enterprise of Europeans and North Americans. But it was desirable that the nationals of these countries should explore their own deserts and rain forests and seas. Enthusiasm was not lacking, and now, with the development of technical assistance programmes of the United Nations and of bilateral organizations, the necessary aid and training had become available and was already in the field.

ROBERT CLARKE

THE GALE OF FEBRUARY 16, 1962, IN THE WEST RIDING OF YORKSHIRE

By C. J. M. AANENSEN and J. S. SAWYER

Meteorological Office, Bracknell, Berks

VERY many people living in and around Sheffield will remember for a long time the disastrous westerly gale of February 16, 1962. The gale commenced at about 0430 G.M.T. in the West Riding and continued for the next 8 h. In Sheffield alone 101,500 dwellings out of a total of 161,000 dwellings were damaged in one way or another, and 98 dwellings (including 69 prefabricated houses) were damaged beyond repair. Elsewhere throughout a broad belt running northwards parallel to the Pennines from North Derbyshire to Northumberland very considerable damage occurred to both buildings and trees.

As soon as the scale of damage became known, Meteorological Office staff in the area made a survey of the type and distribution of damage and later some theoretical and climatological aspects of the storm were considered

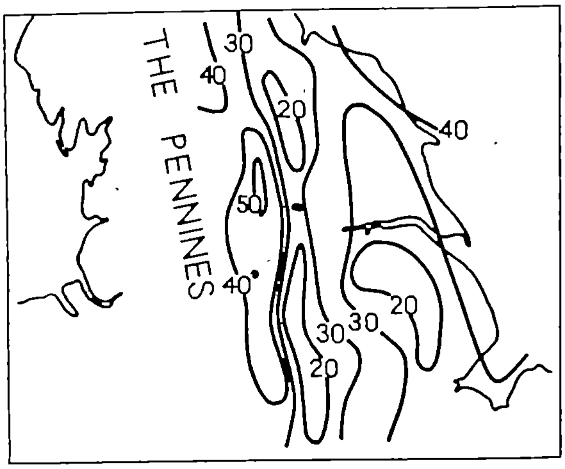

Fig. 1. Mean surface wind speed in knots at 0900 G.M.T. February 16, 1962, in the area east of the Pennines. ● Indicates Sheffield

at the Meteorological Office headquarters. It is proposed to publish a report on this work in detail in the future, but the following summary may be of interest now.

Without doubt the worst hit area was in and around Sheffield, and it was fortunate that a record of the wind strength and direction was obtained from the pressure tube anemometer mounted above the Weston Park Museum in Sheffield itself. The anemometer head is some 35 ft. above the flat roof of the Museum and only slightly sheltered by rising ground to the west. The record shows a maximum gust of eighty-four knots with at least five other gusts of eighty knots and more and thirty-six gusts of more than seventy knots. The recorded direction of the wind was 280°–300°.

An analysis of the various wind speeds recorded throughout Great Britain showed that on the whole this gale was not particularly noteworthy, especially west of the Pennines. In fact the most outstanding feature was that major wind damage to structures and trees occurred in a relatively narrow belt in the lee of the Pennines running approximately from Chesterfield through Leeds to Tyneside. This feature of the wind speed is brought out in Fig. 1, which shows the distribution of surface wind speed east of the Pennines at 0900 G.M.T. It will be seen that as well as the belt of maximum winds close to the Pennines there is a further belt of maximum wind some 40 km to the east with a marked line of lighter winds between and another area of minimum winds in Lincolnshire and the East Riding.

The gale was associated with a strong pressure gradient between a depression moving from Iceland to the Baltic and an almost stationary anticyclone over the eastern North Atlantic. The gale was at its height while the depression was moving across Scandinavia. Inspection of normal synoptic charts showed evidence of a very distorted pressure field over Northern England and this was analysed in detail by Mr. D. C. E. Jones. Of the various charts available, that for 0900 G.M.T. is based on most observations and shows the distortions most clearly (Fig. 2). The interesting features are: (*a*) a trough of low pressure extending north to south on the east side of the Pennines with separate low-pressure centres at Sheffield, Dewsbury and Ilkley; (*b*) a small centre of high pressure to the west of the Pennines between Bolton and Blackburn; (*c*) the intense pressure gradient across the Pennines. The wind was generally from west-north-west over the whole area and was far from a geostrophic balance with the pressure field. The air was accelerated as it passed from regions of high to low pressure and reached its maximum near the centre of low pressure as expected from Bernoulli's equation.

It is well known that the deformation of airflow in the neighbourhood of hills and mountains may give rise to lee wave phenomena and that large variations of surface wind and disturbance of the pressure field occur in association with wave effects aloft[1]. It was natural, therefore, to inquire whether this gale was in some way associated with the topography of the region, particularly in view of the fact that Sheffield lies to the east of the highest part of the southern Pennines. The present state of the theory of lee waves is not sufficient to allow a three-dimensional calculation to be made; but a calculation was carried through for a steady-state, two-dimensional gravity controlled flow over a ridge similar to the cross-section of the Pennines upwind of Sheffield, using the procedure developed by Sawyer[2]. This calculation revealed the existence of a powerful lee wave downwind of the Pennines with the unusually long wave-length of 22 km. In Fig. 3 is shown the calculated streamlines across the Pennines but with the vertical scale exaggerated sixteen times compared with the horizontal scale. It is noteworthy that a large vertical amplitude of perturbation is attained very rapidly as one proceeds from the surface, thus producing a marked packing together of the streamlines below the troughs of the waves. In particular it appears that Sheffield was beneath the second wave trough downwind of the Peak and that theoretically surface winds of thirty-five knots in the undisturbed stream would be increased in the vicinity of Sheffield to seventy-three knots. Thus, in spite of the restriction of the calculation to two-dimensional airflow and the neglect of condensation effects, it is clear from the calculations that intensifications of surface wind in association with lee waves aloft can provide a perfectly feasible mechanism for the exceptional winds at Sheffield.

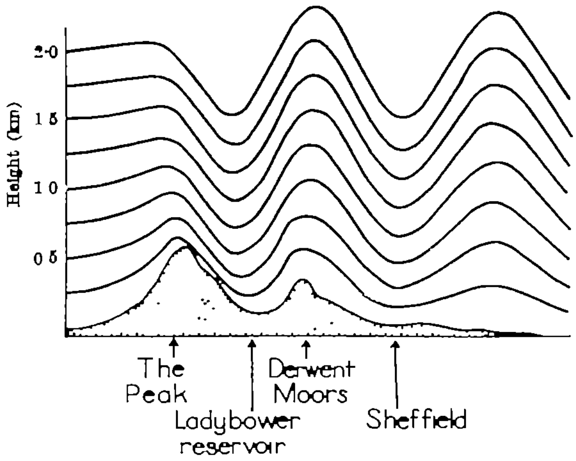

Fig 3 Calculated streamlines for the flow across the Pennines in the vicinity of Sheffield

Damage by westerly gales has been experienced in the West Riding on other occasions, notably only four days earlier on February 12, 1962. Damage on this occasion was by no means so severe in Sheffield but was widespread along the east of the Pennines and was of severity equal to that of the later gale in places from Leeds northwards. The large-scale weather situations on these two occasions were remarkably similar, but on February 12 the air, though stable, did not have such large inversions. Lee waves aloft were again possible and the theoretical calculations again indicated a powerful lee wave system with the wave-length having the exceptionally large value of thirty-eight kilometres. Because of the longer wave-length Sheffield did not lie beneath the trough of the second lee wave downward of the Peak, as on February 16, but somewhat downwind of the first trough. However, there was still a sufficient concentration of low-level streamlines at Sheffield to cause a substantial increase in surface wind speed, as actually happened.

Engineers, builders and meteorologists alike need some idea of the probable frequency of occurrence in Sheffield of severe gales such as that of February 16, 1962. Considerable damage in Sheffield by earlier gales occurred on March 1, 1956, and on December 22, 1894. The Sheffield anemograph records date from March 1958 only, and there are no other anemographs in the area. It is perhaps uncertain whether the usual climatological methods of estimating the frequency of near extreme values are applicable, but comparison by Mr. H. C. Shellard with the long period records for Manchester Airport and Cranwell gives a tentative estimate that a storm of the severity of that of February 16, 1962, would probably come in the 'once in 150 years' category.

SEMICONDUCTIVITY AND CEMENTING ACTION IN HYDRAULIC-BOND TYPE CEMENTS

By A. K. CHATTERJI and T. C. PHATAK

Central Building Research Institute, Roorkee, India

THE variation of electrical conductivity with temperature has been measured of some hydraulic-bond type cements, such as ill-crystallized calcium silicate hydrate, calcium sulphoaluminate hydrate, calcium sulphate dihydrate. Results indicate that these materials may be impurity semiconductors. A probable mechanism of cementing action as a semiconductor surface reaction is suggested.

Electrical conductivity of calcium silicate hydrate, calcium sulphoaluminate hydrate and calcium sulphate dihydrate has been measured at different temperatures. Calcium silicate hydrate was prepared by the interaction in solution of analytical reagent grade calcium nitrate and sodium silicate. Calcium sulphoaluminate hydrate was prepared by the second method mentioned by Jones[1] (precipitation from aluminium salt solution). Calcium sulphate dihydrate was prepared as a precipitate from the interaction of analytical reagent quality calcium carbonate and sulphuric acid. The materials were washed with absolute alcohol to remove any free calcium and excess moisture and were identified by chemical, X-ray diffraction and differential thermal analysis methods. Dehydration of calcium silicate hydrate on heating and the dehydration and phase changes occurring in calcium sulphoaluminate hydrate when heated at different temperatures were also examined. These results are not given here.

For measurements of electrical conductivity the compounds were made into tablets using a 20-mm cylindrical mould and plunger and were compressed in a hand-operated hydraulic press at a 140-kg pressure. The surface of the tablet was cleaned with a fine emery paper, and its dimensions were noted. It was then placed between two spring-loaded platinum electrodes mounted at the end of a tube of fused quartz. The complete assembly was inserted in a tubular furnace with natural atmosphere. The temperature of the furnace was raised at a rate of about 20° C/min through manual control of the auto-transformer. The lead to the electrodes, which consists of two wires of platinum and platinum–rhodium, served the dual purpose of measuring temperature and resistance. These quantities were simultaneously measured with a pyrometer and a megohm bridge.

Curves (*abcd*), (*pqr*) and (*klmno*) (Fig. 1) are respectively for calcium silicate hydrate, calcium sulphoaluminate hydrate and calcium sulphate hydrate and show points of sharp inflexions. The figures at the inflexion points indicate the temperatures in degrees centigrade.

For calcium silicate hydrate the conductivity increases with temperature in the range 50°–150° C (*ab*), decreases in the range 150°–325° C (*bc*) and again increases in the range 325°–750° C (*cd*) and above. For calcium sulphoaluminate hydrate, the portion (*pq*) of the curve corresponds to the portion (*bc*) of calcium silicate hydrate (*qr*) to (*cd*) and the portion corresponding to (*ab*) is absent. It would perhaps have been obtained if the measurements were extended to lower temperatures. In the curve for calcium sulphate hydrate the portions (*lm*), (*mn*) and (*no*) correspond to the (*ab*), (*bc*) and (*cd*) respectively of the calcium silicate hydrate curve. Portion (*kl*) represents rise in resistance owing to the removal of surface moisture.

Change in conductivity with temperature of these materials may be attributed to the escape of water molecules during heating and to the phase changes occurring at the inflexion temperatures. These considerations, however, leave the question regarding the nature of current carriers open. Further, there is always a tempera-

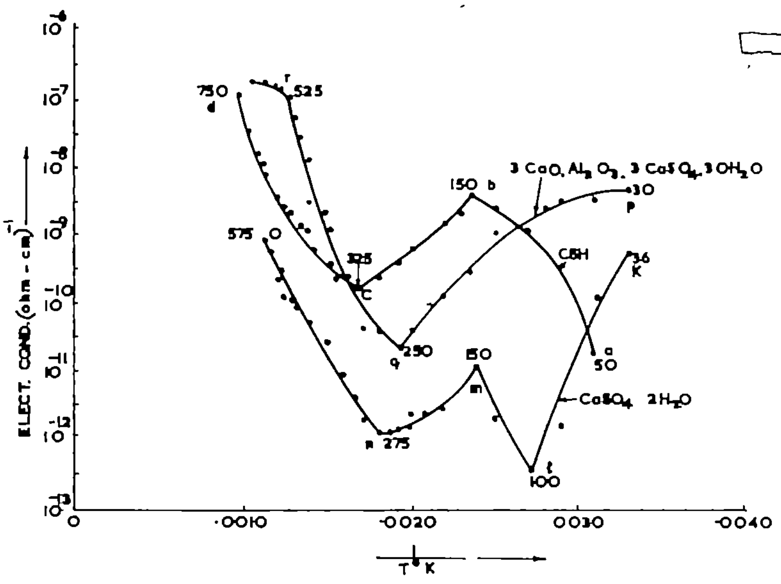

Fig. 1. Variation of electrical conductivity with temperature of the three hydrates

ture-lag in the phase-changes occurring by the two modes of heating—static and dynamic. The following approach provides an answer to the question of carriers and avoids the other issue.

An explanation of foregoing observations may also be given in terms of the possible change in concentration and mobility of the carriers with temperature considering these materials as impurity semiconductors. There is a marked similarity of these curves with those showing temperature-dependence of conductivity for arsenic-doped silicon samples[2]. The explanation for the latter phenomenon is that at low temperatures the conductivity is low as the carriers are frozen and with the rise of temperature ionization of carriers occurs which results in an increase in conductivity. This goes on for calcium silicate hydrate up to 150° C and for calcium sulphoaluminate hydrate possibly close to 30° C (as the curve becomes practically flat about this temperature). For calcium sulphate dihydrate this temperature is 150° C. Drop in conductivity with further rise in temperature—portions (*bo*), (*pq*) and (*mn*) of the curves—occurs owing to the decrease in mobility of the carriers with the rise in temperature[2]. Conductivity again rises with temperature—portions (*cd*), (*qr*) or (*no*) of the curves—owing to intrinsic semiconductivity[2] (or ionic conductivity or superimposition of both depending on the material).

As regards the nature of carriers involved in these materials, it is recalled that hydrogen atoms in solid interstitial solution in a crystal may act as 'donors'. In a similar manner it is assumed that in these hydrates hydrogen ions act as 'holes' and are mobile. It need not be assumed that the hydrogen ions from all the water of hydration act as 'holes'. The hydrogen ions which act as 'holes' are considered to be derived from water molecules retained at higher temperatures at least up to the temperature at which intrinsic semiconductivity begins. Some of the molecules of water may provide for 'holes' and these can act as 'impurities'. On this basis, these hydrates should be considered as impurity semiconductors with 'hole' conduction. This is the basic assumption of the present approach and needs direct verification. (It may be of interest to note that, under certain conditions, water may produce surface states of acceptor type on surface of germanium[3].) From dehydration experiments one can find out the number of water molecules retained at high temperature. This is found to be two for calcium sulphoaluminate hydrate and less than one for calcium silicate hydrate and calcium sulphate dihydrate per molecule of the hydrate. This gives an idea of the number of hydrogen ions, acting as holes, involved in cementing action. That the hydrogen ions from some of the water molecules in the hydrate may behave differently may be the reason why all the inorganic hydrates are not cementitious.

Assuming that the hydraulic bond type cements are '*p*' type semiconductors, cementing action of such cements (that is, the adhesion between such cement and aggregate) is considered to be a semiconductor surface reaction with a 'donor' type bond formed through the capture of 'holes' by the aggregate. Inside the cement crystal, the 'holes' constitute negative valencies which are free and are able to move about throughout the crystal and may appear at any point on the surface of the crystal. Thus the questions of choice or of relative orientation of crystallographic planes involved in adhesion do not arise. As such a reaction will depend on the position of the Fermi-level in the aggregate also, the aggregates with the Fermi-level relatively lying deep will have poor bond. In the present view, adhesion is a semiconductor surface reaction involving capture of 'holes' by the aggregate. This view of adhesion, due to free valencies within the crystal, is opposed to the prevalent view of adhesion due to localized valencies on the cement surface.

It is useful to have the structure of the cementing phase as a gel structure (or glass-like random structure) in order to maintain three-dimensional continuity; but in contrast with the concept held at present that the gel structure is essential for cements, emphasis in the present view is on their semiconductivity. A cementing phase will be preferred as a cement if it has a gel structure, but to behave as a cement at all the essential requirement is its semiconductivity. As in the present case, semiconductivity is considered to be due to 'impurities' and since adhesion, though weak, is developed even at the initial stages of setting of cement, the present view seems to indicate that the cementing crystals are formed from the very beginning of the setting process. This supports Le Chatelier's views.

Hydraulic action may now be considered. Cement clinker minerals react with water—whether in paste or in suspension—at different rates. Tricalcium aluminate reacts very quickly, tricalcium silicate less quickly, β-dicalcium silicate very slowly and the ferrite phase hydrates at a rate slightly lower than tricalcium aluminate. The difference in the rates of reaction with water is attributed to the difference in the basicity of the cationic reactant. The higher the basicity the higher the rate of reaction. For example, tricalcium silicate may be considered to be a basic salt $Ca_2(CaO)SiO_4$ and the high rate of reactivity of tricalcium silicate with water may probably be attributed to the facility for reaction with water possessed by the loosely held calcium oxide part of the structure of tricalcium silicate[4].

There are two views regarding the mechanism of hydraulic action of cement clinkers. According to one, the hydraulic action is considered to be a solution precipitation process. The clinkers go into solution (whatever slight solubility these may have) and the reaction occurs in the water medium with the formation of corresponding hydrates which, because of their still lower solubility, precipitate out[5]. There is another view which considers that the growth of hydrates occurs by solid-state reaction though the solution precipitation process can occur in favourable conditions. From the study of the gel formed during hydration it is held that the hydration process is a solid-state reaction which occurs by diffusion[6].

If it is taken that the hydraulic action is a solid-state reaction, then one would like to identify it with the known types of solid-state reactions. For example, it is known that the chemical reaction on the surface of a semi-conducting crystal is controlled by the position of the bulk Fermi-level in the crystal. Position of the Fermi-level can be raised or lowered by introducing suitable impurities in the crystal. Reactions which occur through transfer of electrons from the crystal are favoured by raising the Fermi-level and its lowering favours the reactions which occur through transfer of holes.

If hydraulic action were a semiconductor surface reaction, then, by introducing suitable impurity in the crystal, say, a 'donor' type impurity, the hydraulic action could be altered. To check this point Portland cement clinker (of composition tricalcium silicate, 37 per cent; dicalcium silicate, 35 per cent; tricalcium aluminate, 11 per cent; the ferrite phase, 8 per cent; free lime 0·65 per cent) was used for the following experiment as individual clinker minerals were not available in sufficient quantities. The clinker was powdered to a size finer than 53μ. A portion of the powder was heated to 800° C for 4 h. Another portion was mixed with 1 per cent of zinc oxide (an '*n*' type semiconducting oxide) and heated similarly. The rates of reaction with water of the clinker powder, clinker powder heated and of the clinker powder heated with the admixture of zinc oxide were obtained by estimating the lime liberated in a given time. It was found that the amount of lime liberated and hence the rate of reactivity with water was highest in clinker heated with zinc oxide and lowest in unheated sample.

When clinker was heated alone, it was in reality heated with calcium oxide—an '*n*' type semiconducting oxide. If some of the lime enters in solid solution into any or all of the clinker minerals, the effect of calcium oxide in solid solution would be to raise the Fermi-level of the crystal. Addition of zinc oxide would raise it further. With rise in Fermi-level more free electrons would be available for reaction on the surface provided such reaction is an 'acceptor' type reaction. The observed enhancement of rate of hydraulic action on heating the clinker may mean that: (*a*) the clinker minerals are semiconductors; (*b*) hydraulic action is an 'acceptor' type semiconductor surface reaction.

There are no published data regarding electrical properties of the clinker minerals. It is only known that $CaO.SiO_2$ is probably an ionic conductor[7], that is the electronic part in any electrical conductivity shown by this material is negligible. Water is practically without any action on this mineral[8]. This may indicate that electronic conductivity of the clinker is a necessary condition for hydraulic action. Though it is not known if clinker minerals are semiconductors there is no bar for these minerals to be impurity semiconductors through either non-stoichiometry or through trace impurities, and clinker minerals are known to have both. Glassy phase clinkers may be glassy phase semiconductors.

In a water molecule the hydrogen and the hydroxyl group are connected by a slight polarized bond with the positive pole on hydrogen atom and the negative pole on the hydroxyl group. The molecule of water on approaching the crystal with appropriate crystallographic structure may get attached to it by 'acceptor' bond through a capture of electron from the conduction-level of the crystal.

Increasing the calcium oxide content in clinker crystals plays a part in influencing their hydraulic action by making more electrons available, for the presence of calcium oxide raises the Fermi-level of the crystals. Rate of hydraulic action thus becomes dependent on the position of Fermi-level in the clinkers and the higher it is the greater is the rate. The difference in the rates of hydraulic action in different clinker crystals may be due to the difference in the position of the bulk Fermi-level of these crystals. Thus tricalcium aluminate should have a Fermi-level higher than tricalcium silicate and the lowest should be in dicalcium silicate. The position of the Fermi-level in the ferrite phase should be controlled by two opposite factors, calcium oxide raising it and ferric oxide ('*p*' type semi-conductor) lowering it. The resultant position should be close to that of tricalcium aluminate and its rate of hydraulic action should also be close to tricalcium aluminate as is actually observed, while from the point of view of basicity the ferrite phase should have a higher rate of hydraulic action than tricalcium aluminate.

When gypsum is 'overburnt' it either does not hydrate or hydrates after a long time. When it is heated more than 1,000° C a part of it breaks up into calcium oxide and sulphur trioxide and the resulting calcium oxide goes in solid solution in the residual calcium sulphate. The product thus formed readily hydrates and this fact is utilized in producing a type of gypsum cement. The explanation of this may also be along the lines given here and parallelism between hydration of cement clinkers and calcium sulphate is obvious. This should be true for hydration of lime, and high reactivity with water for lime may be due to being an '*n*' type semiconductor with relatively high Fermi-level.

Puzzolans are materials which react with lime in presence of water and harden. These fall on the borderline between hydraulic- and reaction-bond-type cements. The reaction between a puzzolan and lime in the presence of water is known to be a chemisorption process. Since a chemisorption process depends on the electrical characteristics of the reactants, it had been suggested that absorption of lime by puzzolan in the presence of water may be a semiconductor surface reaction and for a material to behave as a puzzolan it has to be a semiconductor[9]. These suggestions are made on the basis that the variation of electrical conductivity with temperature of puzzolans like kaolin and kaolinitic clay on firing with and without admixture of zinc oxide was found to be characteristic of semiconductors[9] and an increase in the electrical conductivity of these materials resulted in the decrease of lime absorption[9,10]. Work on lime reactivity of ferric oxide (a '*p*' type semiconductor) has shown that lime absorption increases with the electrical conductivity of ferric oxide and thus the reaction is a '*p*' type reaction on a '*p*' type semiconductor[11]. Applying these results, it has been possible to improve the puzzolanic activity of kaolin and kaolinitic clay[12] and of fired laterite[13].

It appears that the cementing behaviour of a large section of cements—hydraulic-bond type and puzzolans—may find explanation from the point of view of semiconductor chemistry and the cementing action may be governed by a few general principles. It may be that organic cements would also fall in line but nothing can be said yet.

The present view regarding cementing action of hydraulic-bond-type cements may be summarized as follows: cement clinkers and puzzolans are probably semiconductors. The hydraulic action of cement clinkers and the reactivity of puzzolans with lime in the presence of water are semiconductor surface reactions and the rates of such reactions are governed by the position of bulk Fermi-level in these crystals—the higher the Fermi-level the greater the rate. The reaction rate can be altered by changing the position of Fermi-level. Cementing hydrates owe their cementing property to their semiconductivity and these may be '*p*' type semiconductors with some of the hydrogen ions from the water molecules in these hydrates behaving as 'holes' and this distinguishes the cementing hydrates from other inorganic hydrates. Adhesive property of cements is due to these 'holes' acting as 'free' negative valencies which can move throughout the crystal and can appear at any point on the cement surface so that the bonds are not localized on the surface. Adhesion between cement and aggregate is a semiconductor surface reaction and the bond involved is a 'donor'-type bond.

EQUALITY OF VELOCITY OF GAMMA-RAYS OF OPPOSITE CIRCULAR POLARIZATION IN A TRANSVERSE MAGNETIC FIELD

By Dr. V. KNAPP*

Department of Physics, University of Birmingham

THE influence of the magnetic field on the propagation of light has been a subject of a number of investigations. Among more recent ones, those of Farr and Barnwell[1] may be mentioned. Using an interferometer they observed an apparent increase of the velocity of light in passing through a transverse magnetic field of 20,000 *G*. However, the increase observed, about 34 cm/sec, was comparable with the estimated error of the experiment, 19 cm/sec.

A much more accurate experiment was performed recently by Prof. R. V. Jones[2]. He passed a beam of light through a transverse magnetic field of prismatic shape, so that a change in the velocity of light would result in a deflexion of the light beam, just as in an ordinary optical prism. A very sensitive optical lever arrangement was then used to detect any deflexion that may occur. No change in the velocity of light was observed. By pushing the sensitivity of the optical lever to extreme value and by taking very considerable precautions to eliminate or reduce various disturbing effects, such as pressure and temperature variations, the experimental error was minimized so that an upper limit on the change in velocity as low as 10^{-2} cm/sec could be established. This is an improvement of several orders of magnitude as compared with the experiment of Farr and Barnwell. Jones's apparatus, as he pointed out, does not test the possibility of the magnetic field 'splitting' the velocity of light, that is, affecting different circular polarizations in opposite ways. Such an effect is theoretically possible owing to the polarization of the vacuum predicted by quantum electrodynamics[3,4].

Different velocities for two circularly polarized components would, of course, mean the rotation of the polarization plane and could be detected by the usual optical methods—with an arrangement consisting of a source of light, polarizer, analyser and an intensity-sensitive detector of the light passing through the analyser.

What the analyser, polarizer and detector should be depends on the choice of radiation. In choosing the wave-length of the radiation, one has to consider the relative merits of various experimental techniques applicable for respective wave-length regions and the accuracies attainable. If the difference in velocities of two opposite circular polarizations is Δc, and if it is maintained through the time t, the polarization plane will be rotated by an angle $2\pi ct/\lambda$, where λ is the wave-length of the radiation in question.

It would thus at first sight appear clearly advantageous to use short wave-length, that is, γ-radiation. This is, of course, not so simple, the difficulties in polarizing and analysing γ-radiation being comparatively great. For visible light, much less rotation of the polarization plane is compensated by much higher accuracy in measuring this rotation.

The Mössbauer effect, however, offers a new possibility of increasing the accuracy in the determination of the polarization plane and in polarizing γ-radiation.

To obtain polarized γ-rays, one can utilize nuclear reactions, where the outcoming γ-rays can show various degrees of polarization; radioactive decay (selecting the angle of emission of the preceding radiation); or Compton scattering. These are, obviously, not very convenient ways; either one has to face the intensity problem if scattering is used, or an accelerator is needed when producing polarized γ-rays through nuclear reactions.

Now, if one looks at the radiation pattern of a dipole placed in a magnetic field, one can see that the radiation emitted in a direction perpendicular to the magnetic field is, in fact, linearly polarized. Why not then use the magnetic field to polarize γ-rays, dipole transitions being readily available in a radioactive decay? A process of resonant absorption of this radiation by nuclei placed also in an external magnetic field could serve to analyse the polarization. The answer is, of course, simple. Dipole radiation consists of the $m = 0$ and the $m = \pm 1$ components, both linearly polarized in the direction perpendicular to the applied field, and also to each other.

If we attempted to analyse the polarization of dipole radiation in a way suggested here, no change in the intensity of resonant absorption would be seen though the relative orientation of the external polarizing and analysing field is changing. While this statement can be verified for any orientation, it becomes very obvious if one considers the polarizing and the analysing fields to be perpendicular to each other. The $m = \pm 1$ components cannot then excite identical components in absorbing nuclei, as their polarization is wrong; however, their polarization is correct to excite the $m = 0$ component. Similarly, the $m = 0$ can excite the $m = \pm 1$ components. However, although the tacit assumption of this reasoning, that the difference in energy between the $m = 0$ and the $m = \pm 1$ components is small compared with a width of the resonance, is certainly more than fulfilled for the Doppler broadened γ-rays, it can be questioned under the conditions of recoilless emission and absorption when the resonance width is of the order of natural width.

To take the best-known example of a dipole Mössbauer transition, the energy spectrum of 14·3-keV γ-rays emitted without recoil by cobalt-57 nuclei in an iron lattice shows a clear separation in energy of the $m = 0$ and the $m = \pm 1$ components; the strong internal field at the nuclei of such a lattice (of the order of 330 k*G*) affects the energies of the magnetic substrates sufficiently to produce energy differences of several natural line-widths between these components, and external polarizing and analysing fields can serve to orient the magnetic domains and therefore internal magnetic fields. The $m = 0$ and $m = \pm 1$ source components can excite only those of identical energy in the absorber, so we have in effect a source of linearly polarized γ-rays and an analyser with a strong dependence of resonant absorption on the relative orientation of external fields, maximum absorption occurring for parallel external fields and minimum for perpendicular ones.

---

*Present address: Institut Ruder Bošković, Zagreb.

A general plan of arrangement would then be as follows. The source and the polarizer are replaced by cobalt-57 nuclei in the iron lattice, the domains of which are oriented by the external field. The analyser is an iron lattice to which the external orienting field is applied. A proportional counter detects changes in transmission of radiation. This can be done with a good accuracy, up to 0·1 per cent, and consequently small changes in the orientation of the polarization plane can be detected.

Another argument for choosing γ-rays for the detection of the effect of the magnetic field comes from quantum electrodynamics; the effect of the magnetic field on light can occur through the virtual pair production and this is, of course, more probable at higher energies, that is, more probable for γ-rays than for visible light.

The effects of vacuum polarization on the velocity of light are proportional to the square of the field intensity and to the path of the photon through the field[3]. Thus, in order to bring the upper limit as low as possible, one should aim at using the largest and strongest magnetic fields available. At the time the new radial-ridge cyclotron was nearing completion, which offered the opportunity to use a large magnet with little outlay. The maximum field in the magnet was over 18,000 oersteds, falling to 15,500 oersteds at 20 in. diameter and rather more rapidly at larger diameters. The field in the ridge was about 15,000 oersteds. The use of this large magnet (pole diameter 55½ in.), the space available and the source strength determined the experimental arrangement to a considerable degree.

The arrangement with the best sensitivity to the rotation of the polarization plane would be a polarizer with its field parallel (or perpendicular) to that of the main magnet and an analyser with its field at 45°. The experimental procedure with such an arrangement would consist in observing the counting rates in the proportional counter with the field of the main magnet switched on and off.

However, the strong field from the main cyclotron magnet, extending to a considerable distance from the machine, creates serious difficulties for such an arrangement. Unless the analysing magnet was removed several metres from the machine a rotation of the analysing magnetic field would occur when the cyclotron magnet is switched on and off—because of the 45° between the analysing and strong magnetic field. Unless this rotation could be reduced to well below 1° the advantage of this arrangement would be lost. However, removal of the analysing magnet to sufficient distance was inconvenient and would have meant a reduction of the counting rate by a large factor. Thus, it was judged better to avoid the difficulty at the expense of sensitivity to the rotation of polarization plane, by aligning both the polarizing and analysing fields with the main field. Once the higher sensitivity of the first arrangement is sacrificed, a further possibility of improving the geometry appears, that is, the possibility of using the main magnet also to serve as polarizing and analysing magnet. Such a set up, finally adopted for the experiment, gives the minimum distance between the source and the absorber, and the best alignment between the analysing, polarizing and the main field, as one field performs all three functions.

In this arrangement one, obviously, cannot compare the counting rates with the field switched on and off—the main field switched off will not perform its polarizing and analysing function. Instead, one can compare the counting rates at half and at full field. At half field the fringing field is still sufficiently strong to perform its polarizing and analysing function, while any effect depending on the square of the field intensity is reduced to one-quarter of the full field value. This was the procedure used in the experiment.

The source, about 80 mc. of cobalt-57 diffused into the iron foil and giving the Mössbauer radiation of 14·3 keV, and the pure natural iron absorber were placed in front of the two opposite melanex windows on the cyclotron vacuum chamber in which a pressure of 10^{-5} mm mercury was maintained through the experiment.

The absorber was followed by a *PX* 130 xenon-filled proportional counter, the output of which was fed into a single-channel pulse height analyser selecting the 14·3-keV γ-ray peak. The scaler input was gated with a crystal controlled timing circuit, accurate to better than one part in 10,000.

In the course of the experiment, the half-field absorber transmission was compared with the full-field transmission in frequent alternation and the corresponding counting rates—hereafter called *HF* and *FF*—recorded.

To detect any possible effect of the change of the magnetic field on the source and the counter, control readings with the absorber removed were also taken. The effect of the magnetic field on the proportional counter was further investigated in separate tests.

In the arrangement adopted, the polarizing and analysing field changes and one must know whether this could affect the counting rates, possibly due to differences in the degree of polarization of the source and the absorber material. This effect was indeed observed and therefore the experimental procedure had to be such as to enable one to separate such spurious effects from any real ones. This was done by test runs in which the absorber was placed immediately after the source, before the main field, everything else being unchanged. Such test runs were performed in alternation with the normal sequence: source—main field—absorber—counter.

Denoting the test and the normal source—field—absorber sequence with *SAF*, respectively *SFA*, the experiment essentially consisted in repeating the following set of measurements:

Arrangement:	*SFA*	*SFA*	*SAF*	*SAF*
Field:	Half	Full	Full	Half
Counting rate:	*HF*	*FF*	*FF*	*HF*

Results are here expressed as the ratios of counting rates at half and full fields. A total of about 2×10^7 counts were recorded and the following values obtained:

$$SFA \text{ arrangement: } HF/FF = 1{\cdot}0071 \pm 0{\cdot}0015$$
$$SAF \text{ arrangement: } HF/FF = 1{\cdot}0094 \pm 0{\cdot}0015$$

Removing the absorber the following ratio was obtained:

$$\text{No absorber: } HF/FF = 1{\cdot}00017 \pm 0{\cdot}0016$$

The errors quoted are standard deviations, obtained from the spread of the actual readings—the standard deviations calculated from the number of counts being smaller by a factor of two.

One should first note that both *HF*/*FF* ratios deviate from unity; there is an increase of absorption at full field. As can be seen from the *HF*/*FF* ratio when the absorber is removed, the increase is not due to the effect of the magnetic field on the counter. This effect is due to the fact that, although at half field the absorber material reaches a high degree of magnetization, the complete saturation is not yet attained. Thus, there is an increase in absorption when the polarizing and analysing field changes from its 'half field' value of 1,250 oersteds to the 'full field' value of 2,500 oersteds, when the material has reached the magnetic saturation. The existence of the change of the *HF*/*FF* ratio due to the incomplete saturation must also be considered as a possible source of error; should there be an axial asymmetry in the fringing field in two absorber positions, then a different ratio *HF*/*FF* could be obtained for two source—field—absorber arrangements. The field in these positions was carefully measured and it was found that the polarizing fringing field when the field is at its half value is 1 per cent smaller on the source side. The difference in the degree of magnetization in the two positions due to this field difference should be of the order of 0·01 per cent, and the corresponding change in absorption (and in the ratio HF/FF) would be completely negligible in comparison with the standard deviations given.

From the ratios one obtains the increase in HF/FF due to the effect of the magnetic field on the radiation:

$$\Delta(HF/FF) = 1{\cdot}0071 - 1{\cdot}0094$$
$$= -0{\cdot}0023 \pm 0{\cdot}0020$$

that is, $\Delta(HF/FF)$ is in the limits of the values $-0{\cdot}0043$ to $-0{\cdot}0003$. Since the polarizing and analysing fields are parallel, any real effect must give a positive value of Δ, so we shall take the upper limit of the increase in ratio to be $-0{\cdot}0023 + 2 \times 0{\cdot}0020$ or 0·0017.

Assuming, in analogy to optics, that the absorption of linearly polarized radiation is dependent on the square of the cosine of the angle θ between the polarization planes of radiation and of the analyser, the intensity of transmitted radiation can be written in the form:

$$I = A + B \sin^2 \theta$$

For small angles θ, the fractional change of the intensity $\Delta = \Delta I/I = 2B/A\,\Delta\theta^2$ corresponds to the change $\Delta\theta$ in the angle between the polarization planes.

The ratio B/A was determined in a separate calibration experiment, by observing the transmission for parallel and crossed polarization planes. A value $B/A = 1{\cdot}05$ was obtained. With this value, and with the upper limit for the intensity change $\Delta = \Delta I/I = 0{\cdot}0017$, one obtains the upper limit for the rotation of the polarization plane $\theta = 1{\cdot}6°$. The corresponding upper limit on the velocity splitting is obtained from:

$$\Delta c = c \cdot \frac{\lambda}{S} \cdot \frac{\Delta\theta}{360}$$

where S is the path of the photon through the magnetic field and λ its wave-length. Inserting the values ($S = 50$ in., $\lambda = 8{\cdot}6 \times 10^{-9}$ cm) one obtains for the upper limit to the velocity-splitting:

$$\Delta c = 9 \times 10^{-3} \text{ cm/sec}$$

or:

$$\Delta c < 10^{-2} \text{ cm/sec}$$

which happens to be the same as Jones's limit to the changes of mean velocity:

$$\tfrac{1}{2}[(c + \Delta c) + (c - \Delta c)]$$

One might add that this is by no means the limit of accuracy at present available using the Mossbauer radiation. With a stronger source, so as to be able to use the most sensitive arrangement (45° between the polarizer and the analyser), an improvement by a factor of at least 10 will be possible.

I thank Prof. P. B. Moon for the hospitality of his Department and for valuable discussions.

POSSIBLE USE OF ARGON-39 IN THE POTASSIUM-ARGON METHOD OF AGE DETERMINATION

By Prof. JOHN J. NAUGHTON
Department of Chemistry, University of Hawaii, Honolulu

In the determination of ages by the potassium–argon method the generally accepted technique in present practice is to measure the amount of radiogenic argon present in the sample by the method of isotopic dilution, with argon-38 as the diluting isotope. In the present research a new technique has been investigated in which argon-39 is used as the diluting isotope, and is added dissolved in an artificial silicate which approximates the pertinent properties of the rock being analysed. The ease of handling and measurement involved in such a procedure is apparent.

Fechtig *et al.*[1] have reported the use of neutron generated argon-39 in natural silicates and in potassium chloride to measure the diffusion characteristics of argon in these substances. Reynolds[2] has also applied this technique to similar measurements on potash–lime–silica glasses.

For the exploratory experiments a sample of potassium silicate glass was prepared as a melt from high-purity silica glass powder and analysed grade potassium carbonate, and was homogenized by heating at 1,450° C for 3 h. The potassium content of the product was 10·8 per cent. The resultant clear glass was crushed to 40–60 mesh size in a diamond mortar, and was activated in the Brookhaven graphite reactor in the fast neutron section. Argon-39 was produced by the reaction:

$$^{39}\text{K}(n,p)^{39}\text{Ar}$$

After removal from the reactor, and 'cooling' of short-lived activities, the samples were coloured purple from neutron structural interactions. Annealing at 200° C for 2 h removed this colour.

The annealed samples were carefully analysed for argon-39 content by melting in an ultra-high vacuum system. The evolved gases were purified by condensation at liquid nitrogen temperatures and by gettering with titanium sponge. Isotopic dilution with an argon-38 enriched spike was used, and final determination of argon was made with an inert gas mass spectrometer[3]. The argon-39 content was $8{\cdot}54 \pm 0{\cdot}17 \times 10^{-7}$ standard c.c./g.

In use the argon-39 spike was added, dissolved in a weighed amount of ground and sized artificial silicate, to a known weight of similarly sized rock or mineral being analysed for radiogenic argon-40. The contamination of the sample with air argon-40 is the factor which limits the accuracy and usefulness of the potassium–argon method, especially for young minerals. This may amount to as much as 10^{-6} standard c.c. and can completely swamp the radiogenic argon-40 for rocks of ages less than ten million years. Therefore, as a first step the combined samples should be subjected to a treatment to preferentially remove or reduce this contamination. One such treatment is discussed here. For analysis, samples were placed in an apparatus to remove the required representative portion of the argon by melting or crushing, and to purify this gas by suitable freeze-out and gettering[4]. Extraction by melting was carried out in a molybdenum crucible at temperatures of 1,600–1,800° C. It should be emphasized that since only a representative sample of gas from the mineral–artificial glass mixture is needed for analysis by this method, the degree of completeness of extraction of the gas from the sample is not important.

For vacuum crushing the apparatus used was a narrow mortar of stainless steel attached to the ultra-high vacuum system through a glass-to-metal seal. The pestle was a stainless steel piston loosely fitted into the mortar, and attached by a rod to a soft iron armature within the glass portion of the system. The pestle was lifted once a second by this iron core actuated by a solenoid situated outside the apparatus. It was allowed to fall under its own weight to crush the sample. The temperature of the crusher could be controlled by external baths or furnaces for degassing or for temperature-controlled runs. After a typical run of 17 h, a sample was found to have been reduced from 40–60 mesh to 60 per cent through a 200-mesh sieve. Gas was copiously evolved during this crushing process, although the crusher was not as efficient as would be desirable.

Measurement of the argon peaks of the purified gas was made with the inert gas bakeable mass spectrometer. By determination of the 36, 39 and 40 peak ratios, a correction for air argon-40 was applied, and the volume of radiogenic argon-40 in the mineral sample calculated according to the method of isotopic dilution.

The radioactivity of the argon-39 suggests an alternative method of measurement which is at present under investigation. If the air argon contamination can be made negligible by a suitable pretreatment (see later), the total volume of the purified argon in a representative gas sample can be measured, and radioactive counting used to determine the argon-39 content. These two measurements would give the argon-40 to argon-39 ratio necessary for the calculation of the radiogenic argon-40 content of the original mineral sample by the dilution method.

The validity of the application of the isotopic dilution procedure in these instances depends on the identity of behaviour of the argon-39 in the spike, and the radiogenic argon-40 in the mineral. After intermingling by melting there would be little question of this; but during pretreatment for removal of air contamination, or during heat-up to the melting point, there may be some uncertainty that the behaviour of the isotopes of argon will be the same in the different silicates. The property of importance would be the rate at which argon-39 diffuses from the artificial samples relative to the diffusion rate of radiogenic argon-40 in natural silicates at similar temperatures. Therefore, the diffusion constant D was used to measure the efficiency of the annealing of the structural damage produced by neutron bombardment, and for comparison of the diffusion of the various argon isotopes. The particles of the powdered and sized samples were assumed to be spheres of effective radius a, and diffusion was evaluated as D/a^2, thus including the particle size factor and eliminating the uncertainties in its determination. This function could be calculated from the fraction of argon removed during a heating treatment according to well-established models for the solution of the Fick diffusion equation[4].

The heating for diffusion measurements was carried out in the extraction system at temperatures between 500° and 1,000° C for known periods of time. The gas removed was spiked, purified and measured with the inert gas mass spectrometer as was done for total argon determinations. The diffusion values calculated from these measurements are shown in Fig. 1, Section *a*. It will be noted that the diffusion of argon-39 in the artificial samples was the same, within experimental error, as that of radiogenic argon-40 from the natural glasses and microcrystalline rock (dolerite) measured during this work. It can also be seen that there is little significant difference for the diffusion of atmospheric argon-40, despite the intuitive assumption that this argon would be held on surfaces or in microcracks, and would be released at an entirely different rate.

The release of gas on crushing was also investigated in a similar manner. If we assume that the rate-limiting step for the release is the desorption of gas from the surface newly exposed by crushing[5], we may again use the D/a^2 function as a convenience in plotting. D is now a desorption coefficient for the gas leaving the newly exposed surface and a is the radius of the particles resulting from the crushing. We can also plot this as a function of the temperature at which the crushing was conducted. This has been done as shown in Fig. 1, Section *b*. We note that there is little dependence on temperature for gas removal by this process, particularly for the air argon-40. Evidently the rate of removal depends mainly on the rate at which new surface is exposed; in other words, on the efficiency of the crushing process. Most significant is the similar desorption coefficients of radiogenic argon-40 and argon-39, and the dissimilarity in the coefficient for air argon-40 release from these same substances. Again using the analogy with diffusion release, the 'half-life' for removal of a gas is equal to 0·03 a^2/D for particles assumed to be spherical[4]. For air argon-40 removal in this particular crushing machine this is about 80 h, as opposed to 8,000 h for the other argon isotopes. One can be optimistic, then, that these can be decreased to such a value as would make it possible preferentially to remove the air argon-40 contamination within a reasonable time by improvement in the design and efficiency of the vacuum crushing device.

○, ^{40}Ar$_{\text{radiogenic}}$; ×, ^{40}Ar$_{\text{air}}$; □, ^{39}Ar

Using the method of isotopic dilution with argon-39, measurements of the radiogenic argon-40 content of two test materials were made (Table 1). These samples were a young volcanic glass (*KA*-40) and a very old pegmatite muscovite mica which represented extremes in mineral types and argon contents. Both samples were kindly supplied by W. A. Bassett, as were the results for the conventional analyses of the mica. For the argon-39 spiked samples each group represents fractions from a single sample while heating at the temperatures indicated, with or without crushing. The results show order-of-magnitude agreement. The poor agreement, both in precision and accuracy, seems to be a result of the very small gas samples being handled and measured.

For these measurements rock and silicate samples were taken of such a size as to be handled conveniently in

Table 1. Volume of Radiogenic Argon-40, Standard c.c./g of Sample

	Argon-39 spike heating only	Argon-39 spike crushing	Argon-38 spike conventional
Volcanic glass *KA*-40	1·67, 1·79 × 10^{-7} (500°) 6·38 × 10^{-7} (melt)	1·87 × 10^{-7} (250°) 2·53, 1·36, 5·74, 4·90 × 10^{-7} (500°) 1·43, 1·47, 4·11 × 10^{-7} (500°)	2·12, 2·23 × 10^{-7} (melt)
Muscovite mica	1·45 × 10^{-5} (melt) 0·71 × 10^{-5} (melt)	1·09, 3·68 × 10^{-5} (500°)	1·76, 1·85 × 10^{-5} (melt)

existing equipment, with little regard for optimum size of the radiogenic argon samples. Natural glasses are probably most like the spike-containing artificial glass in pertinent properties, such as argon diffusion, but unaltered samples suitable for age determinations are of young ages, hence low in radiogenic argon. For radiogenic argon gas samples in this low range of about 10^{-7} standard c.c., the standard deviation for measurement in the instrument used, without electron multiplier, was about 20 per cent. By the nature of the technique described here, fractional gas samples were taken which varied from 1 to 60 per cent of the total gas, so that the results obtained with these, in turn, exhibited corresponding lower precision. Also, for a material structurally as different from the spike-containing artificial glass as is the mica, the discrepancy observed here was not surprising.

It is believed that the measurements with these two samples were encouraging, but were an insufficient test of the method. As yet, unfortunately, no opportunity has been available to repeat the measurements with equipment designed to give radiogenic argon samples of a size more suitable to this technique. At present, the technique of measurement, using the radioactivity of the samples as described here, is under investigation.

I thank Oliver A. Schaeffer for assistance and other members of the geochemistry group, Chemistry Department, Brookhaven National Laboratory, where this work was done, for discussions.

This research was performed under the auspices of the U.S. Atomic Energy Commission.

INTRINSIC ELECTRIC STRENGTH OF POLYTHENE

By Dr. R. COOPER, C. H. ROWSON and D. B. WATSON

Department of Electrical Engineering, University of Manchester

RECENT experiments[1] with sodium chloride and potassium bromide single crystals have shown that their intrinsic electric strengths decrease slowly with increase in specimen thickness, and also that there are statistical time-lags. The average time-lag decreases rapidly with over-voltage, and it depends on the cathode material—but the electric strengths are independent of this. The foregoing are characteristics of the single electron avalanche breakdown mechanism[2]. The collective electron theories[3], which predict electric strength independent of specimen thickness, cannot apply to these materials. The intrinsic electric strengths of solid dielectrics have previously been considered independent of thickness of the specimen[4] provided this exceeds a few electron mean free paths; but in fact the possibility of there being a small effect is not completely excluded by the available evidence. Measurements made with comparable specimens usually yield appreciable variance of electric strength. A small rate of decrease of electric strength with increase in specimen thickness cannot be established for statistical reasons unless great numbers of specimens are used, or the range of thickness is great. Examination of the literature shows that these conditions seldom have been satisfied, and the question of whether or not the intrinsic electric strength of solid dielectrics depends on specimen thickness needs to be re-opened.

Statistical time-lags have previously been observed[5] in the breakdown of polythene; but, according to Oakes[6], the electric strength is independent of specimen thickness. This conclusion is based on the comparison of a group of specimens with thicknesses between 0·0005 in. and 0·002 in., and a group having thicknesses between 0·002 in. and 0·008 in. However, close inspection of Fig. 7 of ref. 6 suggests that this conclusion is false. In this diagram, breakdown voltage is plotted against thickness for specimens of grade 20 polythene at room temperature. There is a difference in the slopes of the lines which best fit the points at the two extremities of the range of thickness. A detailed analysis of Oakes's measurements yields the following results. There were 41 specimens in the thickness range 0·002 in.–0·008 in. and of these 22 exceeded 0·005 in. The mean electric strength of these 22 specimens was 16·2 MV in.^{-1} and the variance was 1·51 $(\text{MV in.}^{-1})^2$. Values of electric strength were also obtained for 40 specimens of the same grade of polythene in the thickness-range 0·0005–0·002 in. The mean electric strength was 17·8 MV in.^{-1} and the variance was 1·53 $(\text{MV in.}^{-1})^2$. The probability of the difference between the means of the two groups being due to chance variations in the samples is shown, by application of Student's t test, to be less than 0·1 per cent.

We have sought confirmation of the thickness effect by measuring the electric strength of 'Alkathene 7' in the thickness-range 0·001–0·018 in. The specimens were of the plane-recess type, prepared by moulding in a manner similar to that described by Oakes[6], and as in his experiments the electrodes were of colloidal graphite. The diameter of the recess was 3/8 in. for specimens less than 0·006 in. thick, but it was increased to 1 in. for the thicker specimens in order to ensure adequately uniform field at the base of the recess. In Oakes's experiment, the voltage was increased at the rate of about 300 V sec^{-1} until the specimen broke down; in the present investigation a series of 1 : 8,000 μsec voltage impulses was applied to each specimen of thickness less than 0·006 in. and a series of 1 : 120 μsec impulses to the thicker specimens. (The wave-front of 1 : 8,000 μsec impulse increases from 10 to 90 per cent of peak value in 1μsec and the tail decays to half-peak value in 8,000 μsec.) In both cases the amplitude of each impulse exceeded that of its predecessor by 3 per cent. An independent experiment was performed using specimens of thicknesses between 0·002 in. and 0·004 in. which established that the average electric strength was the same for both voltage wave-forms. The results of the experiment is illustrated by Fig. 1 in which electric strength at 20° C is plotted against specimen thickness on a logarithmic scale. The best straight line drawn through the 128 points obeys the law $E = 12{\cdot}8 - 3\ (\log_{10} t)$ where E is in MV in.^{-1} and t is in units of 10^{-3} in. The product moment correlation coefficient is $-0{\cdot}79$, and the probability of this occurring by chance is less than 10^{-3}. The thickness effect present in Oakes's observations is therefore confirmed. The mean electric strength obtained with impulse voltages is, however, only about 80 per cent of the corresponding value obtained by Oakes using slowly increasing voltages. This effect does not appear to be due to the use of different grades of polythene, or to faults in the specimens used for the impulse tests, or to systematic errors in the measurement of voltage and thickness.

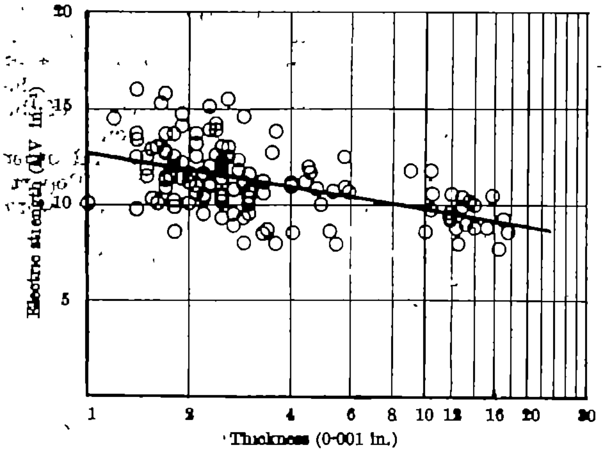

Fig. 1. Electric strength of polythene at 20° C

Measurements using our equipment yielded maximum, average and minimum values of respectively 15·2 MV in.$^{-1}$, 12·7 MV in.$^{-1}$ and 10·6 MV in.$^{-1}$ for the impulse electric strength of 8 specimens of 'Alkathene 7' of thicknesses between 3·5 10^{-3} in. and 4·5 10^{-3} in. The variance was 3·0 $(\text{MV in.}^{-1})^2$. Corresponding values obtained from a group of seven similar specimens tested with slowly rising voltages were 16·8 MV in.$^{-1}$, 15·3 MV in.$^{-1}$ and 12·8 MV in.$^{-1}$. The variance was 1·6 $(\text{MV in.}^{-1})^2$. The difference between the means is significant at the 1 per cent level. Oakes used seven specimens of grade 20 polythene in the above range of thickness. The maximum, average and minimum values of electric strength were respectively 18·3 MV in.$^{-1}$, 16·1 MV in.$^{-1}$ and 13·1 MV in.$^{-1}$, and the variance was 3·0 $(\text{MV in.}^{-1})^2$. The difference between the mean values of 15·3 MV in.$^{-1}$ and 16·1 MV in.$^{-1}$ obtained with slowly increasing voltages is not significant. The cause of the impulse effect is not known but the mean impulse electric strength was also found to be about 80 per cent of the mean value measured with slowly increasing voltage at − 74° C and − 195° C. This fact seems to eliminate an explanation involving the mechanical properties of the material since these change appreciably when polythene is cooled from about 20° C to − 195° C.

An investigation of the influence of cathode material on the mean statistical time-lag at 20° C was made using groups of not less than 50 specimens of 'Alkathene 7'. The specimen thicknesses were within the range 0·002–0·004 in. The voltage-wave rose to its peak value in 0·3 μsec and remained within 1 per cent of this for the subsequent period of 5 μsec. Mean statistical time-lags of 0·9 μsec and 0·5 μsec were obtained using 1 per cent voltage increments and cathodes respectively of colloidal graphite and vacuum-evaporated aluminium. When the voltage increment was 3 per cent the mean time-lag was 0·5 μsec for specimens with graphite cathodes. The difference between the comparable mean statistical time lags of 0·9 μsec and 0·5 μsec is appreciable, but because of the great variance it is barely significant. The experiment was repeated using similar groups of specimens prepared from a fresh supply of 'Alkathene 7', but the mean time-lag for graphite electrodes was about 20 times the value already quoted and the mean electric strength was about 5 per cent less, so that combination of the two sets of results cannot be justified.

The mean electric strength of alkali halide crystals does not depend on the cathode material but Oakes[6] observed a small effect with polythene. In the present experiments mean electric strengths were obtained of 12·4 MV in.$^{-1}$ when the cathodes were of colloidal graphite and 11·2 MV in.$^{-1}$ when they were of evaporated aluminium. The difference between these mean values is significant at the 0·1 per cent level. The specimens were those used for time-lag studies with 1 per cent voltage increments at 20° C. A cathode effect may be accounted for plausibly by assuming the formation of electronic space charge. The possibility of this depends on the magnitude of pre-breakdown current, electron mobility and density of traps, and little is known about these quantities in polythene. If space charges form, the basic assumption of uniform electric field is of course invalid.

We thank Mr. W. G. Oakes, of Imperial Chemical Industries, Plastics Division, for his co-operation in providing records of his experiments and Mr. W. Reddish of the same organization for assistance with the supply of 'Alkathene 7'.

INVESTIGATION OF SMALL CYCLIC STRAINS BY ETCH PITS AT DISLOCATION SITES

By ALWYN H. KING

Materials Research Section, Research and Development Division,
Arthur D. Little, Inc., Cambridge, Mass.

Of the several methods at present available for the more or less direct observation of dislocations, the chemical etching technique is the simplest and most versatile for those materials for which it is appropriate. The development by Livingston[1] and Young[2], independently, of etchants capable of revealing dislocation sites on copper single crystals has extended the scope of this technique greatly, and should lead to an increased understanding of the important dislocation mechanisms involved in the deformation of face-centred cubic materials.

This article describes some of the preliminary results of an investigation in which chemical etching is being used to study dislocation densities and arrangements in face-centred cubic metals in the early stages of cyclic deformation at very low stress amplitudes. The materials used are copper and α-solid solution copper–aluminium alloys, chosen because available evidence[3,4] indicates a definite relationship between free-electron concentration and stacking fault energy within the α-range of this type of alloy system. Since much of the recent work on fatigue in crystalline materials stresses the importance of cross-slip in the development of a fatigue failure[5-7], the stacking fault energy should be an important parameter in determining the fatigue behaviour of face-centred cubic metals. We find, in fact, distinct differences in dislocation arrangement which can be related to stacking fault energy effects, even during the first few cycles of a fatigue test at a stress amplitude considerably less than the macroscopic yield as determined by single crystal tensile tests.

Annealed single crystals of pure copper and copper–aluminium alloys were cycled in a four-point reversed bending apparatus attached to a standard Instron tensile machine. The alloy compositions and maximum shear stress amplitudes on the primary slip system are given in Table 1. Livingston's (111) etchant was used in this investigation and, following the chemical polishing procedure described by Erdmann[2], was effective in producing dislocation etch pits in alloy crystals containing up to 14·8 atomic per cent aluminium. The axial orientation of the crystals was controlled during growth from the melt to ensure a predominance of slip on the primary system during cycling.

Table 1. STRESS AMPLITUDES IN CYCLIC BENDING

Composition	Critical shear stress (kg/mm^2)	Max. shear stress (cyclic) (kg/mm^2)	Stacking fault (ref. 3) energy (ergs/cm^2)
Cu	0·10	0·07	160
Cu + 2·7 Al	0·81	0·51	65
Cu + 5·3 Al	0·95	0 57	20
Cu + 14·8 Al	1·20	0·80	1–3

Some of the observations of interest, representative of the differences between pure copper and the alloys, are illustrated in Figs. 1–7. Differences in etch-pit arrangement among the alloys were very slight during the initial stages of cyclic strain at comparable stresses.

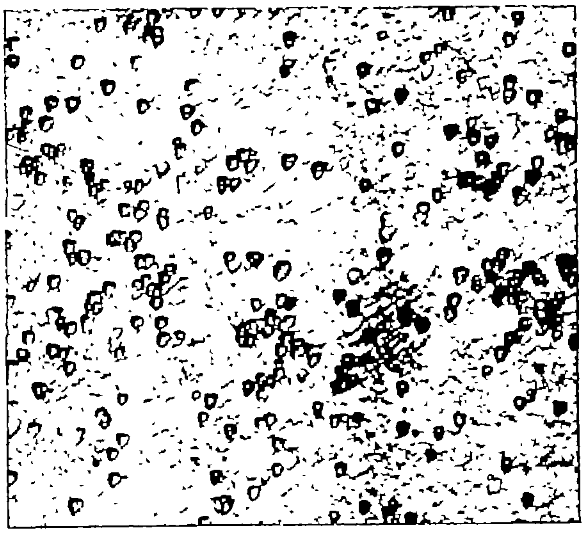

Fig. 1. 'As grown' dislocation arrangement in 99·999 per cent copper (× 135)

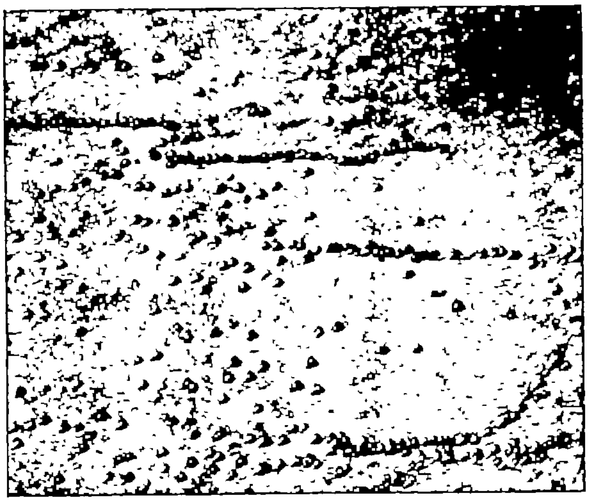

Fig. 2. 'As grown' dislocation arrangement in copper + 2·7 atomic per cent aluminium (× 135)

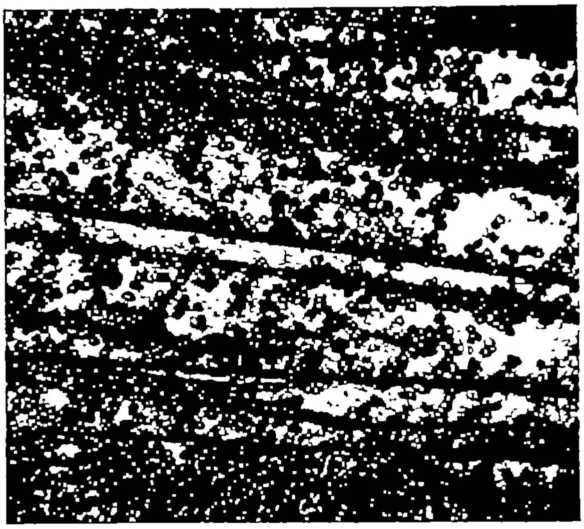

Fig. 3. Dislocations assembly at sub-boundaries after six alternate bending cycles in copper (× 67·5)

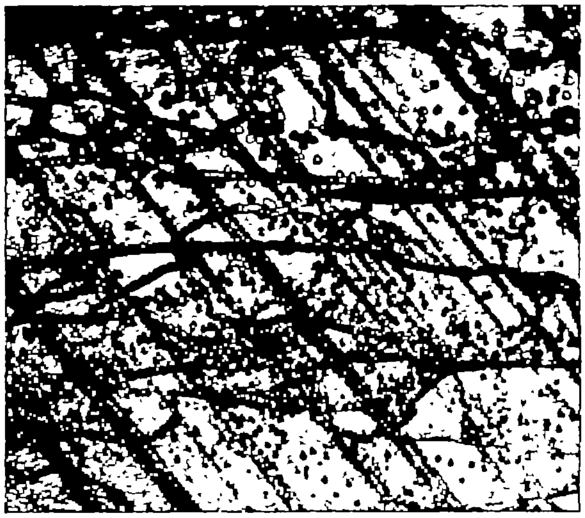

Fig. 4. Slip-band structure in copper–aluminium after six cycles of reversed bending (× 67·5)

Figs. 1 and 2 show the (111) faces of a copper crystal and a copper + 2·7 atomic per cent aluminium crystal, respectively, in the as-grown (annealed) conditions. No great difference in dislocation density is evident, both compositions showing between 10^5 and 10^6 etch pits/cm^2. The arrangement, however, is somewhat less uniform in the alloy, where the pits show a greater tendency to line up in the form of striations and subgrain boundaries. (This tendency becomes even more pronounced in the alloys of higher solute content.)

After 6 cycles of reversed bending at a maximum shear stress of 70 g/mm^2 in the copper specimen, a general increase in dislocation density has occurred, and rather diffuse and regularly spaced slip lines have formed. The etch-pit picture in Fig. 3 illustrates this arrangement quite clearly; a comparison with the more pronounced slip-band structure of Fig. 4 suggests a much greater restriction of the newly generated dislocations to their own slip planes in the alloy, and more freedom of movement of both the grown-in and the new dislocations in the copper. There is an apparent 'assembling' of dislocations along sub-boundaries in the copper, whereas the pit density between slip bands in the alloy remains virtually un-

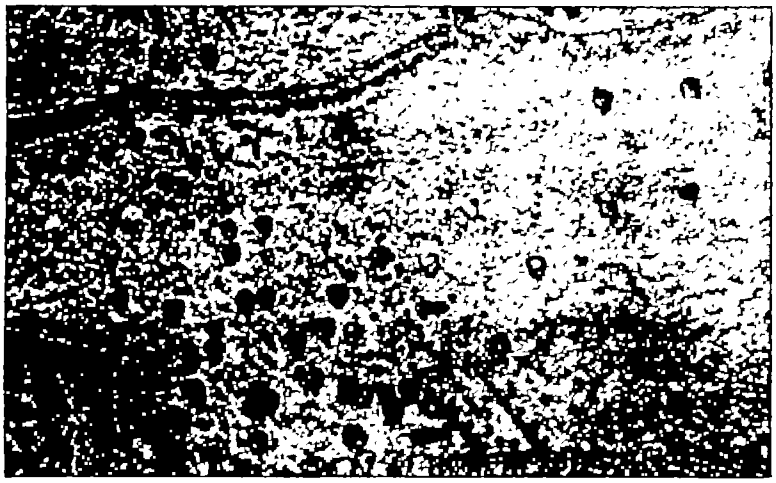

Fig. 5. Dislocation pile-ups in copper + 2·7 per cent aluminium crystal during reversed bending test at maximum shear stress of 0·51 kg/mm², after 3 cycles (× c. 225)

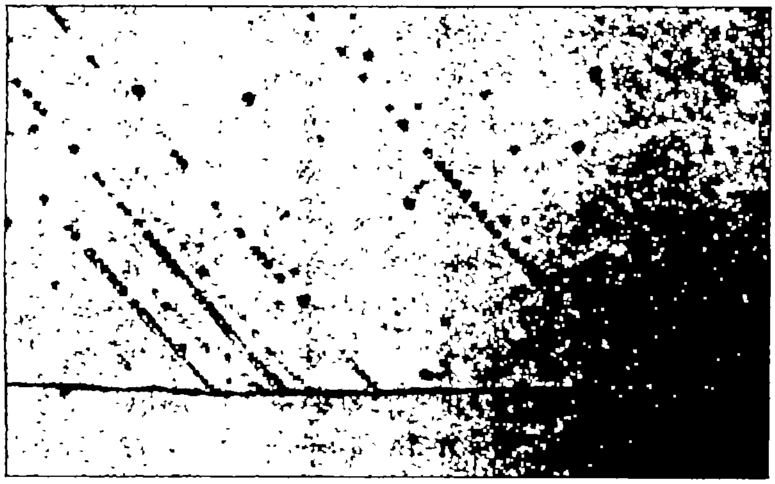

Fig. 6. Same as Fig. 5, after 15 cycles (× c. 290)

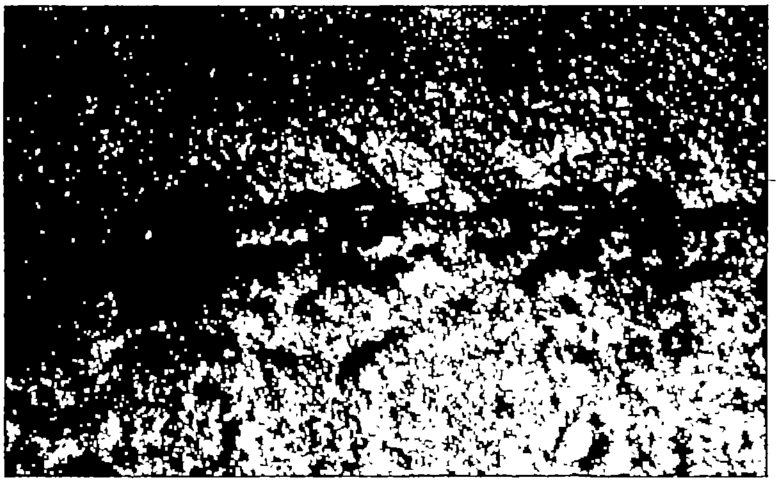

Fig. 7. Same as Fig. 5, after 40 cycles (× c. 200)

changed with increased cyclic strain. There is evidence of a limited amount of slip on secondary planes (the conjugate slip system) after six bending cycles in both the pure copper and the alloys.

Because of the restriction of the dislocations to their primary slip planes in the alloys, pile-ups at barriers such as striations and sub-boundaries have become quite numerous after as few as three cycles at a maximum shear stress of about two-thirds of the macroscopic critical shear stress (Figs. 5, 6 and 7). A study of a large number of these pile-ups indicates that they are in a relaxed condition and consist of small groups of equally spaced dislocations at intervals along the slip plane. It appears that, on release of the applied shear stress, the dislocations tend to run back toward the source, finally arriving at an equilibrium distribution of small groups bounded by minor obstacles on secondary slip planes. The average spacing of these obstacles (about 12 microns) indicates a density of about 7 × 10^5/cm², in reasonable agreement with the original dislocation density in the unstrained specimen. No significant decrease in this spacing is evident within the first 40 cycles of reversed bending.

Etch-pit distributions and densities have been observed at intervals up to a total of 100 cycles of bending. There is little change in the patterns illustrated here between the 6th and 100th cycles. In the alloy crystals the slip bands become more densely populated and somewhat more closely spaced with increased cycling. Some evidence of glide polygonization is apparent at about 100 cycles in the copper specimens, corresponding to a total cumulative strain of about 0·003.

These experimental results reveal significant differences in dislocation behaviour between a pure metal and an alloy of face-centred-cubic structure even in the very early stages of cyclic straining. The observed differences, including the increased pinning effect in the alloys, are in general agreement with a previous suggestion based on tensile test data, namely, that initial hardening of alloys of low-stacking fault energy is largely attributable to a Suzuki-type mechanism wherein solute atoms are concentrated at stacking faults because of their higher solubility in the hexagonal phase[8].

The apparent restriction of the dislocations in the alloy crystals to their own slip planes is thought to be a direct result of the decrease in stacking fault energy with alloying; the more homogeneous increase in dislocation density in pure copper should result in a more rapid initial work-hardening rate (as observed in tension tests) and conceivably a more rapid approach to saturation hardness, with crack initiation at smaller total strain. The limited data available in the literature are in apparent agreement[9,10]. In both tensile and fatigue tests less source activation on secondary slip systems is apparent in the alloys, which is probably due to a latent hardening of secondary slip planes by the intersecting dislocations of primary slip.

The frequent occurrence of pile-ups observed in the alloy crystals at these small strains was somewhat unexpected and lends support to present-day theories that stress the importance of pile-ups in the later stages of hardening.

A more quantitative analysis of these results and the extension of this investigation to include fatigue tests to failure at various stress-levels and distributions is in progress and will be the subject of a later report.

This work represents a portion of an investigation of the mechanism of rolling contact fatigue, supported by the American Society of Mechanical Engineers Research Committee on Contact Fatigue of Rolling Elements.

CÆSIUM-137 FROM FALL-OUT IN HUMAN MILK

By A. ÅARKROG

Health Physics Department, Danish Atomic Research Commission, Research Establishment, Risö, Roskilde

IT is well known that in human milk the ratio between strontium-90 and calcium is lower than in the diet of the mother[1]. Only sparse information exists as regards a comparison of the contents of cæsium-137 (the other long-lived biologically significant fission product) in a mother's milk and in her diet. Several animal experiments have been performed by Wasserman, Comar and Twardock[2] and have shown that the ^{137}Cs/K ratio in goats' milk is 1·4 based on a dietary ^{137}Cs/K ratio of unity.

The following measurements were performed with milk from a primipara 24-year-old Danish woman, who bore a child October 15, 1961. The milk was collected daily during the period November 1, 1961–September 10, 1962. Until the last half of August 1962 the daily mean production of milk was about 1¼ l.; of this, about ¾ l. per day was consumed by her baby; the rest was obtained for analyses. The milk used for analyses was identical to the milk used for the feeding of the baby, as the mother drew out all milk before each feeding and fed the baby from a feeding-bottle. Most of the daily samples were dried and ashed (at 400°–450° C), and the ash was bulked into monthly samples before measurement. These ashed samples have been measured in a 3 in. × 4 in. well-type sodium iodide (Tl) crystal (Harshaw) with a 50-ml. well. Several samples were, however, measured as fresh milk in a 1·6 l. can, which fits around a 3 in. × 3 in. sodium iodide (Tl) crystal (Harshaw). The pulses were analysed in a *TMC*256 channel analyser.

Table 1 shows the results of the monthly measurements and gives furthermore, for comparison, the levels of monthly collected dried milk samples from dairy cows living in the same part of the country as the woman.

Table 1 shows that the human milk (as well as the cows' milk) displays a variation in content of cæsium-137 with time. In the winter and in early spring, before the dairy cows started grazing, the human milk-levels were rather constant: 8·4 ± 0·5 pc. ^{137}Cs/g K. In May the level rose by a factor of nearly four, and in the following three months, June–August, the level was nearly constant: 34 pc. ^{137}Cs/g K. Already, in September, Danish dairy cows start to have an increasing amount of food other than grass, and the effect of this decreasing contribution from grazing was observed both in the human milk and in the cows' milk collected in September.

Table 1. CÆSIUM-137 AND POTASSIUM IN MILK

Sampling period	Human milk: pc. ^{137}Cs/g K	Human milk: g K/g ash	Cows' milk: pc. ^{137}Cs/g K
November 1–December 31, 1961	8·1	0·23	4·5
January 1–31, 1962	9·2	0·21	1·5
February 1–28, 1962	7·1	0·26	3·0
March 1–31, 1962	7·4	0·25	3·5
April 1–26, 1962	10·5	0·26	4·0
May 23–31, 1962	30·6	0·28	22·0
June 1–30, 1962	34·0	0·27	33·0
July 1–31, 1962	34·0	0·28	38·0
August 1–31, 1962	33·7	0·29	37·0
September 1–10, 1962	28·1	0·31	29·0

The relative *S.D.* due to the measurements of the human milk is less than 10 per cent.

As the content of cæsium-137 in the human milk appeared to be nearly constant in the period November–March (Table 1), and as the mother was on a regular diet in this period (1 kg dairy products, 0·15 kg grain products, 0·3 kg fruit and vegetables, 0·2 kg meat, fish and eggs, and 0·6 kg water as tea or coffee), it was anticipated that a steady state between the mother, her diet and her milk had been reached. The mother's diet and her milk were gathered for one week in March. The diet-sampling was performed by having the mother prepare double portions of everything she consumed in the week the experiment ran. The duplicates were put into a pail, which was sent to the laboratory. Six months later, in the beginning of September, the experiment was repeated, but unfortunately the milk-production was decreasing rapidly in this period, and after September 10 only very little milk was secreted. Table 2 shows the results from the two periods.

Table 2 shows that the ^{137}Cs/K ratio is higher in the donor's milk than in her diet. The ratios between cæsium-137 secreted by the milk and ingested with the diet are related to the amount of milk secreted. Thus the percentages of ingested cæsium-137 secreted per litre milk only differ slightly for the two experimental periods, March and September. As probable explanations for the relatively large differences between the observed ratios between milk and diet from the two months, beside the differences due to variation in milk production, one could mention that the daily average intake of potassium with diet in March was 2·8 g against 2·2 g in September, and that the concentration of potassium in the human milk from September was about 20 per cent higher than in the milk from March; but most important, that the September period was just before the end of the lactation period and thus could not be assumed as representing a steady state.

To get an estimate of how much and how long a time it would take for a single oral cæsium-137 dose given by the food to be excreted in the milk, 260 g of reindeer meat from Greenland was given to the milk donor on April 26. Lidén[3] has shown that reindeer meat has a relatively high cæsium-137 content, and thus is suited as a tracer in

Table 2. A COMPARISON BETWEEN THE LEVELS OF CÆSIUM-137 IN HUMAN MILK AND IN THE DIET OF THE DONOR

Sampling period	Sample	pc. ^{137}Cs/g K	pc. ^{137}Cs secreted daily in the milk	pc. ^{137}Cs ingested daily with diet	$\frac{\text{(pc. }^{137}\text{Cs/g K) milk}}{\text{(pc. }^{137}\text{Cs/g K) diet}}$	$\frac{\text{pc. }^{137}\text{Cs secreted}}{\text{pc. }^{137}\text{Cs ingested}}$	Ingested ^{137}Cs secreted per l. milk (per cent)
March 10–16, 1962	Milk	9·2 ± 0·2	6 ± 1	—	1·9 ± 0·1	0·43 ± 0·08	32 ± 6
March 9–15, 1962	Diet	4·9 ± 0·2	—	14 ± 1			
September 4–10, 1962	Milk	27·4 ± 1·5	9 ± 2	—	1·1 ± 0·1	0·17 ± 0·04	28 ± 7
September 3–11, 1962	Diet	24·2 ± 0·5	—	53 ± 5			

The error terms in the table indicate one *S.D.* due to the measurement.

Sampling period	pc. ^{137}Cs/g K	pc. ^{137}Cs/l.	Estimated ^{137}Cs content in the milk from the fall-out background: pc. ^{137}Cs/l.	Accumulated excretion in the milk corrected for fall-out background: pc. ^{137}Cs	Accumulated excretion percentage
April 27–29	220	97	4	372	4·5
April 30–May 2	93	42		524	6·3
May 3–5	60	33		640	7·7
May 6–8	65	28	5	732	8·9
May 9–11	55	25		812	9·8
May 12–14	44	20		872	10·5
May 15–17	48	23	14	922	11·1
May 18–22	30	14		922	11·1
May 23–31	31	15	15	—	—
June	34	16	16	—	—

The relative *S.D.* of the results due to measurements is less than 10 per cent.

human biological experiments. The total content of caesium-137 in the 260 g of meat was measured at 8,300 ± 55 pc. The milk was collected and measured (mostly as fresh milk) during the month following intake. Table 3 shows the results.

This experiment was complicated by the fact that the dairy cows in the part of the country where the milk donor is living began grazing about the middle of May this year and consequently the 'normal' caesium-137 content in the mother's milk increased by a factor of nearly 4 (Table 1) during the experiment. However, it is evident from the figures in Table 3 that about 7 per cent of the ingested dose of caesium-137 was excreted in the milk within the first week after the intake of the reindeer meat, and within a fortnight about 10 per cent was excreted by the milk. For dairy cows, it has been shown[4] that about 10 per cent of a single oral dose of radiocaesium will, in a 7 days collection period, be recovered in the milk.

The present investigation indicates that babies fed on human milk could be exposed to a greater caesium-137 body burden than if they were fed on milk from dairy cows, provided that the diet of the mother shows a greater (about 2–3 times) ^{137}Cs/K ratio than the cows' milk. It should be mentioned that the specific caesium-137 activity per litre cows' milk normally will be greater than in human milk, even if the ^{137}Cs/K ratio is greater in the human milk. This is due to the fact that the concentration of potassium in human milk is only about one-third the concentration of potassium in cows' milk.

NITROGEN METABOLISM OF AFRICAN CATTLE FED DIETS WITH AN ADEQUATE ENERGY, LOW-PROTEIN CONTENT

By R. C. ELLIOTT* and Dr. J. H. TOPPS

Department of Agriculture, University College of Rhodesia and Nyasaland, Salisbury, Southern Rhodesia

In recent years increasing interest has been directed at the protein requirements and nitrogen metabolism of ruminants kept under adverse nutritional conditions[1-3]. Much of this interest has been centred on the urea excretion of these animals[1-3], since ruminants can utilize urea for protein synthesis, and so any mechanism which they may possess to conserve urea is of prime importance. The work of Schmidt-Nielsen *et al.*[1] showed that the camel (*Camelus dromedarius*) excretes very small amounts of urea when deprived of water and fed diets low in protein. Schmidt-Nielsen and Osaki[2] have shown that the excretion of urea nitrogen by sheep kept on a very low crude protein diet is also low. More recently Livingston *et al.*[3] reported a reduction in the amount of urea nitrogen excreted by *Bos taurus* and *Bos indicus* cattle fed rations progressively decreased in crude protein-level and which were also deprived of water.

Studies in this laboratory on the basal nitrogen catabolism and protein requirements of African cattle have shown that low urea nitrogen excretion may be related to the energy as well as the protein content of the ration. Concomitant work has shown also that steers fed rations with an adequate energy content appear to utilize dietary nitrogen much more efficiently than previously recorded. These experiments and the results are briefly described in this article. The nitrogen metabolism of the animals concerned was examined by means of balance trials and the determination of the percentage distribution of nitrogen in the urine.

Twelve Afrikander steers and twelve Mashona steers (a local indigenous breed) were used in the trials. Each breed comprised three groups of four animals aged approximately one, two and three years respectively. Four different rations (crude protein contents 5, 7, 9 and 11 per cent) were fed to each group with the treatments arranged factorially. The rations were formulated to be approximately iso-caloric and consisted of 60 per cent concentrates (a mixture of molasses, cassava, maize and cotton-seed cake) and 40 per cent roughages (lucerne and Rhodes grass hay). The variation of crude protein content was obtained by adjusting the relative amounts of cassava and cotton-seed cake in each feed. The feeds were milled, mixed and cubed so it was impossible for any of the animals to select the more palatable components of the diet. The amount of feed offered to each animal was related to its body-weight and based on the finding of Blaxter *et al.*[4] that the voluntary feed intake of ruminants is directly related to $W^{0.73}$. The actual weight of feed offered (in lb.) was equal to $0 \cdot 152\ W^{0.73}$, where W was the live-weight of the animal in pounds.

In general, the feeds were readily eaten, and only very small mounts of waste were recorded except with the 5 per cent crude protein ration, where feed refusals were appreciable. Access to water was provided at all times. Each nitrogen balance trial consisted of a ten-day preliminary period followed by a seven-day collection period, when total fæcal and urinary collections were made. The total nitrogen intake, fæcal excretion and urinary excretion of each animal was determined for the seven-day collection periods. In addition, the urine samples were analysed for urea, ammonia, creatinine, uric acid, allantoin and hippuric acid content. In every nitrogen balance trial all the 24 animals retained nitrogen, that is, were in positive nitrogen balance. This indicates that the amount of nitrogen supplied was always in excess of the animals' maintenance requirements. The apparent nitrogen digestibility of the feeds did not vary to any significant extent with the age or breed of the animal. The detailed results of these two aspects of the work, together with the feed consumption of the cattle as a function of body-weight, will be presented in another communication.

---

* Seconded from the Federal Ministry of Agriculture.

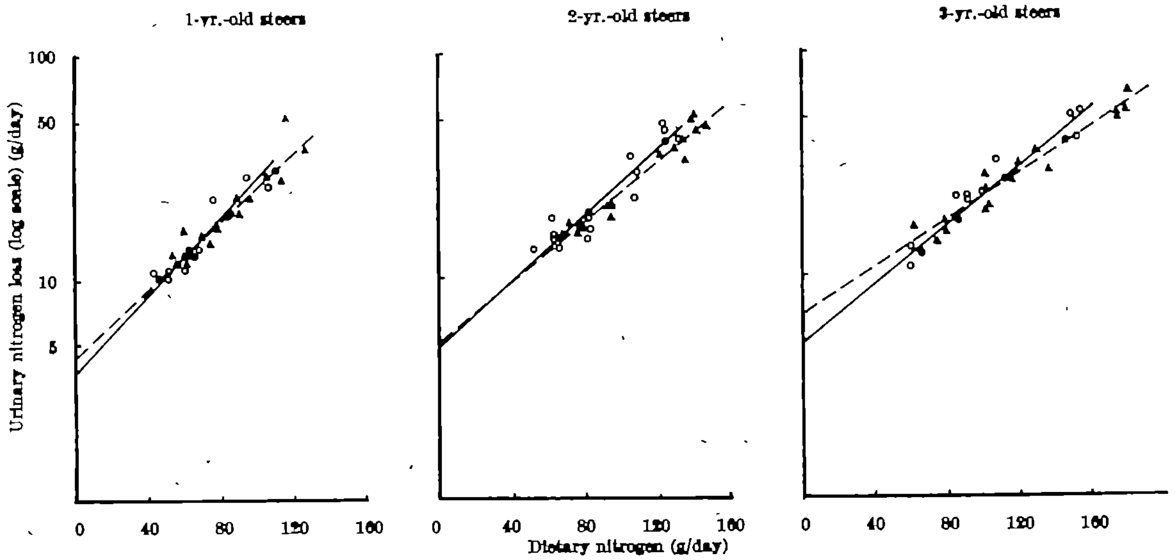

Fig. 1. Urinary nitrogen loss as a function of intake of nitrogen of six groups of African cattle. ○, Mashona; △, Afrikander

In Fig. 1 the logarithm to the base ten of daily urinary nitrogen excretion is plotted against the total dietary nitrogen for each animal in the six breed/age groups. For all groups there is a very high correlation between the two sets of values and the relationship in each case is apparently linear. Extrapolation to zero nitrogen intake gives an estimate of endogenous nitrogen catabolism of the cattle of varying body-weight under trial. These estimates are given in Table 1 together with the mean body-weights of the four animals in each group and the endogenous nitrogen calculated from the following well-used relationship of Brody[7]. Endogenous nitrogen equals 146 $W^{0 \cdot 72}$, where it is expressed in milligrams per day, and W is the body-weight of the animal in kilograms. Examination of the values in Table 1 shows that the endogenous nitrogen obtained is approximately 50 per cent of that given by the Brody relationship.

Table 1. MEAN BODY-WEIGHTS AND ENDOGENOUS NITROGEN (E.N.) CATABOLISM (DIRECTLY ESTIMATED AND CALCULATED USING THE BRODY FORMULA) FOR THE SIX GROUPS OF STEERS

Animal	Mean weight (kg)	E.N. estimated (g/day)	E.N. (Brody) (g/day)
1-yr.-old Mashona	242·9	3·91	8·06
1-yr.-old Afrikander	284·5	4·44	9·03
2-yr.-old Mashona	341·0	4·95	10·31
2-yr.-old Afrikander	401·9	5·06	11·62
3-yr.-old Mashona	394·3	4·96	11·46
3-yr.-old Afrikander	484·5	6·80	13·32

The results of the distribution of nitrogen in the urine of the 24 steers, which are detailed in Table 2, may be summarized as follows. A progressive reduction in the crude protein content of the ration produced a decrease in the amount of urea, ammonia, uric acid, hippuric acid and, in general, allantoin excreted. Creatinine excretion was fairly constant and not affected by a decrease of nitrogen intake. It was, however, closely related to the body-weight of the animal, which agrees with the conclusions of Brody[7]. The largest relative decrease was shown by urea. During the periods of feeding the 5 per cent crude protein ration the urea excretion of the steers was 3 per cent or less of their output on the 11 per cent crude protein feed. In fact, the decrease of urinary nitrogen with protein-level of the ration was mainly due to this declining output of urea.

11	62·9 ± 6·25	5 79	50·97	7·85	3·80	2·66	23 70	5 22

*Mean values for 16 animals.

From Table 3, it will be seen that urea is only a minor constituent while allantoin is the major nitrogenous constituent of the urine during the periods of lowest nitrogen intake. Table 3 also lists the mean biological values of the protein in the four diets as a measure of the efficiency of protein utilization by the 24 steers. The biological values were calculated by the Thomas–Mitchell method using the values obtained for metabolic faecal nitrogen (0·366 g nitrogen per 100 g of dry matter intake) and endogenous nitrogen (endogenous nitrogen in mgm = 95·6 $W_{\text{kgm}}^{0\cdot 675}$). A reduction in biological value as the protein-level was increased is apparent from the results. Further, it is interesting to note that the highest biological values are obtained when the urea excretion is low and the amount of allantoin excreted relatively high.

Two important conclusions may be drawn from the results of the trials. The two breeds of African cattle studied appear to have a low endogenous nitrogen catabolism. This suggests that their protein requirements for maintenance are also low, which supports the recent work of Elliott[5]. In addition, many people from field observations have suggested that indigenous cattle in Central Africa are better adapted to withstand a deficiency of protein than exotic or introduced cattle. It is possible that this adaptation may be manifested in a reduced protein requirement for maintenance. Secondly, cattle fed diets with an adequate energy but very low protein content excrete very small amounts of urea. Reasons for this low excretion are suggested by the work of Chalmers *et al.*[8] and that of Somers[4]. The former workers found that ruminal production of ammonia, the precursor of urea, is low when the diet fed contains adequate energy in the form of available or readily fermentable carbohydrate. Somers concluded that in sheep the return of nitrogen as urea to the rumen by the saliva is likely to be quantitatively important when the intake of nitrogen is low. If both these mechanisms are operating it is reasonable to deduce that the excretion of urea in the urine will be very small.

The results of the trials also showed that the most efficient protein utilization was associated with low urea excretion or alternatively a high percentage of the nitrogen in the urine present as allantoin. The ratio of urea nitrogen to allantoin nitrogen in the urine may be a useful index of protein utilization by the ruminant.

REPRODUCTIVE PERFORMANCE OF FEMALE MINIATURE SWINE INGESTING STRONTIUM-90 DAILY

By R. O. McCLELLAN, M. E. KERR and L. K. BUSTAD

Biology Laboratory, Hanford Laboratories, General Electric Co., Richland, Washington

A LONG-TERM investigation designed to determine the biological effects of daily strontium-90 ingestion in miniature swine has been in action here since 1958. The ultimate objective of the work is to provide data which will assist in evaluating the hazards of dietary strontium-90 for man or his progeny. The animals being used in these investigations are Pitman–Moore miniature swine which have a mature weight of 60–80 kg[1]. The dietary requirements, gastrointestinal tract, and bone mass of miniature swine are quite similar to man. These factors, along with a relatively long life-span, dictated their use in this work.

In considering the long-term effects of any toxic agent, one area of concern is the influence on the reproductive performance of the individual. As shown by the large amount of pertinent data presented at a recent conference on this subject[2], an extensive amount of work has been done on the effects of radiation on reproduction. For the most part, this work was performed on the smaller, commonly used laboratory species. Almost without exception, these experiments have utilized external whole-body γ-, neutron- or X-irradiation. This article summarizes some data on the reproductive performance of a large animal where the source of radiation is internal.

The basic experimental procedure as applied to each level of radionuclide feeding is shown in Table 1. A more detailed description of the experimental design and the procedures utilized has been presented elsewhere[3]. Feeding levels used are 0, 1, 5, 25, 125, 625 and 3,100 μc. of strontium-90 per day. At the two highest levels, the basic experimental procedure is not completed because of the early death of the original females and/or their offspring.

All animals are maintained in group housing, which is equipped with individual feeding facilities to control dietary intake. Strontium-90 is administered each day in a single large feed pellet with the morning aliquot of the ration.

Table 1. BASIC EXPERIMENTAL PROCEDURE

Original females	^{90}Sr feeding initiated at 9 months of age. Breeding to control male initiated at approximately 9·5 months of age.
F_1 generation	^{90}Sr available in utero via placental transfer; suckling period via the dam's milk; 6 weeks to 3 months of age, ^{90}Sr fed at one-quarter the dam's level; 3–6 months of age, ^{90}Sr fed at one-half dam's level; 6 months of age ^{90}Sr fed at dam's level. Breeding to control male begun at 9 months of age.
F_2 generation	Same procedure as F_1 generation, except animals are not bred.

All females scheduled for breeding are checked daily with a vasectomized male to determine if they are in oestrus. Bred females are removed from group housing to individual farrowing pens approximately one week before they are due to farrow. All offspring are weighed shortly after birth.

No apparent differences have been noted in the frequency and duration of the oestrus cycle or in the number of repeat breedings. Difficulties associated with parturition have been minimal in all groups.

Table 2 summarizes birth data on all litters born on the main strontium-90 experiment. No differences in litter size are apparent at levels up to 25 μc. ^{90}Sr/day. The differences which are seen at the 125 μc. and 625 μc.

Table 2. LITTER-SIZE AND BIRTH-WEIGHTS OF ANIMALS IN STRONTIUM-90 EXPERIMENT

	Adult level of ^{90}Sr feeding (μc./day)					
	0	1	5	25	125	625
No. of litters	10	45	19	22	6	2
Average litter size ± *S.D.*	5·6 ± 2·0	5·4 ± 1·5	5·2 ± 1·1	5·3 ± 1·7	4·0 ± 1·4	6·5
No. of offspring	56	242	98	117	24	13
Average birth weight in kg ± *S.D.*	0·73 ± 0·16	0·69 ± 0·15	0·75 ± 0·13	0·69 ± 0·13	0·71 ± 0·12	0·61 ± 0·14

^{90}Sr/day-levels may be real; however, insufficient numbers preclude definitive conclusions. No great differences in average birth weight are noted between levels. At the 625 µc. ^{90}Sr/day-level, there was a suggestion of change with one of the two litters born being of subnormal size, while the other was of normal size. Out of the litters (110) observed to date, only five offspring were stillborn, one control and two each at the 1 µc. and 5 µc. ^{90}Sr/day-levels; this is well within the normal range.

At the 3·1 mc. ^{90}Sr/day-level, the animals succumb at about 100 days after initiation of the feeding, which does not allow time for a term pregnancy. At the time of the death of the animals, developing fœtuses were observed. These fœtuses appeared to be of normal morphology and size. A blood sample obtained from one of these fœtuses was examined and exhibited normal values. Presumably, had the dam survived to term, viable offspring would have been born.

It can be generalized from the experimental data presented that for a large animal comparable in size to man, viable offspring of normal morphology will be born to females fed high levels of strontium-90 daily if the animals survive long enough to allow pregnancy to go to term. It should be recognized that the limited data presented here for higher levels might not permit detection of subtle changes in reproductive performance which would be readily apparent with a larger number of animals. In this regard, it is intended that a more comprehensive statistical analysis of the data will be undertaken when additional data are available for the higher feeding-levels.

These results are not surprising in view of the radionuclide under consideration and its metabolic and physical characteristics. Strontium, with a metabolic pattern analogous to calcium, concentrates almost exclusively in the osseous tissues of the animal. Further, strontium-90, with a half-life of approximately 28 years, decays with emission of a 0·54-MeV β-particle. Its daughter, yttrium, with a half-life of 64 h, decays with emission of a 2·27-MeV β-particle. The range of these β-particles in bone is not great, about 1 mm for the higher-energy β and about 0·2 mm for the lower energy; in soft tissue, the range is somewhat greater.

On the basis of these physical factors, it is readily apparent that in a large animal essentially all the radiation energy from absorbed strontium-90 would be released in bone or adjacent tissue. Furthermore, since the reproductive tissues are not contiguous to bone, the radiation dose from this source would be negligible. Perhaps the greatest source of radiation to the reproductive tissues of the female will be from unabsorbed strontium-90 in the gastrointestinal tract. Considering the thin wall of the gastrointestinal tract, the large percentage of ingested strontium-90 that is not absorbed (about 90 per cent in the adult), and the proximity of the ovaries to the gastrointestinal tract, this may be a significant source of radiation. Preliminary radiation dose measurements at the location of the ovary in an animal fed 3·1 mc. strontium-90 daily for about 100 days verified these assumptions.

Since the developing fœtus has the thickness of the uterine wall and the placental membranes and fluids between it and the gastrointestinal tract, it is doubtful if radiation originating from the gastrointestinal tract would be significant to the fœtuses. Undoubtedly, the greatest source of radiation to the fœtuses of a dam ingesting strontium-90 is the strontium-90 it incorporates into its own skeleton. The fœtuses have the advantage of the various discriminatory processes between the dam and her bone or plasma against strontium relative to calcium, and in addition have the further discriminatory process of the placenta. The overall effect is such that only about one-eighth as much strontium-90 relative to calcium is found in the fœtal bone as is found in the adult[4]. The radiation dose-rate to the fœtal bone reflects this discrimination, so that the average radiation dose-rate to the bone of a full-term fœtus at the 25 µc. per day-level is about 0·5 rad per day. Of significance, too, is that for earlier periods of fœtal life when ossification is less complete, the dose-rate would be much less. The same limitations of range of the β-particles that were pointed out for the adult animal apply to a considerable degree for the fœtuses, since at least in late stages in fœtal life, when ossification is progressing rapidly, the fœtuses have obtained considerable size.

It is well to point out, however, that the foregoing assumptions and the experiment so far only consider the effect of the radiation emitted by the strontium-90 on the reproductive tissues or fœtuses of the young adult swine. It is, of course, conceivable that if these females were bred later in life after a considerable radiation dose had been accumulated by the skeleton and associated tissues, the generalized debilitated condition of the animal might preclude normal reproduction or, possibly, if pregnancy were to occur, the associated stresses might jeopardize the life of the dam or offspring.

We thank W. J. Clarke, V. G. Horstman and J. R. McKenney, who were involved in the initiation of the study, for assistance, the biological technologists of the Experimental Animal Farm for care and handling of the animals, and the members of the Biological Analyses Operation for analysis of the various samples submitted.

This work was performed under Contract No. *AT*(45–1)–1350 between the General Electric Co. and the U.S. Atomic Energy Commission.

DETERMINATION OF THE PARTICLE WEIGHT OF SPHERICAL VIRUSES

By Dr. K. SCHMID* and Dr. H. M. MAZZONE

Laboratory of Protein Chemistry, Massachusetts General Hospital, Harvard Medical School, and Children's Cancer Research Foundation, Boston

RECENT advances in the sedimentation study of solutes resulted in the application of so-called short columns[1,2] which greatly reduces the time required to attain equilibrium conditions, especially for macromolecules. Further, the introduction of the Rayleigh interference optics permits the analysis of dilute solutions of the latter compounds[3]. This article describes the use of the Spinco analytical ultracentrifuge and the short-column method for the determination of the particle weight of plant viruses from sedimentation equilibrium conditions.

A Spinco model *E* ultracentrifuge equipped with Schlieren and Rayleigh interference optics and a rotor temperature control unit was used throughout these

M_e = particle weight obtained by sedimentation equilibrium.

studies. For the determination of the degree of homogeneity and the sedimentation coefficients of the viruses, rotor speeds between 12,590 and 35,600 r.p.m. were selected. A capillary type synthetic boundary cell and the interference optics were used for the measurements of the concentrations of the viruses. The rotor speed for these experiments was, initially, 7,000 r.p.m. and after 25 min was reduced to approximately 4,000 r.p.m. For the equilibrium runs carried out at very low revolutions the speed of the rotor could be satisfactorily controlled by using an *An-J* rotor, the weight of which is 22 lb. The average speeds were derived from the counter of the Spinco ultracentrifuge. The variation in speed amounted to ± 3 per cent. Again the Rayleigh interference optics was found advantageous as a means of recording the distribution of the virus in dilute solutions. The temperature of the rotor, although constant for each run, was in the range of 18°–28°. The calculation of the particle weights was carried out according to Richards and Schachman[8] using $c_b - c_m/c_0$ (Table 1) and also by the slope of the plot ln c versus x^2 (Fig. 1).

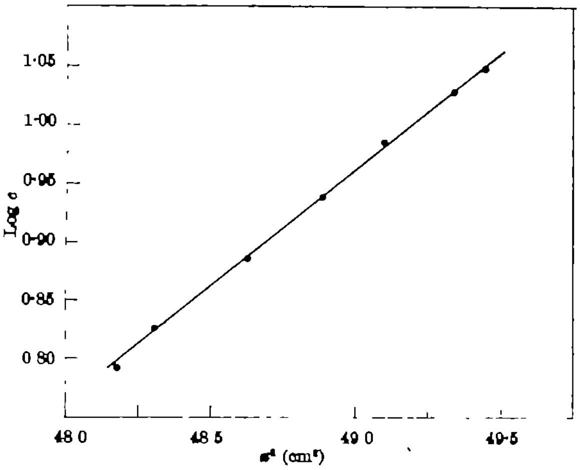

Fig. 1. Plot of log c versus x^2 from sedimentation equilibrium data for brome mosaic virus. The conditions of the experiment are given in Table 1

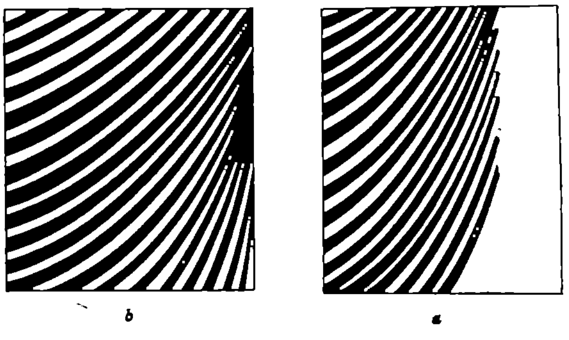
The following viruses were examined: turnip yellow mosaic virus (TYMV) and bushy stunt virus (BSV) (Dr. C. Knight, Virus Laboratory, University of California, Berkeley), brome mosaic virus (BMV) (Dr. M. Brakke, Department of Plant Pathology, University of Nebraska, Lincoln) and southern bean mosaic virus (SBMV) (Dr. W. C. Price, Department of Plant Pathology, University of Florida, Gainesville). On sedimentation velocity analysis these viruses, after dilution with 0·1 M sodium chloride to give a concentration between 0·2 and 2 per cent, appeared essentially homogeneous at the time of our experiments. The calculated sedimentation coefficients, corrected to standard conditions, were 98*S* (virus concentration 2·0 per cent) and 115*S* (0·3 per cent) for TYMV, 90*S* (1·0 per cent) and 91*S* (0·25 per cent) for BMV, 112*S* (0·7 per cent) for SBMV and 114*S* (2·0 per cent) and 131*S* (0·3 per cent) for BSV. These values are in good agreement with those reported in the literature[4-6,9]. TYMV, SBMV and BSV each contained a minor component which accounted for less than 1 per cent and the sedimentation coefficients of which were very similar to those of the viruses.

Table 2. ATTAINMENT OF SEDIMENTATION EQUILIBRIUM OF CERTAIN PLANT VIRUSES AS JUDGED BY THE CONSTANCY OF THE NUMBER OF FRINGES OF THE OPTICAL PATTERNS

Time of centrifugation (h)	No. of fringes SBMV	No. of fringes BSV
1	5·0	2·6
2	6·0	4·5
3	6·5	5·5
4	7·8	5·5
5	8·5	6·0
6	9·0	7·0
7	10·0	7·6
20	9·8	7·5

The conditions of centrifugation are given in Table 1.

The particle weights of the viruses investigated are given in Table 1 and are in close agreement with the known values. Further, the particle weight of BMV and BSV calculated from the slope of the plot ln c versus x^2 was found to be $5{\cdot}2 \times 10^6$ and $9{\cdot}4 \times 10^6$, respectively. For all determinations, rotor speeds between 1,000 and 1,300 r.p.m. and virus concentrations between 0·15 and 0·24 per cent proved to be optimal. A higher speed of 1,967 r.p.m. consistently resulted in accumulating virus material at the bottom, solvent-oil interface of the cell. A minute accumulation of virus at this interface could readily be detected by Schlieren and at low concentrations by the interference optics (Fig. 2). If solutions with concentrations above 0·35 per cent were analysed even at a speed of approximately 1,000 r.p.m., deposition of solute was again noted (Fig. 2). The observed height of the columns for the experiments reported in Table 1 was close to 1 mm. Under these conditions, equilibrium as judged by the constancy of the fringes of the optical patterns (Table 2) was obtained after 6–8 h of centrifuga-



b *a*

Fig. 2. Interference patterns from ultracentrifugation analyses of SBMV. The pattern on the right (Fig. 2*a*) was obtained by centrifugation of a 0·35 per cent solution of SBMV at 1,495 r.p.m. Accumulation of virus particles at the bottom of the cell is indicated by the loss of fringes in this section. If the virus concentration was decreased to 0·18 per cent but the analysis performed at the same rotor speed (Table 1) no accumulation of virus occurred at the bottom of the cell (Fig. 2*b*)

tion. However, all runs were continued for a total of 20 h to ascertain that true sedimentation equilibrium had been attained and that no material was deposited at the bottom of the cell. For the viruses studied the time for attainment of equilibrium derived from the equation of Van Holde and Baldwin[1] for a column height of 1 mm and an assumed F^{α}-factor of less than 1·0 would be less than 24 h. Thus, for the short-column method, if applied to macromolecules of the size and shape of those of the viruses investigated, the rotor speed should probably not exceed 1,400 r.p.m. nor the virus concentration be in excess of 0·25 per cent.

The first report of the particle weight of a virus derived from sedimentation equilibrium is probably that of McFarlane and Kekwick[15], who investigated BSV using a column of approximately 2 mm and a speed of 1,500 r.p.m. Equilibrium was obtained between 48 and 96 h and a value of $7·6 \times 10^6$ was calculated. Recently, Beams *et al.*[16], using a magnetically supported ultracentrifuge, briefly reported the particle weight of BSV and SBMV to be $7·8 \times 10^6$ and $6·3 \times 10^6$, respectively. Although the value for BSV obtained by Beams *et al.* agrees with that of McFarlane and Kekwick, there is a discrepancy between these values and the value reported herein. Determination of the particle weight by other methods such as light scattering[10], direct particle counting[11], sedimentation and diffusion[7–9], sedimentation and intrinsic viscosity[12] and X-ray scattering[13,14] yielded values from 8·9 to $10·6 \times 10^6$ with an average of $9·7 \times 10^6$, which agree well with our data.

We thank Drs. M. Brakke, C. Knight and W. C. Price for supplying the viruses.

DONOR AND HOST CONTRIBUTION TO SPLENOMEGALY IN HOMOLOGOUS MOUSE CHIMÆRAS

By IRMGARD M. ZEISS* and MILES FOX†

ANIMALS tolerating the presence of living homologous spleen cells in their organism may be described as 'homologous spleen cell chimæras'. Splenomegaly is a recognized phenomenon in the early stages of such chimærism. It is caused, or at least accompanied, by an immunological reaction of donor cells against their host, the so-called 'graft-versus-host' reaction. This may be concluded from observations in suitable donor–host combinations. Six relevant examples based on evidence published by Simonsen[1] and Michie, Woodruff and Zeiss[2] are summarized in Table 1. The apparent relation of the graft-versus-host reaction to splenomegaly, together with the fact that immunological reactions involve cell proliferation[3–5], suggests multiplication of donor cells as the direct cause of the spleen enlargement. Gorer and Boyse[6], in distinguishing between the host and donor component in chimæra mouse spleens by means of specific cytotoxic antisera, found that donor cells may constitute the vast majority of the total spleen cell population, which implies a considerable donor cell multiplication. However, the proportion of each component seemed to depend on the genetic relation of the host and donor strains used. Biggs and Payne[7] traced the donor cells in chimæra chick embryos by the sex chromosome difference, and found 44 per cent of the dividing cells to be of donor origin.

On the other hand, according to Davies and Doak[8], donor cells—if at all demonstrable—form a very small minority of the dividing cells in enlarged spleens of chimæric mice. Similarly, the analysis of mouse chimæra spleens by the discriminant spleen assay[9] nearly always revealed a donor cell minority[9]. Moreover, Howard, Michie and Simonsen[10] were able to show that in F_1 hybrid mice injected with spleen cells from a parent strain splenomegaly is mainly due to a host cell proliferation. The use of different test systems may to some extent account for the discrepancies in the various observations.

The evidence now seems to favour the view that at least in mouse chimæras splenomegaly is mainly due to host cell proliferation. But this does not rule out the possibility of a phase of intense mitotic activity of donor cells which must be expected to occur if the postulated immunological reaction does in fact take place. The present investigation was therefore designed to permit the detection of donor and host cell proliferation, even if one of these factors were relatively small. The study was based on the analysis of large numbers of dividing cells from chimæra spleens, utilizing the abnormally short chromosome pair of the *CBA*/*T*6 mouse as a marker for donor cells.

Induction of chimærism. Members of *A*-strain litters were injected intravenously within 24 h of birth with 15 million adult *CBA*/*T*6 spleen cells. Test animals and uninjected litter mate controls were killed 3, 5, 6, 7, 9 and 10 days after injection and their body and spleen weights recorded. These specimens formed the 'main experimental series', but in addition a one-day specimen and two specimens each for the second and sixtieth day after injection were available.

Chromosome preparation. The methods described by Ford and Hamerton[11] and Rothfels and Siminovitch[12] were combined and modified to allow analysis of a large number of dividing cells in each specimen. A detailed description of the procedure has been published elsewhere[13].

Evaluation of specimens. In all test and control preparations of the main series the number of metaphase nuclei

Table 1. PRESENCE OR ABSENCE OF SPLENOMEGALY IN DIFFERENT DONOR–HOST COMBINATIONS

	Recipients, strain and age	
Donor, strain and age	*A* new-born	(*B*/*C*) F_1 4–8 days old
B adult	splenomegaly	splenomegaly
A adult	no splenomegaly	no splenomegaly
B foetal	no splenomegaly	no splenomegaly

Splenomegaly only occurs if the donor is capable of reacting immunologically against the host, while the host is defenceless, or virtually defenceless.

$$* \text{Relative spleen weight} = \frac{\text{spleen weight} \times 1{,}000}{\text{body-weight}}$$

in 10,000 nuclei was counted, and in each of the chimæra preparations the chromosomes of 363–790 metaphase nuclei, mostly divided into batches of 100, were screened for the presence or absence of the marker chromosomes. Only those nuclei were included in the analysis in which at least 39 of the 40 chromosomes could be clearly distinguished. The reliability in typing metaphase nuclei was checked by 151 blind tests in pure preparations of *A* and *CBA/T*6 spleen cells. In the first 52 tests 6 out of 17 *A* cells and 2 out of 35 *CBA/T*6 cells were incorrectly classified. In the following 99 tests only 1 out of 62 *A* cells was filed in the wrong category, while all 37 *CBA/T*6 cells were correctly identified. There was thus a possibility of overestimating the number of donor cells in the test spleens. To avoid this pitfall all cells in the chimæra specimens which could not be classified with certainty were excluded from the analysis. Of those cells thought to be of donor type the position on the slide was noted and the cells were rechecked after the discernment had been re-sharpened by studying pure preparations.

In four instances the numbers of dividing donor cells were observed in 50–70 batches of 10 cells, which were later combined to make units of 100. In these specimens the frequency distribution of dividing donor cells was examined for its agreement with that expected in a binomial distribution. The observed data gave a satisfactory fit with those predicted and it was thus assumed that the distribution was in fact binomial. With large samples the binomial distribution very closely approaches the normal distribution. In this study, therefore, the mean number of dividing donor cells in a specimen and the 95 per cent confidence interval were estimated from the results in batches of 100 cells according to the formulæ for normally distributed items.

Splenomegaly. The basic requirement of the study—that all chimæras should show splenomegaly—was actually accomplished, as may be seen from Table 2. It seems convenient and permissible for judging the significance of the spleen enlargement to adopt the standards elaborated by Michie, Woodruff and Zeiss[4], because the *A*-strain recipients of the present experiment were derived from one of the colonies on which the data of reference are based. Accepting that for a comparison of one test and one control animal a relative spleen weight ratio of 1.32 significantly exceeds the normal variability, only two of the chimæras—*G*68/1, 3 days; and *G*69/3, 6 days—fail by a little to comply with this standard. As both these animals were killed before splenomegaly reached its peak it may be assumed that by a later date they may well have had acquired a significant enlargement. It seems justifiable therefore to conclude that a graft-versus-host reaction was in process in every one of the chimæras studied.

Rate of spleen cell proliferation. The use of 'Colcemid'—though essential for suitable chromosome preparations—rendered the estimation of the true mitotic rate in chimæra and control spleens impossible. However, as both test and control animals had been exposed to the effect of similar doses of the drug, a comparison of the number of metaphase nuclei in 10,000 nuclei allows at least a relative evaluation of mitotic activity. From this it is apparent that during the 3–10-day period the mitotic activity in chimæra spleens always exceeds that of their litter mate controls (Table 3). The mean excess of metaphases in chimæras (77·22 per cent) was found to differ significantly from zero; $0·02 < P < 0·05$.

In the controls cell proliferation seemed to proceed at two markedly different levels. Statistical analysis of the data shows that the mean number of 99·33 metaphases/10,000 nuclei in the 3–6 day specimens differs significantly from the mean (231·20) of the 6–10 day specimens ($P < 0·01$). This division into two phases of mitotic activity is somewhat obscured in the chimæras (Table 3). The difference between the mean numbers of metaphases in the corresponding time intervals is suggestive but not statistically significant ($0·05 < P < 0·10$).

Donor and host contribution to cell proliferation. The fact that the chimæra spleen cells are a mixed population consisting of unknown quantities of host and donor cells makes the evaluation of the results in absolute terms impossible. In spite of this, two definite statements can be made; first, during the 3–10-day period, dividing donor cells, invariably demonstrable, constitute only a minority—though of varying magnitude—of all dividing cells in the chimæra spleens; and secondly, however high their absolute mitotic rate may be, depending on the unknown number of donor cells which settled in the chimæra spleen, donor cell multiplication alone cannot account for the increased overall mitotic activity of the chimæras. On the contrary, even after subtracting the donor contribution from the total number of metaphases there remains a considerable excess of host metaphases, which is probably significant (Table 3). The calculated average excess of 68 per cent of host metaphases underestimates the true rate of excess of host cell multiplication, as it is related to 10,000 chimæra (host plus donor) nuclei instead of 10,000 host nuclei. For this reason the difference between this average excess and zero (for which P was found to be $< 0·1$ but $> 0·05$) may be more significant than is apparent here.

Table 3. COMPARISON OF THE MULTIPLICATION RATE OF CELLS IN CHIMÆRA AND CONTROL SPLEENS AND CONTRIBUTION OF HOST MITOSES TO SPLENOMEGALY

Specimen	Age (days)	Metaphase nuclei/10,000 nuclei Chimæra	Metaphase nuclei/10,000 nuclei Control	Ratio chimæra/control*	Ratio host contribution† in chimæra/control
G68/1	3	143	101	1·42	1·34
G68/2	3	180		1·78	1·72
G69/3	3	141	123	1·15	1·13
G68/3	5	311	74	4·20	4·15
G69/4	6	271	229	1·18	1·18
G67/3	7	365	253	1·44	1·28
G66/2	9	471	216	2·18	2·02
G64/2	10	196	173	1·13	1·10
G65/3	10	369	285	1·29	1·24

* The average percentage excess (77·22 per cent) of chimæra metaphases over control metaphases differs significantly from zero; $0·02 < P < 0·05$.

† The calculation of the host contribution is based on the mean percentage of donor cells in all dividing cells of the specimen (Table 4). For the difference between the mean excess (68 per cent) and zero P was found to be $0·05 < P < 0·1$.

Table 4. DONOR CELL CONTRIBUTION TO SPLEEN CELL MULTIPLICATION IN CHIMÆRA SPLEENS

Specimen	Age (days)	Absolute spleen weight (mg)	Metaphase nuclei analysed Sample size	Metaphase nuclei analysed No. of samples	Mean percentage donor cells in analysed metaphases	95 per cent confidence interval

Table 5. EARLY AND LATE DATE CHIMÆRAS. COMPARISON OF SPLEEN WEIGHT AND MITOTIC ACTIVITY, AND ESTIMATION OF THE NUMBER OF DIVIDING DONOR CELLS

Age (days)	No. of mice chim.	No. of mice contr.	Relat. spleen weight ratio chim./contr.	*Mitotic rate per cent chim.	*Mitotic rate per cent contr.	No. of metaphases analysed	Percentage donor mitoses spleen	Percentage donor mitoses marrow
1	1	1	0·98	0·01	0·30	50	0	—
2	2	1	1·08	0·03	0·65	100	0	—
60	2	2	1·64	0·00	—	300	2	0·5

* These figures are based on the estimated total number of cells and total mitoses in the spleen.

Donor cell multiplication. A comparison of the absolute spleen weights and the percentages of donor cells in dividing cells of the 3–6-day specimens (Table 4) suggests a constant absolute division rate in the donor cell population in the face of increasing numbers of dividing host cells. A striking break in this process of 'dilution' of donor mitoses by increasing numbers of host mitoses is apparent at 7 days, when donor mitoses gain considerable ground in spite of intense host cell proliferation (Tables 3 and 4). After this sudden outburst of donor cell multiplication, 'dilution' of dividing donor cells by rapid host proliferation (9 days) and a decline in donor cell multiplication (10 days) jointly seem to reduce the proportion of donor mitoses. There is thus evidence, in spite of the difficulties of obtaining information about the true rate of division in donor cells, which suggests that at about 7 days an enormous multiplication of donor cells occurs.

Observation in 1-, 2- and 60-day specimens. As may be seen from Table 5, there was no indication of splenomegaly in the 1- and 2- day specimens, nor were donor mitoses observed in the spleen. However, it is interesting to note that in these chimæras the mitotic activity, compared with that in their controls, appears considerably depressed.

In the 60-day specimens a minority of donor mitoses persisted, and was found to occur even in the bone marrow. Both chimæras had survived runt disease, and although smaller than their uninjected litter mates, were apparently healthy. The high relative spleen weight ratio, which might suggest a persistence of a sub-lethal graft-versus-host reaction, is partly the result of the lower body weight of these animals.

Discussion. The results of this experiment once again demonstrate the predominant role of host cell proliferation in chimæra splenomegaly, but they also reveal a phase of intense donor cell multiplication which may well be a decisive factor in the timing of peak enlargement.

Recently, the immunological capacity of new-born mice[14] and the importance of host contribution to splenomegaly in hybrid/parent strain chimæras (that is, F_1 hybrids injected with spleen cells from an adult parent strain donor)[13] have been demonstrated. The latter observation implies that a factor other than a host-versus-graft reaction—possibly a mechanism of self-protection—is involved in the host cell proliferation. Therefore three factors must be considered when trying to interpret the increased mitotic activity, and the rise and fall of host and donor cell multiplication in the chimæras of the work reported here; first, a graft-versus-host reaction; secondly, a host-versus-graft reaction; and thirdly, a hypothetical protection mechanism, which is set into motion by the effects of the graft-versus-host reaction. As the observations in hybrid/parent strain chimæras quoted here suggest that this protection mechanism is in action as early as 6 days, graft-versus-host and host-versus-graft reaction, and cell proliferation of such ætiology must be expected to occur at an even earlier stage. The 'dilution' of donor mitoses by increasing numbers of host mitoses in the 3–6-day specimens of this experiment may thus possibly illustrate the waning of the donor and host cell multiplication resulting from the partners' reaction against one another, and the commencement of the host's protective activity. This interpretation is further supported by the finding of Fox[15] that in hybrid/parent strain chimæras—(*CBA* × *C57BL*)F_1/*CBAT6*—a majority of donor mitoses (60 per cent) at the second day after injection is reduced to a minority (8–10 per cent) by 4 days.

In comparing these high proportions of donor mitoses in hybrid/parent strain chimæras with the data presented here, it would seem that the generally low level of donor mitoses in this study, besides reflecting the degree of immunological antagonism in the strain combination, is characteristic of homologous chimærism induced in new-born mice which, although they will eventually become tolerant of the donor cells, are initially capable of at least weekly reacting against them. (Eventual tolerance in the present chimæras—had they been allowed to survive—may be assumed by analogy with the observation that the injection of 9–15 × 10^6 *CBA* spleen cells into new-born *A* mice induced tolerance in most cases[2].)

Depression of mitotic activity in the very early stages after spleen cell injection seems to be a common feature in both hybrid/parent strain chimæras[15] and the homologous chimæras of this experiment. However, as non-specific causes cannot be ruled out yet, it would be premature to describe the phenomenon as an essential part of the graft-versus-host reaction.

The sudden increase of donor mitoses at day 7 again raises the question as to the nature of the proliferation. Is it of graft-versus-host reaction type or do donor cells suddenly join in the host's protection efforts? As a little later (at 9 days) the proliferation of host cells also reaches a peak, the feature might be explained as an overlap of a second immunological assault of the partners on one another and the host's renewed protective response, but no definite interpretation can be offered at the present time. The distinction between the three phenomena which might possibly be involved may, of course, have an important bearing on the concept of the mechanism which leads to immunological tolerance. If this later stage of host and donor cell proliferation was in fact the expression of a secondary immunological response of host and donor to one another's antigens, it could be assumed that tolerance is not achieved before such a reaction has occurred.

Most of this experimental work was carried out in the Department of Surgical Science, Edinburgh, where both of us were guests; one of us (M. F.) while holding a clinical research fellowship from the Medical Research Council, and the other (I. M. Z.) while on study leave from the University of Otago, New Zealand. We thank Prof. M. F. A. Woodruff for his hospitality and guidance. We also thank Mr. R. S. Booth, Mathematics Department, University of Otago, for his advice on the statistical handling of the data, and Drs. B. F. Heslop and N. W. Nisbet (Department of Surgery, Otago University), and Dr. D. Michie (Department of Surgical Science, Edinburgh) for criticism of the draft manuscript.

BREEDING OF THE CHILEAN OYSTER (*OSTREA CHILENSIS* PHILIPPI) IN THE LABORATORY

By P. R. WALNE

Ministry of Agriculture, Fisheries and Food, Mussel Purification Tanks,
Conway

THE 1948 Lund University Expedition to Chile[1] collected samples of *Ostrea chilensis* from the northern part of the Golfo de Ancud and in the neighbouring Bahia de Ancud, where they were found on stony beaches and on sand and mud down to depths of 11 m. In one of the samples collected in November 1948, several specimens brooding eggs and larvæ were found which were stated to measure 0·5–0·75 mm and 0·7–1·2 mm respectively. This is abnormally large for *Ostrea* eggs and larvæ and suggested that all the larval development would occur while being brooded in the mantle cavity and that the duration of the planktonic stage would be very short. A similarly reduced planktonic stage has been recently reported for the New Zealand oyster, *O. lutaria*[2].

A consignment of *O. chilensis* was received in good condition in this laboratory on September 17, 1962, and placed in glass tanks with running sea-water. Within a few hours a number of early embryos were aborted, indicating that some of the oysters were brooding when they arrived. Four liberations of larvæ were obtained in October during which period the temperature of the water gradually decreased from 15° to 11° C. This range is approximately that found in the late spring and early summer on their natural grounds[3]. Thirteen liberations occurred in November when the temperature was being maintained at 11°–14° C.

The larvæ at liberation had a well-developed foot and eyespot, and mostly metamorphosed within a few hours on the glass and slate sides of the tank and on mussel shells suspended for spat collection in the tank. The shell shape agreed with that figured by Ranson[4] although the size was less than that estimated by Soot-Ryen[1]. The mean and range of shell-length of six liberations are given in Table 1.

Table 1

	Mean	Range
1	435μ	390–510μ
2	477μ	430–500μ
3	475μ	450–490μ
4	490μ	460–510μ
5	492μ	450–520μ
6	491μ	460–510μ

The larvæ were sufficiently active to swim up to the surface film, although the velum is small compared with that of *O. edulis*. The gill rudiment, consisting of 6–8 projections on the left side, is more pronounced than in the mature larvæ of *O. edulis*. Some larvæ isolated in a glass beaker had not become attached 24 h later, suggesting that clean glass was not a favourable surface, although two specimens had metamorphosed without attaching—a phenomenon which has also been seen in *O. edulis*. Some of the larvæ which had not metamorphosed were placed on mussel shell and two became attached in the next 5 h, indicating that metamorphosis can be delayed for at least 24 h.

Two brooding adults have been opened and the number of eggs or embryos estimated (broods of *O. edulis* of this size would contain about 500,000 embryos) (Table 2) Early embryos are white in colour, but at the later stages the brood is light brown in colour instead of the grey or black of *O. edulis*.

Table 2

	Mean diam.	Internal vol.	Dry meat wt.	No. of embryos
1	60 mm	15·0 ml.	1·18 g	66,600
2	51 mm	11·5 ml.	0 94 g	62,800

One adult was observed to be spilling a few eggs in the exhalent current. When opened few were in the inhalent chamber but there were many in the exhalent chamber and filling the water tubes of each demibranch, and more were seen issuing from the genital pore. The eggs, which measured 323 × 264μ, were exceptionally large for a lamellibranch with pelagic larvæ. Thorson[5] noted that the largest lamellibranch egg to develop into a pelagic stage (*Yoldia limatula*) has a diameter of 150μ; those species with larger eggs have a direct non-pelagic development. In *O. edulis* the egg is 150μ in diameter and in *O. lurida* 100μ. A number of individuals of *O. chilensis* have been observed to spill either eggs or early embryos in the exhalent current, and it is suggested that this is caused by the difficulty of forcing these very large eggs through the gills into the inhalent chamber.

Some of the adults which had spilled eggs or early embryos over a period of 3 days were separated from non-breeding individuals. When one was opened 11–13 days later the larvæ had grown to a mean shell length of 331μ at a temperature of 13°–15° C. When another was opened after 27–29 days the larvæ had a mean shell length of 390μ; the temperature in the second part of the period had been 9°–14° C. A sample of this brood was cultured and at 13°–14° C the shell length of the larvæ grew at about 10μ per day. A rudimentary foot was seen on the third day and on the seventh day the foot was well developed, a row of rudimentary gill filaments was visible and the eye spot was clearly developing. On the eleventh day one spat was found attached to the wall of the vessel and many on the fourteenth day. It is probable then that the incubation period at temperatures of 13°–15° C is about 5–6 weeks.

The spat have grown well after settlement and some exceeded 1 mm in length within 12 days at 13°–15° C. The very short free-swimming larval life suggests that *O. chilensis* might be a valuable species to introduce into British waters, since the loss of larvæ by tidal currents and predators would be substantially reduced and most of the settlement would take place near to the parent stock. The temperature at which breeding occurs is lower than the 17°–20° C required by *O. edulis*, and this could result in an earlier production of spat and, since the larvæ at release are more mature than those of *O. edulis*, spatfall would presumably be more reliable. There is the possibility, however, that production of larvæ would continue for a large part of the year, resulting in thin oysters with a proportion 'white sick' during the normal marketing season. In this case *O. chilensis* might be suitable only for the cooler waters of the British Isles. In external appearance it closely resembles *O. edulis* and in the imported sample the oysters were in excellent condition.

PHYSICS

Perturbations in the S_2 Spectrum

The pressure effect on the predissociation of diatomic molecules is an experimentally well established phenomenon; but the detailed perturbation mechanism is not yet clear. In this communication, some new observations are reported on the well-known predissociation in the $B^3\Sigma_u^- \rightleftarrows X^3\Sigma_g^-$ system of S_2 (ref. 1). In absorption, the v'' progression shows, in pure sulphur vapour, a sudden intensity increase starting from $v' = 9$. In the emission spectrum the $v' > 9$ bands are missing. If a large amount of foreign gas is added to the absorbing vapour, new perturbations occur in the absorption spectrum, and in the emission[2] spectrum the missing ($v' > 9$) bands appear[3].

Lochte-Holtgreven[3] finds the $v' > 9$ levels to be pressure perturbed; but Kondratjew and Olsson observe modifications of the rotational structure in the bands $v' < 9$, which are usually not perturbed. The perturbations in emission are due to collisional removal of the predissociation according to Asundi[2], but to the population increase of the levels $v' > 9$ according to Christy and Naudé[4]. The experiment reported here may clarify the foregoing process.

We essentially repeated Kondratjew and Olsson's experiments increasing the collisional effect. Nitrogen gas at 70 cm mercury was replaced by xenon gas (atomic weight 9 times greater) at a pressure at 2 kg/cm². The absorption spectrum of sulphur obtained in the presence of 2 kg/cm² of xenon contained in a cylindrical silica vessel 15 cm long is illustrated by spectrum *B* of Fig. 1. It may be compared with spectrum *A* obtained in absence of foreign gas. The comparison between the two spectra shows that the vibrational perturbation is partially removed when the pressure is increased. In spectrum *B* all bands have the same apparent structure and are regularly distributed in the spectrum, as though there were no perturbation or predissociation. As a quantitative check, the relative intensities of the bands should be compared with the relative transition probabilities in the $v'' = 0$ progression. The Franck–Condon factors are estimated by direct calculation of the overlap integrals using the Morse wave function. The results obtained are given elsewhere. In spectrum *A*, an important discontinuity is seen at $v' = 9$.

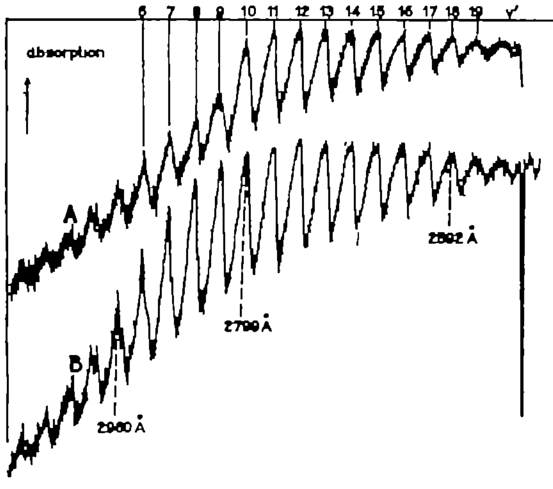

Fig. 1. Comparison of the microdensitometer tracing of spectrum *A* obtained in pure sulphur at low vapour pressure with that of spectrum *B* obtained in the presence of xenon at 2 kg/cm² pressure showing the removal of the perturbation by collision

The pressure-induced perturbation of the rotational lines was investigated with a 'JACO–EBERT' grating spectrograph and a 0·5 Å per mm reciprocal dispersion. The rotational absorption lines of the λ 2828·9 Å (0·9) band show a considerable broadening in the presence of xenon gas as compared with that in pure sulphur vapour. In the usual qualitative investigation of the effect of predissociation on the shape and the width of absorption lines, the inverse process of emission by atomic recombination is usually neglected. At low gas pressure the contribution of the emission is negligible; but, when the gas pressure is increased, the atomic recombination can no longer be neglected, for the intensity and shape of the emission lines depend not only on the relative values of radiationless and absorption probabilities but also on the atomic radiative recombination rate. It is indeed plain that if the atoms formed by photodissociation can partially recombine in a three-body collision process before they separate completely, the apparent radiationless transitional probability will be reduced.

In short, the foregoing experiments show that the pressure perturbations observed in the $B^3\Sigma_u^- \rightleftarrows X^3\Sigma_g^-$ band system of S_2 are of two kinds: (1) the vibrational perturbation closely connected with 'inverse predissociation' process; (2) the apparently independent rotational perturbation of the $v' < 9$ levels.

Dependence of Angular Width of High-frequency Diffraction on Sound Wave-length

It has been well established[1,2] that, in the case of diffraction of light by very-high-frequency sound waves only the first order of diffraction appears in the field of view and it attains the maximum intensity when the sound wave-front is tilted to the corresponding Bragg reflexion angle. Any further tilt from this position results in gradual diminution of intensity and finally in the disappearance of the diffraction order. The angle over which the intensity of the diffraction order is distributed is called the 'angular width of high-frequency diffraction'.

David[3], following Brillouin's theory, gave for intensity I_{+1} of the first order the following expression, assuming the higher orders to be of negligible intensity:

$$I_{+1} = I_m \left[\frac{\sin \frac{\pi L}{\lambda^*} \varphi}{\frac{\pi L}{\lambda^*} \varphi}\right]^2 \qquad (1)$$

where I_m is the maximum intensity of the first order, L is the length of the sound path traversed by the light beam,

λ^* is the sound wave-length in the medium and φ is the angle of deviation of the sound wave-front from the Bragg position. It can be seen by differentiating the expression (1) that the angular width of high-frequency diffraction depends only on the value of the parameter $(\pi L/\lambda^*)$. That is to say, for very high frequencies and large lengths of the sound field, the phenomenon of characteristic reflexion of light gains importance. The angular width of diffraction does not depend on any other factor like the wave-length of the incident light or the intensity of the sound field.

It has been shown[4] that the intensity of the first order attains its maximum when $L = \mu_0\lambda^{*2}/\lambda$. This value of L makes the parameter $(\pi L/\lambda^*)$ equal to $(\pi\mu_0/\lambda).\lambda^*$—where μ_0 is the refractive index of the medium and λ is the wave-length of light used for diffraction—showing that the angular width of high-frequency diffraction is directly proportional to the sound wave-length in the medium.

Intense diffraction orders are produced at several ultrasonic frequencies and their intensity maxima at the corresponding Bragg angles are adjusted to be the same with the help of a photo-tube, by controlling the power input to the crystal. The crystal holder is tilted towards either side of the Bragg position and the exact position of disappearance of the diffraction order is judged by the photo-tube. The expression (1) clearly predicts the positions of disappearance, which occur whenever $\frac{\pi L}{\lambda^*}\varphi = n\pi$, where $n \neq 0$ is any integer. This can be simplified and written, in the case of the first order, as:

$$\varphi = \frac{\lambda^*}{L} \qquad (2)$$

The values of φ calculated from the relation (2) and those obtained experimentally by the photo-tube are tabulated in Table 1 for several sound frequencies utilized in this investigation using water as the medium for sound propagation.

Table 1. TEMPERATURE, 28° C; L, 1·5 CM

Frequencies of ultrasonics (Mc/s)	φ (in min of arc) Calculated from (2)	 Measured by photo-tube
23·06	15·0′	16·5′
49·97	7·0′	8·0′
73·04	5·0′	5·0′
91·20	4·0′	4·5′
144·0	2·4′	3·0′
164·0	2·1′	2·2′
184·0	1·9′	2·0′

Table 1 shows a remarkable agreement between theory and experiment. However, the measured values by the photo-tube are slightly higher than those calculated from expression (2) and this slight deviation is due to the fact that the sound field is not the ideal one with undamped amplitude as assumed in the theory.

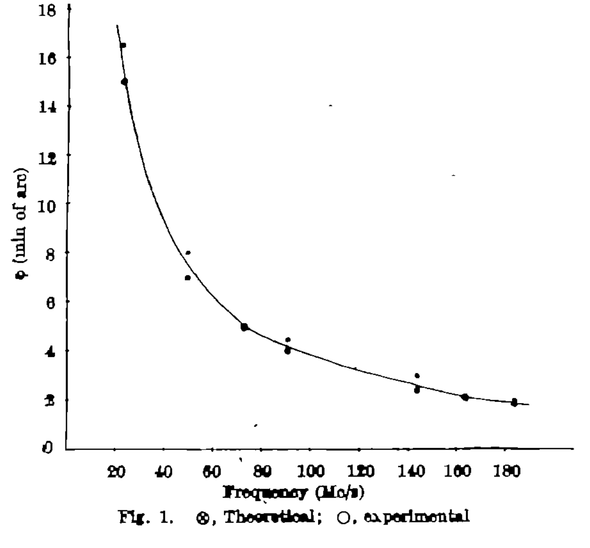

Fig. 1. ⊗, Theoretical; ○, experimental

A plot of the values of φ against sound frequency is shown in Fig. 1. The curve clearly indicates the dependence of the angular width of high-frequency diffraction on sound wave-length. The angular width is scarcely two min of arc and the sound wave-length is only about thirteen times the wave-length of light at the highest frequency used in this investigation.

Pressure Calibration of a Tetrahedral Anvil Device

THE tetrahedral anvil high-pressure device was first described by Hall[1] in 1958. The pressure calibration of this device was based on the resistivity measurements of Bridgman[2]. Because the calibration points based on those measurements have been revised downward[3], the original linear plot of sample pressure versus applied force no longer has validity. In a preliminary determination of the shape of a calibration curve based on the newer values of the calibration points, curve A (Fig. 1) was obtained. These values were obtained with an apparatus containing 7-in. hydraulic rams and triangular tungsten-carbide anvils which were 0·781 in. in edge-length. The calibration wires were inserted in silver chloride cylinders 5/32 in. in diameter which in turn were inserted in the pyrophyllite tetrahedrons, which were about 25 per cent oversize (edge-length). A thick coating of iron oxide mixed with water was applied to the assembled tetrahedron before it was pressed. The use of tetrahedrons which were 35 per cent oversize caused the samples to be more distorted by the flattening of the ends of the silver chloride cylinders, as described elsewhere[4]. Tetrahedrons which were only 15 per cent oversize transmitted the applied force to the calibration wire less effectively. In this case about 10 per cent more ram force was necessary to attain 25 kbars on the calibration wire.

Curve B (Fig. 1) was obtained under the same experimental conditions as here, except that the pyrophyllite tetrahedrons, completely assembled, were dried at 90° C for 2 h after the iron oxide was applied[5]. In addition to this substantial increase in efficiency, the deformation of the sample was reduced. Results obtained following

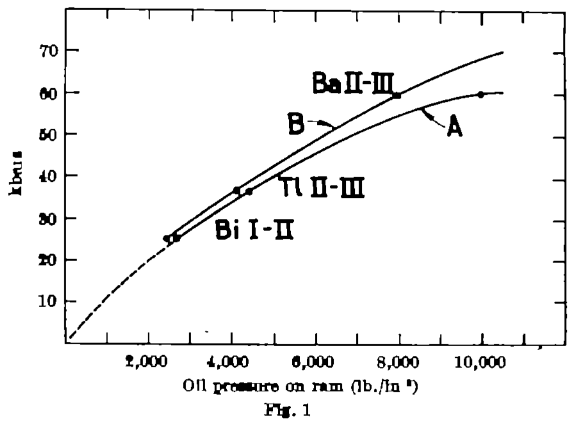

Fig. 1

this procedure were reproducible to about 1 or 2 per cent. It should be observed that the points on curve B can be connected by a nearly straight line which does not pass through the origin. Preliminary experiments indicate that sample porosity may reduce the efficiency of pressure transmission by 5–10 per cent.

The pressure-transmitting qualities of pyrophyllite can also be improved by heating the tetrahedrons to 650° C for several hours before the samples are assembled. This treatment causes the pyrophyllite to be about 10 per cent more efficient in pressure transmission. However, this procedure apparently reduces the elasticity of the pyrophyllite, because frequent blow-outs were observed on decreasing the applied pressure.

GEOLOGY

Association of Dolomite and Anhydrite in the Recent Sediments of the Persian Gulf

A. WELLS[1] has recorded the presence of dolomite associated with aragonite and gypsum in the Recent sediments of the higher parts of the tidal flats around the Qatar peninsula in the Persian Gulf. A similar environment of coastal lagoons and tidal flats extends eastwards from Qatar along the Trucial Coast towards Oman. This communication refers to a short core collected from the higher part of the coastal flats (the sabkha) in the Sheikdom of Abu Dhabi, some 200 miles east of Qatar. The core, 20 cm in length, was taken from the surface of the sabkha on the mainland approach to the Abu Dhabi causeway.

Wells interpreted the dolomite and gypsum around the Qatar peninsula as having been "derived from sea-water left behind in the sediment on the upper part of the tidal flats and concentrated by evaporation during the time between spring or storm high tides, although it has not yet been established to what extent the dolomite is primary and to what extent it is a penecontemporaneous replacement of pre-existing carbonate". The distribution of dolomite in the core from Abu Dhabi, which is described in this communication, indicates that the dolomite is an early diagenetic replacement mineral.

In the Abu Dhabi core, aragonite, calcite, dolomite and halite have been identified. Gypsum, which occurs in the sample described by Wells[1] from Qatar, has not been found, but anhydrite occurs in considerable amounts. The vertical distribution of these components is shown in Fig. 1. The uppermost 8 cm consists essentially of an accumulation of sand- and silt-sized grains of quartz and carbonates, associated with evaporitic halite and anhydrite. This buff-coloured upper part rests on a cream-coloured, very fine-grained carbonate mud, which is well laminated at certain levels. Halite occurs throughout, but anhydrite, which characterizes the superficial parts of the core, has not been identified below 4 cm. At a depth of 9–14 cm from the surface the carbonate is almost exclusively aragonite, but below this level dolomite makes its appearance in detectable amounts. The ratio of dolomite to

Fig. 1

aragonite increases downwards from less than 1 : 1 at 15 cm to approximately 2 : 1 at 20 cm.

The anhydrite is clearly an evaporitic component, but the vertical distribution and mutual relationships of the dolomite and aragonite suggest that the dolomite is an early diagenetic replacement of aragonite. Although wind-blown grains are scattered throughout the length of the core, there is nothing to suggest that the dolomite is detrital. All the available evidence indicates that it was formed *in situ* and is chemical in origin.

Owing to the extremely low annual rainfall, the pore fluids in the sabkha are supplied by the high salinity sea water of the adjacent lagoons. The waters of the tidal lagoons are alkaline with pH values up to 8·0. In the sabkha, which extends inland for 7 miles near Abu Dhabi, the ground-water is acid with the pH varying between 6·0 and 6·2. Transitional pH values are found in a narrow zone along the seaward margin of the sabkha. During October 1962 the ground water-level in the sabkha stood at approximately 75 cm below the surface, although it varied slightly from place to place. The ground water temperature averaged 35° C. A lateral and vertical migration of these fluids within the sediment is caused by evaporation from the sabkha surface. It is thought that the pore fluids, probably rich in magnesium, bring about the transformation of aragonite to dolomite. However, until a more detailed field and laboratory study has been completed this conclusion can only be a tentative one.

The mineral identifications were made by the X-ray diffraction powder method. The dolomite consistently showed an absence of the superstructure reflexions (221) and $(11\bar{1})$. This feature is characteristic of protodolomites[2]. The dolomite identified by Wells is rich in calcium ($Ca_{54}Mg_{46}$) and has an expanded lattice which suggests that it may also be a protodolomite, although Wells did not record the absence of the superstructure reflexions.

It is of interest at this stage of the investigations, that the dolomite is associated in the Qatar region with gypsum and at Abu Dhabi with anhydrite, in what at first sight appear to be similar environments.

Recent work on a series of short cores taken across the seven mile width of the sabkha near Abu Dhabi has revealed the presence of abundant gypsum. A complex, and as yet not understood, series of relationships exists between the gypsum and the anhydrite. The results of these later investigations will be more fully described elsewhere.

This communication is based on work forming part of a programme of research on the Recent sediments of the Trucial Coast, Persian Gulf, financed by the Department of Scientific and Industrial Research.

The Cabot and Great Glen Faults

IN his recent contribution to this journal, Prof. Tuzo Wilson[1] describes the Cabot fault in the eastern coastal region of North America and compares it with the Great Glen fault which bisects the Scottish Highlands from the Firth of Lorne to the Moray Firth. He finds that transcurrent movements on the line of the Cabot fault occurred during an interval extending from late Devonian to early Carboniferous times, and cites Kennedy's[2] similar findings for the age of movements on the Great Glen fault as additional evidence of the close similarity of the two faults.

I have been engaged in a detailed investigation of the history of movements on the Great Glen fault, and have reached conclusions which are relevant to the question of the equivalence and possible former continuity of the Cabot and Great Glen faults. I have found conclusive evidence that while a sinistral transcurrent movement of the type recognized by Kennedy[2] postdates the emplacement of the Morvern-Strontian and Foyers "Newer Granite" complex, this movement was completed prior to the deposition of the Middle Old Red Sandstone in the area about Loch Ness and the Moray Firth. The presence of sediments of undoubted Middle Old Red Sandstone lithology[3] among the sheared rocks of the fault-zone has resulted from further and distinctive transcurrent movements, of somewhat smaller magnitude than those of early Old Red age, which occurred in Tertiary times. These later movements, which were dextral in sense, are chiefly recognizable because they have caused the dislocation of the Skye Tertiary dyke swarm at the line of the Great Glen fault. Prior to these movements, the major outcrops of the Middle Old Red Sandstone astride of the fault showed a detailed correspondence, as regards both geometry and lithology, such as is not apparent at the present day.

The dating of the major sinistral movement on the Great Glen fault is thus more narrowly defined and is earlier than the age interval found by Kennedy[2] for the same dislocation. The comparability of this fault with the Cabot fault is therefore much less close than is claimed by Wilson[1].

NORMAN HOLGATE

Department of Geology,
University of Glasgow.

[1] Wilson, T., *Nature*, **195**, 135 (1962).

[2] Kennedy, W. Q., *Quart. J. Geol. Soc. Lond.*, **102**, 41 (1946).

[3] Eyles, V. A., and MacGregor, A. G., *Geol. Mag.*, **89**, 426 (1952).

THE new information provided about the Great Glen fault by N. Holgate is naturally welcome. I am grateful to him for pointing out its possible bearing on my suggestion[1] that the Great Glen and Cabot faults might have been two ends of the same fault, if Europe and North America had been joined together at the time of the formation of these faults, and if the continents had afterwards moved apart. Granted that Holgate's views are correct, there are still at least three points to be settled before they can be held to have invalidated my suggestion, although they may have modified it.

First, if the supposed date of faulting can be changed in an area so well studied as is most of Scotland, so can the age of the Cabot fault. I hinted in my paper at the conflict in the views which have been published about the age of faulting in Massachusetts and Rhode Island. If there appears to be less conflict in northern Newfoundland, it is because the areas of fossiliferous rocks are small and they have been little studied. D. M. Baird and officers of the Geological Survey of Canada have been so kind as to confirm in conversation that the age of the Cabot fault is neither firmly nor precisely established.

Secondly, the argument has been made more complex by R. Dearnley's description[2] of the Minch fault between the Outer Hebrides and the mainland of Scotland. It is said to be similar in age and displacement to the Great Glen fault, but it is not precisely dated since "the available evidence, though fragmentary and inconclusive, suggests that the fault-movement occurred probably after the intrusion of the Lower Old Red Sandstone lamprophyres and almost certainly before the intrusion of the (supposedly Permian) camptonites"[2]. Dearnley regards the Great Glen, Minch and other minor faults as members of the same fault system.

Thirdly, displacements of tens of miles on fault zones hundreds of miles long must have been spread over considerable periods of time. Displacements may have been renewed after long intervals of quiescence as Holgate points out. Where a fault zone has several branches, movements may have occurred at different times on different branch faults.

Thus the whole situation is that the displacements which were found by Holgate to have occurred in Scotland before the deposition of the Middle Old Red Sandstone might have occurred in North America, without yet being detected; while the Lower Carboniferous movements found in North America could have their counterparts in the Minch fault without calling into question Holgate's observations along the Great Glen fault.

Thus, it is still possible to believe that the Cabot fault may be the same age as the Great Glen fault alone and even easier to maintain that it corresponds to the whole Great Glen–Minch fault zone.

Devonian Conodonts in Stratigraphic Succession of Malaya

IN 1958, when correlating the pre-Tertiary stratigraphic successions then known in Malaya with those in Thailand, Alexander[1] indicated that no sediments of Devonian age had been proved in either country at that time, although the possibility existed of their occurrence. During the course of a short visit to Malaya in July–August 1962, at the invitation of the Geological Survey, one of us (K. J. M.)[2,3] was given and collected a number of rock specimens for conodont identification.

One random specimen picked up from the Government limestone quarry at Kanthan, Chemor, Perak, appears to have yielded three index fossils from the Upper Devonian[4], namely, *Polygnathus normalis* Miller and Youngquist, *Palmatolepis minuta* Branson and Mehl?, and *Ancyrodella nodosa* Ulrich and Bassler. However, further work will be necessary for systematic checking and confirmation before full descriptions can be prepared and published.

It is too early yet to assess the full implications of the discovery, and this preliminary announcement is being made to indicate the increased probability of an almost complete succession without major break of strata from Upper Cambrian to Triassic in Malaya.

Sponge Spicule Pebbles at Hut Point Peninsula, Antarctica

PEBBLES that range up to 20 mm in diameter composed entirely of sponge spicules, originally found by Priestley[1], are sparingly distributed over the loessic gravelly soil of the two square miles of ice-free area at the southern tip of Hut Point Peninsula, lat. 77° 51′, long. 166° 48′ E.

The pebbles are extremely resilient and appear to have been eroded out of loess by the wind. By experiment it was found that the pebbles readily pick up sponge spicules and build them on to their surface in continuity with those below.

Sponge spicules are not uncommon in the loess of Hut Point Peninsula, and are common in marine sediments dredged from the Antarctic sea-bed. Sponges make up a large part of the bottom fauna of the sea-bed around the peninsula.

The sponge spicules which form the pebbles are considered to have been blown from sea-bed that was exposed during the last glaciation when the level of the sea was lower, to have been concentrated on ice surfaces because of their high albedo relative to rock fragments, and to have aggregated into pebbles on the ice by wind action. The pebbles were probably blown to Hut Point Peninsula when the loess was being deposited.

I shall be interested to learn of other occurrences of such pebbles, either fossil or recent.

Transport of Pebbles over Smooth Ice in Antarctica

AT Hut Point Peninsula (lat. 77° 51′ S., long. 166° 48′ E.) pebbles of basalt up to 17 mm in diameter with some sand and silt have recently been blown half a mile up a snow-free ice slope to be stopped by snow cover 200 ft. higher than the foot of the slope. After being halted the pebbles melt their way down into the ice. The pebbles are probably transported during winter when southerly gusts reach a velocity of up to 120 knots.

At present only a small portion of the ice-covered part of the peninsula is free of snow, and the pebbles which are being wind transported now are entirely of local basalt. Widely distributed pebbles of granite and sandstone which are foreign to the peninsula are scattered through the gravelly loessic soil of the ice-free part. The pebbles have an unusual size distribution, already noted by David and Priestley[1], that is similar to that of the basalt pebbles, modal diameter being 16 mm, and maximum diameter, with the exception of a single pumice pebble, being not more than 18 mm. Because of their size distribution, it is considered that the pebbles were blown from the mainland some 30 miles to the west, probably during the last glaciation when there was more ice cover but less snow cover and the climate was colder, windier, and probably considerably drier than at present.

Pebbles with a similar shape, composition, and size distribution are abundant in dredgings from the nearby sea-bed, and wind transport of pebbles over smooth ice may have been of considerable importance in the past.

CRYSTALLOGRAPHY

Crystal Structure of β-Tricaprin

THE triglycerides belong to a large class of compounds, the lipids, that are widely distributed in biological systems and frequently are structurally or functionally important. In spite of the interest in the part played by the triglycerides in such systems, no complete single crystal structural studies have appeared except that of Vand and Bell[1], who reported the chain structure and packing in β-trilaurin.

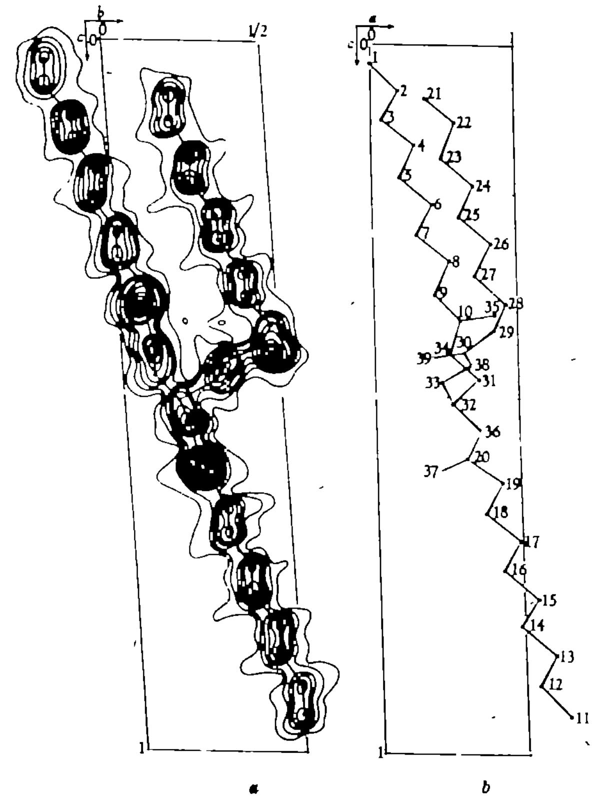

Fig. 1. *a*, F_o synthesis showing one molecule projected along [100]. Contours at integral values of electron density beginning at 1 e.Å^{-3}. *b*, Skeleton of molecule as viewed along [010]

The crystal structure of β-tricaprin has now been solved and refined in part from incomplete three-dimensional equi-inclination Weissenberg data collected with iron $K\alpha$-radiation (λ = 1·937 Å). Masses of plate-like crystals of the β-form (m.p. 31·9° C) were grown at 0° C by slow evaporation of hydrocarbon or hydrocarbon–ethanol solutions. The triclinic unit cell has parameters a = 5·50 Å, b = 12·10 Å, c = 27·03 Å, α = 85·25°, β = 87·30°, γ = 79·64° for the cell chosen according to Dirichlet[2]. Statistical treatment of the results of Ramachandran and Srinivasan's[3] modification of the method of Howells, Phillips and Rogers[4] indicated a centre of symmetry. Hence the space group was assumed to be $P\bar{1}$.

The structure was solved essentially from a Patterson projection along [100] and packing considerations, and the pronounced sub-cell lent evidence supporting the indicated orientation for the hydrocarbon chains. The position of the glyceryl group was initially chosen on the basis of steric considerations, and a Patterson projection along [100] based only on the non-sub-cell reflexions served as a validity check. Refinement by ΔF syntheses gave sufficiently good y, z co-ordinates to permit approximate evaluation of the x co-ordinates and to enable refinement to proceed with the general hkl data.

Fig. 1 *a* is an F_o synthesis showing the electron density of one molecule projected along [100]. The general configuration of the molecule shows well in this projection and may be described as an unsymmetrical 'tuning fork'. Two hydrocarbon chains with two ester oxygen atoms and two of the glyceryl carbon atoms form one long, nearly straight, chain. The third hydrocarbon chain branches off from the remaining glyceryl carbon atom, by way of the ester oxygen atom, bends and packs in parallel to and between the other two chains of adjacent molecules. The difference in configuration of this chain in the region of C$_{33}$ and C$_{36}$ shows to advantage when the molecule is viewed along [010] (Fig. 1*b*).

For approximately 600 observed reflexions, the present value of R is 0·179 with an over-all isotropic temperature factor parameter B = 3·0 Å^2 for the C and O atoms. The structure is being refined further and a more detailed account will appear elsewhere.

The computational part of this work was supported by a grant of computer time from the Research Computer Laboratory, University of Washington, and by grant *A*–3288 from the National Institutes of Health.

Unusual Twinning in Graphite

ACCORDING to the Kennedy interpretation[1] of twinning in graphite, the twin boundary can be regarded as the result of insertion or removal of a full hexagon width on alternate planes in the hexagonal lattice. This means that the twins are regions of the crystal which are misoriented in relation to the matrix by an angle of tilt, tan^{-1} a/c, a and c being the unit cell dimensions, equal respectively to the width of a hexagon and the distance between alternate basal planes. This interpretation is corroborated by the recent work of Freise and Kelly[2], there being no doubt that the twin composition plane is $\{11\bar{2}1\}$ with respect to the morphological axes (conventional notation). In Kennedy's paper, theoretical reasons are adduced which favour the existence of $\{11\bar{2}1\}$ rather than $\{1\bar{1}01\}$ twins, which result from the insertion or removal of a hexagonal length, $2a/\sqrt{3}$, into every other plane. It is also stated that "No cases of the observation of a $\{1\bar{1}01\}$ twin composition plane appear to have been reported, although it may be possible to produce such twins in thin flakes of very perfect graphite". This statement forms the basis of this communication.

We have studied twins on the surfaces of over a thousand crystals of natural, Ticonderoga graphite[3-5]. The crystals are frequently not perfect single crystals, but are com-

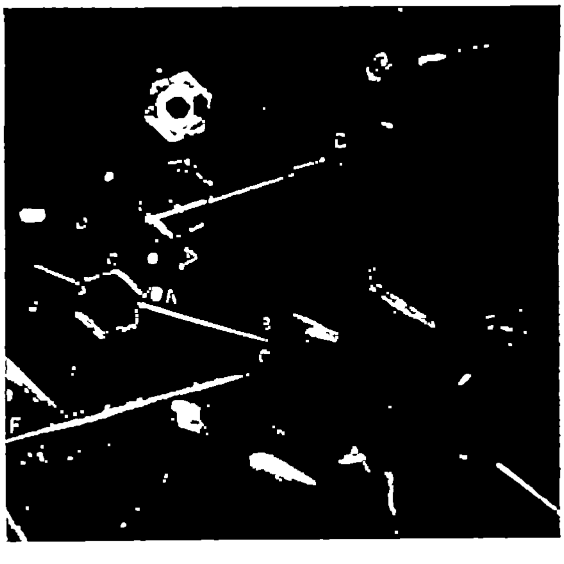

Fig. 1. (0001) surface of oxidized Ticonderoga graphite showing unusual twin (× c. 145)

posed of two or more flakes of highly perfect graphite twisted with respect to one another[4]. Almost invariably the twins were of the form $\{11\bar{2}1\}$. Very occasionally, however, twins which intersect the usual ones at 30° or 90° may be identified—they are therefore of the form $\{1\bar{1}0l\}$, l being unity if the angle of tilt is $\tan^{-1} 2a/\sqrt{3}c$. The twin AB (Fig. 1) which cuts the side of the pit C at 90° and the twins DE and FG at 30° is unusual and must clearly be composed of $\{1\bar{1}0l\}$ planes. Moreover, since this twin is not visible at the base of the pit C, and since the pit depth is about 1μ, we have evidence here which suggests that the perfect graphite flake on which the unusual twin appears is quite thin.

The views of Kennedy are therefore substantiated by our observations; but complete verification awaits the experimental determination of the angle of tilt which, if $l = 1$, $a = 2{\cdot}461$ and $c = 6{\cdot}708$ (refs. 4 and 6), should be 22° 57′.

This work was supported, in part, by the U.K. Atomic Energy Authority, Harwell. We are indebted to the Department of Scientific and Industrial Research for maintenance grants (to E. E. G. H. and B. R. W.) and Prof. A. J. Kennedy for his suggestions.

CHEMISTRY

Spontaneous Phase Changes during Rapid Cooling of Beryl Melts; their Detection and Characterization

A FUSION-QUENCH sequence as a means to opening the very refractory cyclo-silicate mineral beryl, $Be_3Al_2Si_6O_{18}$, is the basis of a well-known extractive process[1] in beryllium metallurgy. Much of the fundamental chemistry involved has been obscured by uncertainties surrounding the constitution of beryl melts and the crystallization paths which they can follow during cooling at rates too swift to allow equilibrium to be attained. We have found non-equilibrium ordering processes, and their dependence on thermal conditions, to be of importance in determining the chemical reactivity of chilled beryl melts. The difficulty of systematically studying events occurring spontaneously during the course of rapid cooling has been overcome by a refinement to the technique of high-temperature microscopy[2]. In addition to being able to observe the melt directly, heat effects, accompanying phase generation during chilling, can be detected. A series of pseudo-liquidus temperatures associated with any crystallization can be defined, and any dependence that the ordering processes occurring in the melt may have on variation in the rate of cooling can be established.

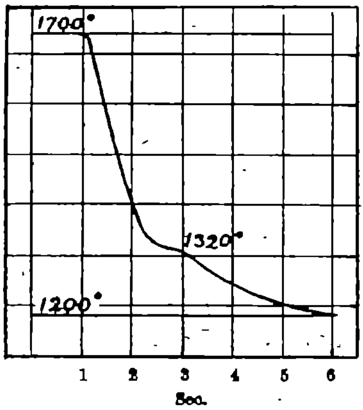

Fig. 1. Cooling-rate to 1,320°, 250°/sec

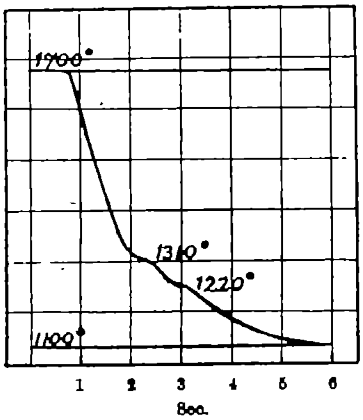

Fig. 2. Cooling-rate to 1,310°, 325°/sec

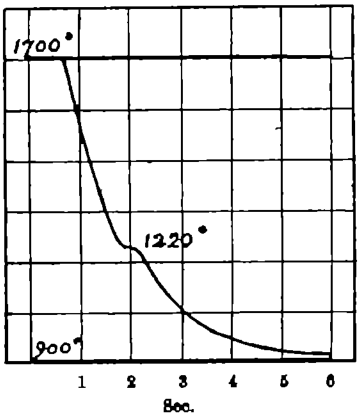

Fig. 3 Cooling-rate to 1,220°, 435°/sec

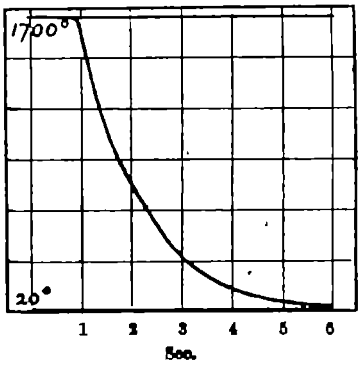

Fig. 4. Cooling-rate to 1,220°, 750°/sec

To achieve this the thermoelectric E.M.F. from the thermocouple microfurnace is monitored during cooling by a cathode-ray oscilloscope. The evolution of heat, signalling a phase change, is marked as an arrest on the E.M.F. (temperature) versus time trace. Initial cooling rates can be varied by altering the lower temperature to which the melt is quenched.

Provision is made for this by incorporating two parallel, interswitched, heating circuits into the instrument. Pre-heating of the system to any desired temperature by means of one channel can precede elevation to the desired temperature of the melt by the second channel.

The specimen is quenched in water immediately following the thermal arrest by impelling a water stream over the thermocouple with simultaneous cut-off of the heating current. Quenching rates of 10,000°/sec are thus achieved. The sample is removed and examined by X-ray methods to identify the crystalline phases.

Arrest temperatures and cooling rates are measured directly from the photographic record of the cooling curves. Four such curves are shown in Figs. 1–4. These are selected from many which trace an interesting relationship between the rate of cooling and the structures generated. The arrest at 1,320° (Fig. 1) was shown to arise from the simultaneous generation of beryllium oxide and mullite. The temperature at which they appear together is depressed to 1,310° when the cooling rate is increased and a second discontinuity marks the appearance at 1,220° of a new phase (Fig. 2). At a still higher rate of cooling (Fig. 3) ionic segregation into beryllium oxide and mullite was completely prevented and only one arrest, corresponding to the emergence of the new phase, noted. On quenching in air to room temperature the rate of cooling through these characteristic pseudo-liquidus temperatures was such as to prevent any crystallization and an X-ray-amorphous glass was produced (Fig. 4). This behaviour of beryl melts is fully reproducible.

The new phase is of uncertain composition, but wider investigations concerned with defining the conditions governing its formation and its mode of thermal decay strongly support the view that it is a metastable hybrid orthosilicate of beryllium and aluminium genetically related to both mullite and phenacite. The lines of its X-ray spectrum closely correspond to all those of natural phenacite for which l is either 0 or divisible by 3. It has a hexagonal unit cell; $a = 7 \cdot 38$ Å; $c = 2 \cdot 82$ Å.

Micro-packed Columns for Gas Chromatography

As long ago as 1956, Dr. A. J. P. Martin pointed out[1] that operation of thermal conductivity detectors at reduced pressures should enable them to measure samples at the µg-level and he states that columns would be correspondingly smaller in diameter, perhaps 0·2 mm.

No work has been reported on such a system, and many workers have expressed the opinion that conventional packed columns of such small diameters could not be fabricated and would not be practical. I have confirmed that the system suggested by Martin is not only practical, but also gives good results and is surprisingly easy to fabricate.

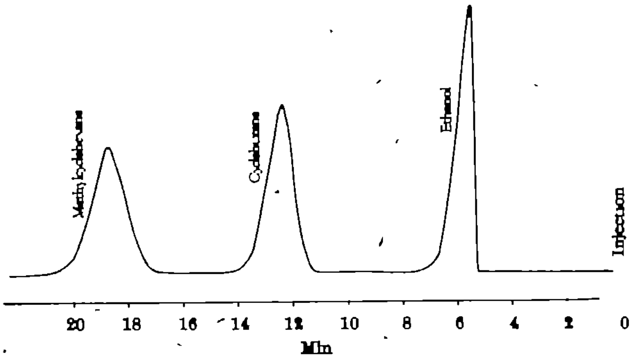

Fig. 1. Chromatogram with packed capillary. 2 m × 0·25 mm. Carrier, nitrogen; column, squalane; temp., 75°; sample, 1·3 × 10^{-6} g; flow-rate, c. 0·027 c.c./min (column conditions)

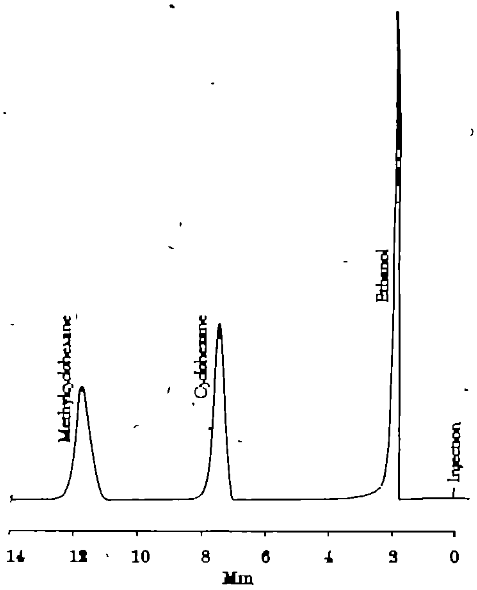

Fig. 2. Chromatogram with packed capillary. 2 m × 0·5 mm. Carrier, nitrogen, column, squalane; temp., 75°; sample, 1·3 × 10^{-6} g, flow-rate, c. 0·16 c.c./min (column conditions)

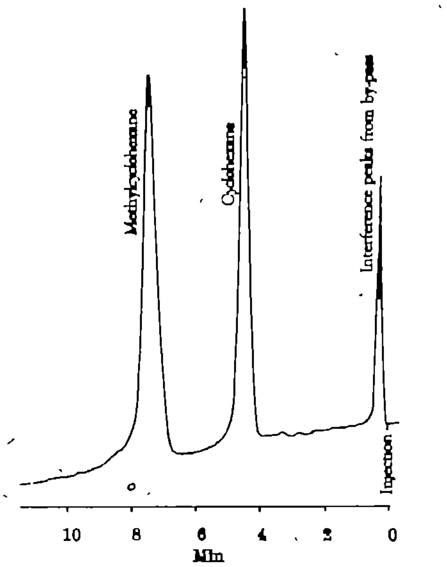

Fig. 3. Chromatogram with 0·5 mm packed capillary and thermistor detector. Carrier, hydrogen; column, squalane; temp., 75°; sample, 10^{-6} g; flow-rate, c. 0·25 c.c./min (column conditions)

Two columns were made, one of 0·25 mm internal diameter and one of 0·5 mm internal diameter. Each was 2 m long, made of stainless steel, and packed with dry glass beads of 0·04 mm diameter which were afterwards coated by passing a 10 per cent solution of squalane through the column. Packing was assisted by vibration and presented no difficulties. A wire insert prevented the beads from falling out.

The 0·25-mm column gave 1,000 theoretical plates for methyl*cyclo*hexane at 75° C and an inlet pressure of 130 cm (Fig. 1). The 0·5-mm column at 200 cm inlet pressure gave 2,800 theoretical plates for methyl*cyclo*hexane and a performance index[2,3] of 700 at a flow-rate of approximately 0·25 c.c./min at N.T.P. (Fig. 2).

The 0·5-mm column was later fitted into a Perkin-Elmer model 451 'Fractometer' and had a capillary restriction between the column exit and the thermistor detector (cell volume, 0·5 c.c.). The exit pipe of the instrument was connected to a vacuum pump so that the detector pressure was about 15 mm (estimated); the column outlet pressure was estimated at approximately

100 cm. A stream splitter was used to introduce smaller samples.

Peaks were 20 per cent wider (Fig. 3) than those for the flame detector; this is attributed primarily to the change of carrier gas from nitrogen to hydrogen, with an additional effect if the detector pressure were higher than estimated.

The detection limit (twice noise-level) for these particular conditions was 2×10^{-12} g/sec (which is about five times worse than a flame ionization detector yielding 0·4 coulombs/g), corresponding to a concentration of 5 p.p.m. in the detector.

Mosaic Permselective Membranes

We have succeeded in preparing ion-permselective membranes from a sheet of commercial polyethylene which are cation-selective on part of their surface and anion-selective on the adjoining part with a sharp line of demarcation between them[1]. To this end we treated the original polyethylene film either with sulphuryl chloride in the liquid or vapour state or in a mixture of chlorine and sulphur dioxide gas, in the light of incandescent lamps. Swelling by addition of carbon tetrachloride enhanced the reaction. A film, 0·1 mm thick, reacted completely in 2–3 h at about 50° C. This sulphochloride film was washed in carbon tetrachloride, dried, and half of it was pressed between two sheets of rubber with two metal plates. The rest of the film projected from this device and was immersed in a bath of tetraethylene pentamine at 80° C for 2 h. It became yellow and was transformed into an anion-selective membrane: the pentamine molecules became linked by sulphamide bonds into the film. The device was then opened and the whole film immersed into a 5 per cent solution of sodium dihydroxide in 1 : 1 dioxane/water. In this bath all sulphochloride groups which had been protected from amination between the rubber sheets underwent hydrolysis to sulphonate groups whereas the aminated part of the film was not disturbed. The sulphonated portion of the membrane proved to be strongly cation-selective, having 95 per cent permselectivity and a resistance of 2 ohms/cm². The aminated portion was anion-selective with 87 per cent permselectivity, but improved after methylation with alcoholic methyl bromide to 96 per cent, its resistance being 1 ohm/cm².

Such mosaic membranes may be of technical interest since they provide the possibility of in effect joining two membranes to each other. They are also interesting from the point of view of electrochemistry.

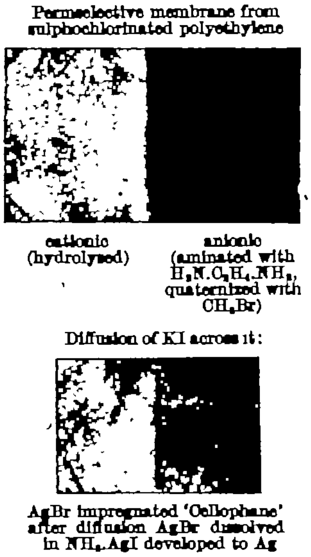
Enhanced Salt Diffusion along the Border-line of Mosaic Permselective Membranes

An ideal permselective membrane between, for example, a salt solution and water only allows its counter-ions to pass at the moment of immersion. The ions which have passed are attracted to the surface by their partners of opposite charge which remained on the other side: both sides of the membrane become charged and under ideal conditions the Nernst potential is established. This prevents further counter-ions from passing the membrane so that no actual diffusion of salt takes place. The same holds true for a membrane of opposite charge, only the signs are reversed. However, at the border-line between two permselective membranes of opposite sign a new situation has to be expected. Anions and cations respectively are present on the two sides of the borderline. Here they eliminate, or in any event weaken, the potential difference in the neighbourhood of the border because they neutralize each other's charges. Thus it should be possible for further anions and cations to pass across their respective, adjacent, domains. Actually salt should diffuse across the membrane along the borderline, anions and cations passing through beside each other on both sides of the border.

We have succeeded in demonstrating this effect. The membrane was soaked in distilled water and pressed against a pad of filter paper which had been soaked in a 1 per cent sodium iodide solution. In order to immobilize all iodide ions which had diffused anywhere across this mosaic membrane (preceding communication) we prepared a sheet of 'Cellophane' impregnated with silver bromide by successive immersion in silver nitrate and potassium bromide solutions and rinsing with water. This 'reagent "Cellophane" ' was pressed against the free surface of the mosaic membrane. It acquired a bluish-grey colour in the daylight by photoreaction but changed over to yellow silver iodide wherever iodide ions reached it, demonstrating exactly where diffusion had been going on. This diffusion pattern may be fixed in the following manner: silver bromide dissolves in concentrated ammonia solution whereas silver iodide does not, hence bathing the reacted 'Cellophane' for 1–2 min in it removes all unreacted silver bromide. The pale yellow silver iodide, on the other hand, can be easily transformed into black silver by immersion in any photographic developer. Fig. 1 is the photograph of a mosaic membrane with the photograph of its diffusion pattern below it; it has been prepared in this manner. The black line on the diffusion pattern at the border between cationic and anionic parts of the membrane definitively proves that our assumptions concerning enhanced diffusion along the border are correct.



Permselective membrane from sulphochlorinated polyethylene
cationic (hydrolysed)
anionic (aminated with $H_2N.C_2H_4.NH_2$, quaternized with CH_3Br)
Diffusion of KI across it:
AgBr impregnated 'Cellophane' after diffusion AgBr dissolved in NH_3. AgI developed to Ag

Fig. 1

The aforementioned technique is not quite so simple. For one thing, membranes are never ideal and always allow salts to diffuse across them to some extent. It is important that this 'illegal' diffusion be small and not very different across the cationic and anionic parts of the membrane, otherwise borderline effects become swamped. Diffusion across the hydrolysed, cationic, sulphochloride sheet is appreciably stronger than across its counterpart if it has been aminated with tetraethylene-diamine. This is because the large attached amine molecule fills the pores in the membrane. Therefore, we changed over to ethylenediamine instead, quaternizing it with methylbromide after amination. Diffusion across this anionic membrane was slightly stronger than across the cationic part, but detection of the border effect became possible. Secondly, the diffusion experiment itself is very time-sensitive: under-exposure or over-exposure of the diffusion pattern ruins the experiment. In our case, with membranes 0·1 mm thick, 1–2 min proved to be the right time for diffusion.

Not much can be said about the breadth of the active surface along the border-line. However, it certainly is very narrow. We measured actual diffusion of potassium chloride from an N/10 solution against distilled water across the cationic, the anionic and the border-line part of the mosaic membranes using a 2-mm wide, 40-mm long slit for the experiment. Diffusion across the anionic part was about twice as quick as across the cationic part, but it was impossible to measure enhanced diffusion along the border-line: the phenomenon which is so easily demonstrated on the picture evidently proceeds along so narrow a strip that it is swamped in the diffusion of the adjacent normal membranes.

It seems possible that diffusion across border-lines between anionic and cationic membranes might play a part in nerve conduction[1]. The change-over of the nerve potential from inside negative to its opposite together with the enhanced diffusion of salts across the nerve membrane at the point at which the electric impulse is passing could be due to a wave of sign-inversion running along the nerve. This could be because acidic sites in the membrane become esterified to choline or this choline ester hydrolysed, thus changing the sign of fixed ions from negative to positive or vice versa.

Crystal and Molecular Structure of Titanium (IV) Ethoxide

BOTH speculation and controversy on the stereochemistry of the trimeric titanium (IV) alkoxides[1–4] have followed the discovery[5] of their trimeric nature in solution. Opinions have differed on which structure is stereochemically reasonable and on which structure will account in a natural way for the hydrolysis products of titanium (IV) alkoxides, the so-called titanium oxide-alkoxides of composition $Ti_{3x+1}O_{4x}(OR)_{4x+4}$. These titanium oxide-alkoxides have been characterized, at least for $x = 1$ and $x = 3$, as solids[1]. The purpose of this communication is to indicate that titanium (IV) ethoxide is a tetramer in the solid, and hence that this long-awaited X-ray analysis of a titanium (IV) alkoxide not only fails to confirm one of the proposed structures, but also makes unreasonable the assumption, implicit in much of the recent discussions, that the species in solution are identical with those precipitated from solution.

R. L. Martin and G. Winter very kindly supplied several crystals of titanium (IV) ethoxide already mounted and sealed in soft-glass capillary tubes. Methods of preparation and analysis as well as techniques involved to maintain anhydrous conditions have been described previously[6,7]. Crystals from two different batches were examined and found to have identical unit cells. The white, prismatic crystals of titanium (IV) ethoxide belong to one of the space groups C^6_{2h} — $C2/c$ or C^4_s — Cc of the monoclinic system with $a = 19·50$, b (unique axis) $= 14·67$, $c = 17·14$ (all ± 0·03 Å), $\beta = 106·1 \pm 0·3°$. A density of 1·28 g/cm^3 calculated for 16 $Ti(OC_2H_5)_4$ in the unit cell is in satisfactory agreement with a density of 1·23 g/cm^3 found by Crowe and Caughlan[8] and with a density of 1·24 g/cm^3 measured by Martin and Winter by flotation of the crystals in benzene–ethylene dibromide solutions.

From these data alone it is probable that titanium (IV) ethoxide is dimeric or tetrameric. Nevertheless, a complete X-ray determination of the crystal structure was carried out. Three-dimensional X-ray data were collected at room temperature with copper radiation by the equi-inclination Weissenberg technique, and the intensities were estimated visually. The structure was solved by standard procedures: the space group $C2/c$ was assumed; the titanium positions were inferred from a three-dimensional Patterson function; these positions lead to only very slight contributions of the titanium atoms to the l-odd reflexions. As a result, a Fourier synthesis, based on the signs of the l-even reflexions from the titanium contributions, has, in addition to the titanium peaks, two sets of eight major peaks in the asymmetric unit that are related by a false mirror plane. From geometrical considerations one set of eight was chosen. Subsequent least-squares calculations and Fourier syntheses have led to the refinement of the titanium and oxygen positions and to the determination of approximate carbon positions. There is considerable thermal motion, and perhaps some thermal disorder. The temperature factors for titanium are about 6 Å^2, for oxygen about 8 Å^2, and for carbon somewhat higher. Work is in progress to resolve some of the overlapping carbon peaks in the difference Fourier. The usual R factors for the 572 observed reflexions are: 0·12 for all atoms; 0·23 if carbon atoms are omitted; 0·46 if carbon and oxygen atoms are omitted. None of the unobserved reflexions has a calculated intensity which exceeds the estimated minimum. The over-all good agreement is taken as justification for the assumption of the space group $C2/c$.

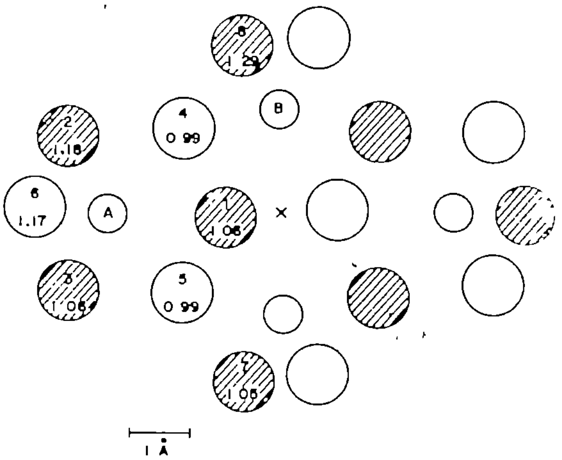

Fig. 1. The tetrameric titanium (IV) ethoxide molecule projected on to the *ab* plane. The four titanium atoms (smaller circles) are in the plane. The cross-hatched oxygen atoms are below the plane; the clear oxygen atoms are above the plane at distances (in Å) from the plane given beneath the atom number. The '×' marks the centre of symmetry of the molecule

The titanium–oxygen arrangement is shown projected on the *ab* plane in Fig. 1. The molecule is tetrameric, and possesses a centre of symmetry. The four titanium atoms lie at the corners of a planar rhomb. Above and below the titanium plane are nearly planar oxygen layers. The titanium atoms are octahedrally co-ordinated by oxygen atoms. There are three different oxygen–titanium interactions. Oxygen 1 is bonded to three titanium atoms at an average distance of 2·23 Å; oxygens 4 and 5 are each bonded to two titanium atoms at an average distance of 2·03 Å; the other five independent oxygen atoms are terminal, with an average distance of 1·77 Å. The estimated standard deviation of a Ti–O bond-length is 0·03 Å, and there are some significant variations among bond distances of a given type. The ethyl groups spread out from the oxygen atoms and lead to a molecule that is approximately cylindrical in shape. All intermolecular contacts are normal.

The structure depicted in Fig. 1 has several satisfying features, most prominent of which are the octahedral co-ordination of the titanium atoms and the readily visualized termination of polymerization. The relation of this structure to those of the titanium (IV) alkoxide species present in solution is as yet unknown. The structure is sufficiently different from any proposed for the trimeric species so that, at the least, reconsideration not only of the features of those structures but also of the proposed mechanisms of hydrolysis seems necessary. What is more important, however, is a re-examination of the evidence in favour of the trimeric species as the largest present. To this end Martin and Winter, as reported in the following communication, have carried out extensive cryoscopic molecular weight studies on titanium (IV) ethoxide and butoxide in benzene. They indeed find evidence for a tetrameric titanium (IV) ethoxide species in benzene solutions.

I thank Prof. R. L. Martin and G. Winter for their wholehearted co-operation.

This work was carried out under the auspices of the U.S. Atomic Energy Commission.

Association of Titanium (IV) Alkoxides in Benzene

The single crystal X-ray structure determination of titanium (IV) ethoxide described in the preceding communication establishes the fact that the molecule is a tetramer formed by the stacking of four TiO_6-octahedra so that edges are shared (Fig. 1). Dr. Ibers's analysis also confirms the long-accepted belief that intermolecular attachment between $Ti(OC_2H_5)_4$ molecules is through ethoxide bridges (two per titanium atom) and reveals that two types of intramolecular ethoxide bridges can be discerned in the molecular unit.

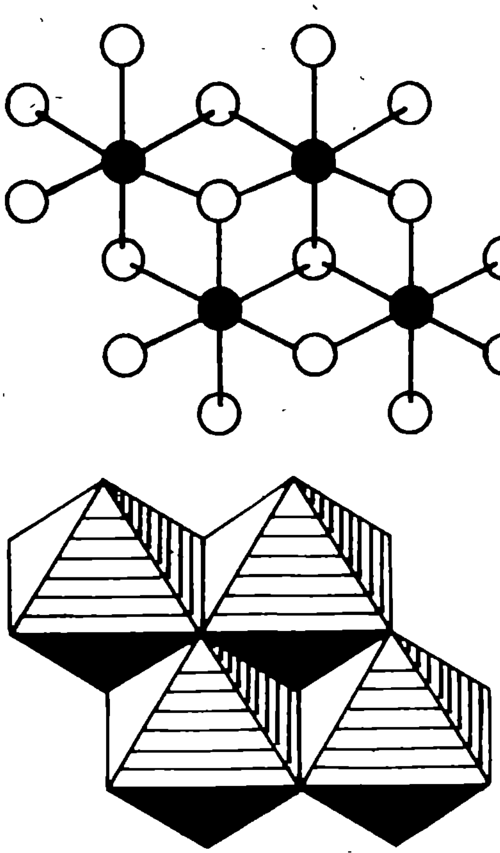

Fig. 1. Molecular structure of $Ti_4(OC_2H_5)_{16}$ showing two types of ethoxide bridging groups and the stacking of the TiO_6-octahedra

While it is not unknown for a structural entity in the solid state to differ from that present in solution, it now becomes important to extend previous cryoscopic measurements in benzene[1,2] to higher concentrations to establish whether the degree of association of titanium (IV) *n*-alkoxides can, in fact, exceed three.

For titanium (IV) *n*-butoxide we have now increased the range of concentration over which molecular weight measurements have been made from 15·1 × 10⁻² to 34·0 × 10⁻² molal, that is, approximately 11·5 wt. per cent (Fig. 2). The degree of association of the butoxide at the highest concentration is 2·6. We have also recently completed studies of the concentration dependence of the degree of association of titanium (IV) ethoxide in benzene using the techniques described elsewhere[2]. The data are presented graphically in Fig. 2 and it will be seen that although the curve rises more steeply than for the *n*-butoxide, even at the highest concentration the experimental degree of association has not exceeded three. Activity effects and problems associated with supercooling intervene in more concentrated solutions so that it cannot be resolved whether average degrees of association greater than three occur

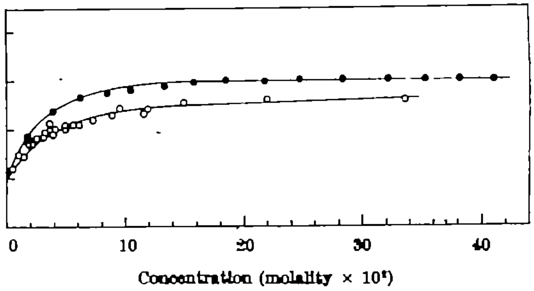

Fig. 2. Degree of association, *n*, of titanium (IV) *n*-alkoxides in benzene. ●, $R = C_2H_5$; ○, $R = n, C_4H_9$

It is significant, however, that while the new data for the butoxide can still be described by the curve previously derived[2] for an equilibrium involving monomeric, dimeric, and trimeric species in benzene, such a description is no longer adequate for the ethoxide. The introduction of at least one further equilibrium species, namely a tetramer, is required to fit the experimental variation of the average degree of association with concentration. Since the experimental values for the butoxide can also be fitted in terms of a similar set of equilibria, it is not possible to resolve cryoscopically whether for this compound also the limiting degree of association is greater than three.

Cryoscopic studies in solvents other than benzene are being made.

Hydration of the Alite Phase in Portland Cement

CALORIMETRIC studies[1-3] indicate that the rate of hydration of the alite phase (tricalcium silicate) in neat Portland cement pastes reaches a maximum 6–11 h after mixing. Two heating cycles, or periods of high heat evolution, are found with all cements; some show a third. The first, occurring immediately on mixing, is most likely due to the dissolving of soluble species and to an initial rapid reaction of the aluminate phase. The second cycle, which reaches a maximum 6–11 h after mixing, is assigned largely to the alite phase. The third heating cycle shown by some cements is attributed to the exhaustion of sulphate ion (gypsum), the breaking down of the ettringite coating on the tricalcium aluminate particles, and the subsequent rapid hydration of the remaining aluminate to $Ca_4Al_2O_{18}\cdot XH_2O$. X-ray diffraction work in this laboratory offers direct evidence that the foregoing conclusion regarding the alite phase is correct.

Twenty grams of a Portland cement are made into a neat paste in a 50-ml. polyethylene beaker using a water-to-cement ratio of 0·25. Hydration is carried out in a carbon dioxide free atmosphere at 95 per cent relative humidity, 25° C. After a predetermined period, the sample is broken up, and the hydration stopped by thoroughly washing with acetone. It is then dried in a vacuum oven for 1 h at 70° C and 10 in. of mercury. A 10-g portion is ground with 10 per cent MgO (periclase) by weight. The 2·11 Å MgO line and the 1·76 Å cement line are used for the X-ray analysis. The 1·76 Å line in the diffraction pattern of a Portland cement is due mainly to the alite phase[4]. The small contribution that belite makes to this line is neglected.

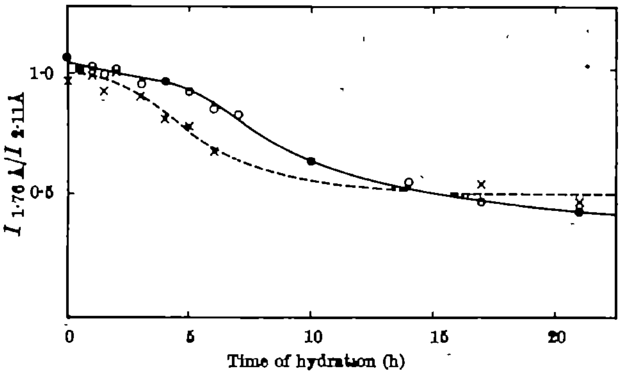

Fig. 1. Hydration of the alite phase in a Type I Portland cement. O, No additive present; ×, calcium chloride added 1·0 per cent by weight of solid material

Fig. 1 is a plot of the ratio of the intensity of the 1·76 Å line to the 2·11 Å MgO line versus the time of hydration for a Type I Portland cement. Each point is the average of three samples. Much of the alite hydration occurs during the period 5–15 h after initially mixing the cement with water. The hydration rate reaches a maximum about 7 h after mixing. When calcium chloride is added to the mix water at a concentration equivalent to 1·0 per cent by weight of calcium chloride to anhydrous cement, the maximum rate of hydration occurs about 2 h earlier. The hydration of the alite phase in the presence of calcium chloride is also shown in Fig. 1. The slight difference in the points at which the two curves intersect the y-axis is due to the fact that the two experiments were carried out on two different diffraction units with slightly different counting periods.

Hydration of neat pastes on the X-ray goniometer itself in a specially designed sample compartment confirms the general nature of the alite reaction. When hydrated in this manner, the alite reaction is most rapid 5–10 h after mixing and reaches a maximum about 6 h after mixing. This technique also shows that a commercial calcium lignosulphonate delays the occurrence of this period of rapid hydration. In Fig. 2 the y-axis is relative. A strict quantitative comparison is not possible when the reaction is followed in the paste itself. This is due to preferred orientation problems and the lack of an internal standard stable in the alkaline cement–water system. No reliable numbers can be obtained during the first few hours of hydration while the paste is still plastic.

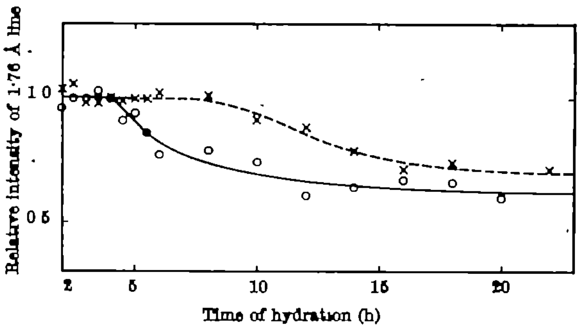

Fig. 2. Hydration of the alite phase in a Type I Portland cement. O, No additive present; ×, a commercial calcium lignosulphonate added, 0·30 per cent by weight of solid material

These results have an interesting relation to at least one physical property of cement pastes and mortars. Calcium chloride is commonly used to accelerate the set of Portland cements, calcium lignosulphonate to retard it.

Preparation of Carcinogenic Polynuclear Hydrocarbons labelled with Tritium by Wilzbach's Method

THE need for radioactive labelled polynuclear hydrocarbon carcinogens, to be used in biological investigations, led to an investigation of the feasibility of a tritium exchange procedure for their preparation. Wilzbach's method[1] offers a simple method of labelling complex compounds which are comparatively difficult to synthesize. However, the procedure has its attendant problems in that, during exposure to tritium gas, concurrent with the exchange reaction, tritium will tend to be taken up by reducible compounds present. The purification of the product must, therefore, ensure removal of the high specific activity by-products.

Samples of benzo(a)pyrene, 7,12-dimethylbenz(a)anthracene and 20-methylcholanthrene (500 mg of each) were exposed to tritium gas for 2 weeks. The specific activities of the products were, respectively, 0·80, 0·46 and 0·70 mc./mg. The distribution of radioactivity in the products was examined by chromatographing 15–100 μg samples on Whatman No. 1 paper in a dimethylformamide–isooctane system[2]; the chromatograms were cut into sections and eluted. The ultra-violet absorption spectrum of each fraction was taken in isooctane and the radioactivity assayed by liquid scintillation counting. Recovery of radioactivity was virtually 100 per cent and of the polynuclear hydrocarbons 90–100 per cent (these being in the single fluorescent zone on each chromatogram). Less than 10 per cent of the radioactivity was associated with the fluorescent zones, the remainder being mainly at the starting line and below the fluorescent zone. These

Table 1. RECOVERY OF TRITIUM IN REACTION PRODUCTS OF PURIFIED HYDROCARBONS

	7,12-Dimethylbenz(a)anthracene	Benzo(a)pyrene	20-Methylcholanthrene
Initial activity (d/s)	275,000	660,000	289,000
Treated with OsO_4, hydrolysed, dehydrated and allowed to oxidize, activity (d/s)	232,000	484,000	204,000
Tritium recovered (%)	84	73	71
Product	5,6-quinone (ref. 4)	4,5-quinone (ref. 4)	6,7-quinone (ref. 4)
Theoretical activity recovered for random labelling (%)	87	83	87
Mild oxidation with $Cr_2O_7^{--}$ activity (d/s)	168,000	376,000	160,000
Tritium recovered (%)	61	57	55
Product	7,12-benz(a)anthraquinone	1,6- and 3,6-quinones (ref. 5)	9-methyl-7,12-benz(a)anthraquinone-8-acetic acid (ref. 6)
Theoretical activity recovered for random labelling (%)	62	83	81
Vigorous oxidation with MnO_4^-, activity (d/s)	121,000	240,000	107,000
Tritium recovered (%)	44	31	37

Theoretical activity recovered for random labelling (%)	38	67	25

fractions showed no ultra-violet absorption and must, therefore, contain material of very high specific activity.

Approximately 400 mg of each of the tritiated products was chromatographed on a 28 × 8 cm column of magnesia-'Celite'[8] and eluted with hexane–benzene, followed by mixtures of hexane–benzene–acetone. The non-fluorescent material preceding the fluorescent zone was collected in two portions, the beginning of the fluorescent zone next and the bulk of the fluorescent material in the fourth fraction. Each was evaporated to dryness and the material in the fourth fraction was crystallized from benzene–ethanol, this being the tritiated polynuclear hydrocarbon.

The yields of crystalline material were, respectively, benzo(a)pyrene 81 per cent, 7,12-dimethylbenz(a)-anthracene 92 per cent and 20-methylcholanthrene 92 per cent. All had sharp melting points, in agreement with those of the pure non-radioactive compounds. It is notable that the dimethylbenz(a)anthracene was colourless, whereas most samples of the non-radioactive compound are yellow, even after purification. The specific activities of the three crystalline hydrocarbons were—benzo(a)pyrene 0·045 mc./mg (11·3 mc./m.mole), 7,12-dimethylbenz(a)anthracene 0·018 mc./mg (4·5 mc./m.mole) and 20-methylcholanthrene 0·017 mc./mg (4·6 mc./m.mole). These values were almost unchanged after recrystallization. Paper chromatography of the compounds after two crystallizations, first on Whatman No. 1 paper in the dimethylformamide–isooctane system, followed by chromatography of the fluorescent zone on acetylated paper with toluene/methanol/water (1 : 10 : 1) as mobile phase[9], showed that more than 90 per cent of the radioactivity, in each case, was in the fluorescent zone containing the polynuclear hydrocarbon. Bearing in mind that some small amount of oxidation probably occurred on each paper chromatogram, this was evidence that the three tritiated hydrocarbons were sufficiently pure for biological experiments.

The distribution of tritium in the three polynuclear hydrocarbons was studied by oxidation to known products, the loss of radioactivity in the course of these reactions (tritium was removed as tritium oxide) being compared with that expected if the tritium were distributed randomly in the molecule. One series of reactions involved oxidation with osmium tetroxide to dihydrodiols, which were dehydrated to phenols and these allowed to oxidize to quinones[4]. The second series of reactions involved oxidation in glacial acetic acid with chromic acid to quinones and quinone acids, followed by further oxidation with acid permanganate to polycarboxylic acids[5–7]. The aromatic products of these reactions were extracted with benzene after dilution with water and the radioactivity assayed. The results are given in Table 1. The absorption spectra of the reaction products showed the absence of the hydrocarbons and the presence of quinones. It appears that tritium was distributed randomly in 7,12-dimethylbenz(a)anthracene, but not in benzo(a)pyrene or 20-methylcholanthrene.

Approximately half the radioactivity of the crude tritiated products was in strongly adsorbed material, probably phenols and other oxygen containing compounds, which could only be eluted by acidification of the absorbent.

The fractions eluted from the column chromatograms below the fluorescent hydrocarbon zone contained reduction products of the polynuclear hydrocarbon and constituted almost half the radioactivity of the crude tritiated products. Paper chromatography of these fractions in the dimethylformamide–isooctane system revealed the major portion of the radioactivity in material travelling near the solvent front, which probably consisted of perhydro compounds. There were fluorescent bands of smaller R_F on each of the chromatograms and these were eluted and examined spectroscopically. Those with indications of the presence of identifiable compounds were rechromatographed in the same system until background absorbing material was removed and spectra were obtained which could be compared with those of known compounds.

No identifiable reduction products were obtained from 7,12-dimethylbenz(a)anthracene. Two reduction products of 20-methylcholanthrene were identified spectroscopically as 6,7-dihydro and 17,20,22,23-tetrahydromethylcholanthrene[9], the yields and specific activities being, respectively, 760 and 180 μg, 6·6 and 15·9 mc./mg. Two reduction products of benzo(a)pyrene were identified as 4,5-dihydro and 7,8,9,10-tetrahydrobenzo(a)pyrene[9], the yields and specific activities of these being, respectively, 86 and 45 μg, 18 and 38 mc./mg. Two other reduction products of benzo(a)pyrene, both with high specific activity, had well-defined spectra but could not be identified with any known compound. One was spectroscopically identical with pyrene and the second had a spectrum similar to that of 7,8,9,10-tetrahydrobenzo(a)-pyrene, but with considerably more fine structure. These two compounds remained chromatographically homogeneous after chromatography in several different systems.

The spectrum of tritiated 7,8,9,10-tetrahydrobenzo(a)-pyrene was identical with that of the non-radioactive compound except that the wave-lengths of the absorption maxima were translated 4 mμ towards the visible. The chemical identity of the two compounds was established by crystallization from hexane of 50 mg of the non-radioactive compound with 40 μg (1·5 mc.) of the radioactive compound, which gave 31 mg of crystals of specific activity 0·028 mc./mg.

The exposures to tritium gas were conducted by the New England Nuclear Corporation. This investigation

was supported by grant C-5170 of the National Institutes of Health, U.S. Public Health Service.

Observations on Potassium Hexacyanotitanate (III)

Schläffer and Götz[1] have recently prepared a complex cyanide of titanium by reacting a liquid ammonia solution of titanium (III) bromide with excess potassium cyanide. Chemical analysis of the dark green precipitate leads to the empirical formula $K_5Ti(CN)_8$. However, comparison of the absorption spectra with those of known trivalent titanium complexes[2,3] showed that the compound contained hexaco-ordinate titanium and should be assigned the formula $K_3Ti(CN)_6 \cdot 2KCN$. Although eight co-ordinate titanium (III) has been reported[4], and cyanide usually results in the highest co-ordination number of the central metal ion, the agreement of the absorption spectra with hexaco-ordinate complexes makes the higher co-ordination doubtful[3]. Carduck[5] has also reported the existence of a dark green complex cyanide of titanium having the formula $K_3Ti(CN)_6 \cdot 3KCl$ prepared by mixing stoichiometric solutions of titanium (III) chloride and potassium cyanide in liquid ammonia. The excess potassium chloride could not be removed from the precipitate by repeated washings with liquid ammonia. It is not clear how the excess potassium-cyanide or potassium chloride is bound to the parent complex[3], but the bond is apparently strong enough to resist removal when washed with excess liquid ammonia[1,5].

Work conducted in this laboratory has shown that a non-contaminated compound possessing the expected hexaco-ordination and the formula $K_3Ti(CN)_6$ may be prepared by mixing stoichiometric aqueous solutions of titanium (III) chloride and potassium cyanide. A typical preparation involved the following steps: titanium (III) chloride prepared by the Union Carbide Metals Co., with a minimum purity of 98 per cent, and potassium cyanide (J. T. Baker's 'Analyzed Reagent' grade), were used for each preparation. Entrained oxygen was removed from the solid reagents by successively applying vacuum and then bleeding the system with argon. This process was repeated five times in order to ensure the absence of oxygen. The distilled water used in the preparations was boiled to remove dissolved oxygen. Argon was bubbled through the water while it cooled and for 48 h afterward. A micro-Winkler oxygen determination[6] on a sample of the water treated in this manner showed that there was considerably less than 0·1 p.p.m. dissolved oxygen present. All glassware used in the preparation was rigorously dried and stored under argon in a dry-box equipped with a vacuum line. A dry-box was used, even though water was present, to ensure oxygen-free conditions. To start the actual preparation, an aqueous solution of 3·90 g (0·06 mole) of oxygen-free potassium cyanide in 250 ml. distilled water was stirred vigorously while a solution of 1·54 g (0·01 mole) anhydrous titanium (III) chloride in 100 ml. distilled water was slowly added. A deep blue curdy precipitate formed immediately and was filtered on a glass frit by a vacuum as soon as it settled. The precipitate was washed with six 25 ml. portions of the oxygen-free distilled water and dried under the argon atmosphere. (Anal., calculated for $K_3Ti(CN)_6$: K, 36·51; Ti, 14·91; CN, 48·58; found, K (as the tetraphenylboron salt), 36·46; Ti (as the oxide after igniting the cupferrate), 14·80; CN (by an argentometric titration after fusion with metallic sodium), 48·12.) When excess cyanide is used in the preparation the deep blue precipitate has the formula $K_3Ti(CN)_6 \cdot KCN$, an apparent seven co-ordination. The extra potassium cyanide was removed by successive washings with distilled water with considerable difficulty. Apparently, in both the aqueous and liquid ammonia systems the extra potassium cyanide and potassium chloride are rather strongly attached to the parent $K_3Ti(CN)_6$. The difference in colour observed between the compound prepared in the aqueous system (deep blue) and that prepared in liquid ammonia (dark green) could be due to a type of crystallization isomer similar to the solvation isomers obtained in the violet and green forms of hexhydrated titanium (III) chloride[7]. The absorption spectra of titanium (III) salts lead one to expect violet or blue colours due to the amounts of red and blue light transmitted[2,8].

Qualitative magnetic measurements by electron paramagnetic resonance indicate that the compound $K_3Ti(CN)_6$ is paramagnetic, quite typical of trivalent titanium compounds with one unpaired electron at the 3*d* level.

On prolonged contact with de-oxygenated water, or on immediate contact with air, the deep blue potassium hexacyanotitanate (III) becomes oxidized. The initial oxidation proceeds quite rapidly, resulting in a pale blue solid which approaches the composition $K_3Ti(CN)_6 \cdot K_2Ti(CN)_6$. Once a 1 : 1 ratio of Ti^{III} to Ti^{IV} is attained, oxidation proceeds more slowly until a snow white product is obtained which yields titanium dioxide, potassium hydroxide and potassium cyanide on contact with water. If the complex cyanide of tetravalent titanium—potassium hexacyanotitanate (IV), $K_2Ti(CN)_6$—does exist, it is quite different from other known complex transition metal cyanides which are hydrolytically stable[9].

When the deep blue solid was placed in a sealed tube under an argon atmosphere it was found to be stable for 10–12 days after which the colour slowly turned to pale blue. Possibly the titanium (III) was attacked by the oxygen in the glass.

BIOCHEMISTRY

Glucose-6-phosphate Dehydrogenase and Aldolase in Lenses of Lactose-fed Rats

IT has been shown that in lenses of galactose-fed rats there is a decrease of glucose-6-phosphate dehydrogenase[1,2] and aldolase[3]. These findings support the statement that there is an interference of glucose metabolism in the lens during the development of galactose cataracts. In the previous experiments[1] glutathione reductase was also determined as a coupled system with the glucose-6-phosphate dehydrogenase through the utilization of the oxidized and reduced forms of nicotinamide-adenine dinucleotide phosphate (NADP). The activity of the glutathione reductase was reduced similarly to the glucose-6-phosphate dehydrogenase. Incubation of normal lens homogenate with galactose or galactose-1-phosphate showed no inhibitory effect on the glucose-6-phosphate dehydrogenase or aldolase activities[2,3]. Considering these results, and also that a lowered amount of soluble proteins per mg lens was found in the lactose-fed rats[3], we came to the conclusion that this was due to a decreased protein synthesis in lenses in this condition. However, aldolase was more affected than glucose 6-phosphate dehydrogenase, which may indicate a more direct action on the glycolytic pathway, which is, quantitatively, the most important pathway of glucose metabolism in lens[4]. The former experiments were performed independently with two different sets of rats. In order to know which of the two pathways is affected first, another group of animals was examined.

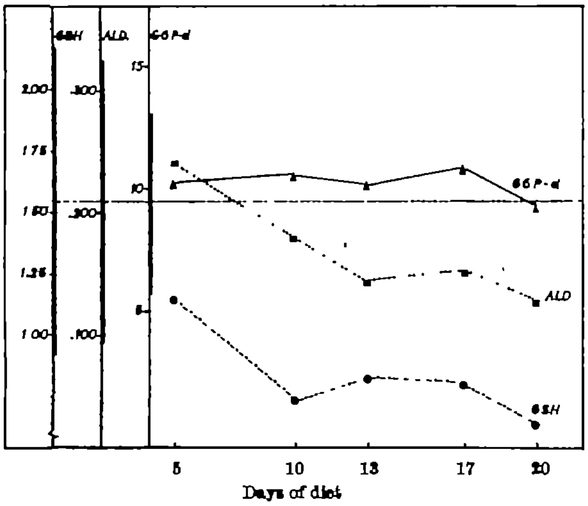

Fig. 1. On the ordinate, GSH (reduced glutathione)-level is given in µg/g lens; G6P-d (glucose-6-phosphate dehydrogenase) activity is expressed as the change in optical density at 340 mµ in 10 min/mg of lens; ALD (aldolase) activity is given in µmoles of substrate converted in 1 h/g lens. The horizontal broken line indicates the mean of paired lenses of eight normal animals. The thicker part of each ordinate shows the range between the mean ± 2 *S.D.* Two animals were killed on each day indicated; the values shown are the mean of both rats

Albino rats, weighing less than 100 g at the beginning of the experiment, were given a diet containing 40 per cent lactose and 60 per cent normal rat chow. Concurrently, another set of rats was maintained on a diet containing 40 per cent cane sugar and 60 per cent normal diet. This low galactose diet was chosen in order to obtain slower changes in the enzyme activities of the lenses. At appropriate intervals the rats were killed by decapitation, and the lenses removed immediately. Both lenses were homogenized with ice-cold distilled water in a glass tissue homogenizer in an ice-bath, and centrifuged at 4° C at 12,000*g*. The supernatant solutions were assayed for glucose-6-phosphate dehydrogenase by Zinkham's modification[5] of the method of Glock and McLean[6], and for aldolase according to Sibley and Lehninger[7] and following Fleisher[8]. In these experiments the level of reduced glutathione was also determined as an index of one of the earliest measurable changes in the lenses of galactose-fed rats[3], according to Beutler's modification[9] of the method of Grunert and Phillips[10].

Fig. 1 shows a very early fall in the glutathione content of the lens, even with this low galactose diet. It may also be seen that the aldolase activity decreases earlier than the glucose-6-phosphate dehydrogenase. After 20 days of feeding, aldolase fell to a lower value than the mean minus one standard deviation of the normals, while glucose-6-phosphate dehydrogenase was still normal. These experiments indicate that even though there is a decrease of the phosphogluconate pathway in the development of cataracts, the glycolytic pathway is affected perhaps more intensively than the other.

Concentration of Nicotinamide Adenine Dinucleotide in Carrageenin-induced Proliferation

It has been shown[1] that the inhibitory effect of cortisone on the respiration of rheumatoid synovial tissue could be reversed by the addition of nicotinamide adenosine dinucleotide (NAD), and as there have been many reports[2,3] of lowered co-enzyme levels in rapidly proliferating tissues, the NAD concentration of normal and proliferating synovial tissue has been determined. Proliferation was stimulated in rabbit synovia by injection into the femorotibial joint of 2 ml. of a 0·2 per cent solution of carrageenin in saline[4]. The synovia were removed after 1, 2, 3 or 5 days. One knee of each rabbit was injected, the other being used as control. A fairly wide range in NAD values between rabbits was found but little difference between knees of the same rabbit. NAD and $NADH_2$ were extracted from the synovial tissue by the method of Jedeikin and Weinhouse[5] and estimated by the fluorescent method using methylethylketone and alkali[6].

Results obtained for NAD are given in Table 1. Values obtained for $NADH_2$ were one-tenth of those for the NAD.

The buffers used in the extraction of NAD did not affect the deoxyribonucleic acid phosphorus (DNA–P) content of the tissue so that it was possible to estimate the DNA–P content of the residue after centrifuging. The residue was washed and DNA–P extracted by the method of Schneider[7] and estimated by Burton's modification of the diphenylamine reaction[8]. The NAD results are thus expressed on a wet weight and DNA–P basis. It is seen that after the first day there is a rise in the co-enzyme concentration on a wet weight basis but when related to DNA–P, that is on a cellular basis, there is a fall in the concentration per cell until the fifth day. The lowest levels are seen on the first and second days after injection, corresponding to the day before and the day of greatest proliferation as shown by the mitotic index[4]. By the fifth day when the rate of proliferation slows down, the difference between injected and normal knees is not significant.

The effect of artificially increasing the concentration of NAD on carrageenin-stimulated growth has been investigated using the granulomata formed in rats by a dorsal subcutaneous injection of 0·2 ml. of a 2·5 per cent solution of carrageenin. 0·2 ml. of a 1·0 per cent aqueous solution of NAD was injected immediately after the carrageenin and a further 0·4 ml. after 2 and 5 days. The rats were killed after 9 days and the granulomata removed and weighed. An equal number of control rats received distilled water instead of the NAD solution. The average

Table 1. NAD Concentrations in Normal and Proliferating Rabbit Synovia

Days after injection	No. of rabbits	NAD concentration µg/g wet weight (µg/g ± *S.E.*)		Ratio of NAD to DNA-P $\frac{\mu g\ NAD}{\mu g\ DNA\text{-}P} \pm S.E.$		
		Left knee (Injected)	Right knee (Control)	Left knee (Injected)	Right knee (Control)	*P**
0 normals	9	19·1 ± 1·2	19·6 ± 1·5	0·42 ± 0·03	0·43 ± 0·045	>0·05
1	8	16·3 ± 2·1	19·8 ± 2·2	0·24 ± 0·03	0·37 ± 0·04	<0·001
2	12	23·6 ± 1·7	21·3 ± 1·3	0·30 ± 0·03	0·44 ± 0·03	<0·001
3	14	28·6 ± 2·4	19·9 ± 1·8	0·31 ± 0·02	0·39 ± 0·03	<0·01
5	6	27·0 ± 1·5	16·8 ± 1·5	0·22 ± 0·01	0·34 ± 0·02	>0·05

* Significance of variance between treated and control knees.

weight for granulomata from 14 rats treated with NAD was 0·544 ± 0·052 g while for control rats the value was 1·18 ± 0·10 g. The difference between these two results is significant ($P < 0{\cdot}01$). Rats which were injected with a 0·5 per cent solution of adenine instead of NAD had granulomata which were not significantly different from the control rats.

Thus, it has been shown that the NAD concentration per cell of carrageenin-stimulated proliferating tissue is lowered and increasing the NAD concentration exerts an inhibitory effect on cell division. A similar inhibition of growth by NAD has been shown in the case of methylcholanthrene sarcoma in rats[9].

Nomenclature of Serum Proteins

HISTORICALLY, the first names and definitions of serum proteins were based on their solubilities. The classification established by Tiselius consists of five or six zones of electrophoretic mobility.

In order to be able to define the constituents of a mixture by at least two entirely independent criteria, we developed immuno-electrophoretic analysis[1]. This technique permits the definition of the constituents by their electrophoretic mobility and by their immunochemical specificity. Moreover, in certain cases, it is possible to introduce in the same experiments, by the use of special staining reactions, a third definition: either enzymatic activity or chemical composition. In the case of human serum, with the aid of convenient immune sera, 30–31 independent constituents can be distinguished[2]. In the sera of some other species similar, but generally smaller, numbers of constituents (due probably to the use of less-potent immune sera) have been described[3,4]. The multiplicity of components detected by immuno-electrophoretic analysis has obliged us, since our first investigation, to elaborate a simple nomenclature which would follow the general trends of the classification of Tiselius. Thus, we use the same Greek letters and indices to define the mobility zones; but we add Roman capital letters to designate the various components present in each zone.

The detection of some new constituents has necessitated our introducing the designation by the Greek letter ρ of those which migrate faster than the serum albumin, in order to stress their rapidity (this designation is preferable to 'prealbumin', because it is not a precursor of serum albumin) and by the letter α_0 those migrating in the zone of serum albumin and of distinctly greater electrophoretic mobility than the α_1 (ref. 2). The immuno-electrophoretic analysis has shown that the proteins which have been designated as γ-globulins form a 'family' of constituents[4], the members of which, although possessing the same antigenic specificity when analysed with hetero-immune sera, have mobilities which extend up to the zone of α-globulins. Therefore, when we detected a new component, the mobility of which was greater than the classical mean value accepted for the γ-globulins, we classified it as a β_2-globulin (ref. 6) and called it β_2A. Another globulin migrating in the same zone, but possessing a very high molecular weight, was called γ_1-macroglobulin by Kunkel *et al.*[7] and later β_2M by us[8].

In science, generally, one tries to preserve the name proposed by the author who first described a substance. Unfortunately, in recent years in different publications, designations have been used which may create confusion. The existence of common determinant groups on the proteins which we call γ, β_2A and β_2M and the existence of antibodies among them has led Heremans[8] to group them as immuno-globulins. More recently, several authors designate all of them by γ and divide them into γ_1 and γ_2 (some add even γ_3 for the slowest).

At first glance it would not seem important to call γ_1 those constituents which we classified as β_2, but, if one admits such a nomenclature, How can one designate those proteins which have the same antigenic specificity and the same sedimentation constant as the slowly migrating γ-globulins, but which possess mobilities of the β- or even of the α-globulins? If we give the name of γ_2 to the slowly migrating γ-globulins, it would be illogical and contrary to the general basis of the classification to designate also by γ_2 those which migrate in the β- or α-zones. On the other hand, if these latter are called γ_1, as some authors do, it would be necessary to find a criterion or a precise definition of the limits which would separate the 'family' into γ_1 and γ_2. So far, we have never observed experimentally, either by mobilities or by general antigenic specificity, any indication of the existence of such limits. The name of γ_{SS} has been proposed to designate the main γ-globulin family[9]; but this would unnecessarily introduce a complication in the usual classification.

Furthermore, it is known that with some immune sera one observes two extended and more or less parallel lines corresponding to γ-globulins and that sera of young children show two distinct γ-globulin precipitation lines, which would indicate some differences in antigenic determinants. Therefore, it seems to us logical to designate by γ without numerical indices the whole 'family', giving the elongated line of specific precipitation and possessing a 7_S sedimentation constant, but to use letters (γ_A; γ_B) for the parallel lines, and to continue to use β_2A, β_2M, β_2B, β_2C to indicate the distinct constituents which migrate in the β_2-zone and which do not necessarily belong to the immuno-globulins. Finally, in the case, for example, of mouse sera the number of relatively slow-migrating components seems larger than in human sera and an additional zone, β_3, has been envisaged to designate some of them[9,10].

It would certainly be desirable that the somewhat complicated nomenclature which we have been obliged to introduce, should be replaced by special names given to every detected component, as soon as its role and physical-chemical properties become known, as, for example, haptoglobin, caeruloplasmin, transferrin, etc.

Isolation of Two Permeability Globulins from Human Serum

A PERMEABILITY factor, activated by dilution or surface contact, has been described in the β-globulin fraction of human serum[1]. This substance, designated *PF/dil*, seems to have much in common with the enzyme kallikrein first noted by Frey[2]. Whether the serum of any given species contains one, or more, permeability globulin has so far not been clear. Based on similarities of hypotensive and permeability properties, it has been suggested that *PF/dil* and serum kallikrein may be the same[3]. Indeed, di-isopropyl phosphofluoridate (DFP) and soybean trypsin inhibitor seem to inactivate both[4-6]. Permeability globulins from guinea pig serum have been reported with the electrophoretic mobility of α_2 (ref. 1) as well as γ-globulin[7]; whether this indicates two molecular species, or is an artefact of preparative procedures, is not certain. Early chromatographic work begun by one of us (J. P. L.) on certain lots of Cohn Fraction III, obtained commercially from human plasma, had suggested the presence of more than one non-dialysable permeability active substance. We wish to report the isolation of two permeability globulins, differing in their electrophoretic mobility and chromatographic behaviour, from sera of normal young men.

Permeability activity was assayed by its bluing action in the guinea pig skin, essentially as described by Miles and Wilhelm[8].

Samples of normal human serum, when subjected to preparative starch-block electrophoresis, demonstrated broad, merging peaks of activity in the γ- and β-globulin regions. Although these findings suggested the presence of two factors with differences in electrophoretic mobility, it was not possible to separate them completely from one another. We therefore turned to ion-exchange chromatography on DEAE cellulose.

As seen in Fig. 1, the proteins of whole serum were separated with the use of a variable ionic gradient, and two, non-dialysable, discrete peaks of permeability-inducing substances were found. The first of these (*A*) was eluted with a buffer conductivity of 0·0066 mhos, principally with the serum γ-globulins. The second peak (*B*) desorbed from the column at a higher ionic strength (between 0·0200 and 0·0351 mhos), along with a mixture of γ- and β-globulins. Because of the small amounts of active material present, attempts at starch-block electrophoresis of these fractions failed to recover activity, so that preliminary fractionation of larger amounts of serum was undertaken.

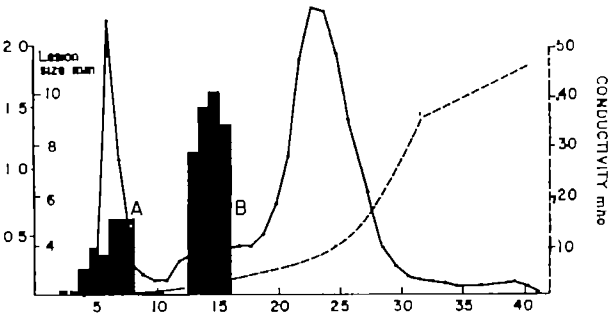

Fig. 1. DEAE cellulose chromatography of 4 c.c. of whole serum. Starting buffer: 0·005 M phosphate—conductivity 0 0069, pH 8·10, final buffer: 0 0125 M phosphate + 1 M sodium chloride—conductivity 0·459, pH 8 10. 10 c.c. collected in each tube. Column 20 cm × 2 cm packed with DEAE cellulose (approx. 9 g, 0·92 m.equiv./g) under 5 lb./in.² pressure. Bioassays were carried out in dilutions of 0·15 M saline. ——, Protein concentration; ---, conductivity; shaded, bioassay of 1 : 3 dilution of content of each tube

247 ml. of pooled human serum were fractionated with ethanol, according to the method 10 of Cohn *et al.*[9]. Permeability increasing activity was present mainly in fractions I + III-3, and III-1, 2, with trace amounts in fraction III-0. The first two of these fractions were separately chromatographed on DEAE cellulose, under the same conditions as for whole serum. From each fraction, two peaks of activity were again recovered in the same positions as shown in the elution diagram for whole serum (Fig. 1).

Samples of fraction *A* obtained from the chromatography of the two ethanol fractions were pooled, as were those of fraction *B*, and each was run in starch-block electrophoresis, with good recovery of activity. The permeability activity in fraction *A* migrated towards the cathode in the manner of the serum γ-globulins. Activity from *B* moved towards the anode with the mobility of β-globulin.

Active samples of *A* and *B* were recovered after electrophoresis and each was rechromatographed on DEAE cellulose, with no change in chromatographic behaviour.

The active fractions *A* and *B* were both inhibited by 50 μg/ml. of soy-bean trypsin inhibitor, or 5×10^{-4} M DFP after incubation at 4° C for 1 h.

Treatment of guinea pigs with the antihistamine diphenhydramine (20 mg/kg intraperitoneally, 2 h before testing) did not prevent the action of either permeability globulin.

In view of the report[10] of little affinity of serum kallikrein preparations for DEAE cellulose, the identity of the γ-globulin factor with serum kallikrein, and of the β-factor with *PF/dil* of Miles may be suggested.

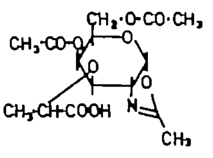
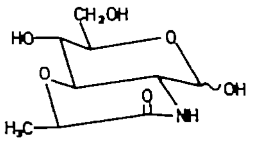
Acetyl Derivatives of Muramic Acid

ATTEMPTS to prepare the fully acetylated methyl ester of muramic acid for subsequent use in the Koenigs-Knorr condensation have led to some unexpected compounds. A lactam II ('muramo lactam') was obtained when muramic acid[1,2] was treated with diazomethane at 0° and the excess evaporated immediately to avoid methyl glycoside formation[3]. Lactam II, which can also be obtained by the action of di*cyclo*hexylcarbodiimide (DCC) in dimethyl sulphoxide for 48 h at room temperature, had negligible methoxyl content, negative ninhydrin and lactone[4] reactions and a broad absorption in the infra-red spectrum at 1,655 cm^{-1}, indicating its lactam character.



(I)



(II)

Acetylation of muramic acid with pyridine and acetic anhydride (24 h at 40° C) and crystallization of the product from ethanol gave a mixture of two isomeric compounds III and IV in 26 per cent yield. Chromatography of the residue from the ethanolic mother liquor on silicic acid gave more of crystalline IV and a further crystalline isomeric compound V. Compound IV appears to be sensitive to even mildly alkaline agents. Similar acetylation of lactam II and crystallization from ethanol gave compound III in 37 per cent yield.

The infra-red spectra of III and IV do not show amide II bands; the spectra are not changed by treating the compounds with diazomethane so it is unlikely that either compound could be an isomeric acid oxazoline I. It is therefore assumed that they are anomers of tri-*O*-acetylmuramo lactam and, if this is so, the optical rotations indicate that III has the β- and IV the α-configuration. The infra-red spectrum of V shows amide I and II absorptions and with the analytical figures this indicates that V is a fully acetylated 6- or 8-membered lactone of *N*-acetylmuramic acid. Another lactone of muramic acid has been reported[5].

For the preparation of *N*-acetylmuramic acid VI, the use of acetic anhydride, which might cause intramolecular cyclization, was avoided and *N*-acetoxyphthalimide[6] (prepared in 84 per cent yield from acetyl chloride and finely ground sodium *N*-hydroxyphthalimide[7] in benzene) was used. Triethylamine (1 equiv.) in methanol was added to muramic acid (1 equiv.) in about 90 per cent methanol at 0°, followed immediately by *N*-acetoxyphthalimide (1·4 equiv.) in ethyl acetate. After 0·5 h at room temperature the solution was evaporated, the residue dissolved in water and filtered. Treatment with 'Amberlite 1*R* 120' (H$^+$ form) until the filtrate was acidic, extraction with portions of ethyl acetate (until these no longer coloured sodium bicarbonate solution) and evaporation of the aqueous solution gave VI as a crisp foam in nearly quantitative yield.

Acetylation of VI and crystallization from ethanol gave the lactone V (32 per cent yield). Methyl *N*-acetylmuramate VII (found —OCH$_3$, 10·8 per cent, calculated 10·1 per cent) was prepared from VI with diazomethane and could not be crystallized. Acetylation of VII gave a product which was separated by chromatography on silicic acid into two isomeric fractions, VIII (crystallized from benzene) and IX (crystallized from ethanol). The overall yield of crystalline VIII and IX from muramic acid was 69 per cent in the ratio 9 : 1. From the analyses, these are assumed to be the anomers of methyl tri-*O*-acetyl-*N*-acetylmuramate, and the optical rotations indicate that VIII has the α- and IX the β-configuration.

Combination Analysis of Rabbit Serum Proteins, using High-resolution Porath Zone Electrophoresis and Starch-gel Electrophoresis

Two-dimensional electrophoresis by the method of Poulik and Smithies[1] provides a powerful tool for the identification of serum protein bands separated in unidimensional starch-gel electrophoresis. It has in some cases revealed the presence of unsuspected components which are masked by others in the unidimensional run[2]. The method is, however, severely limited by small loading of protein sample possible by means of filter-paper insertion. Some improvement may be gained by making the preliminary run in agar where not only is the loading higher but also the resolution is more powerful than on paper. Thus two α_1 and two α_2 components are to be distinguished in agar runs of rabbit serum[3].

In order to start the starch-gel electrophoresis of the second phase of a two-dimensional analysis with an adequate loading of protein, it was decided to concentrate fractions from a Porath zone electrophoresis experiment. Protein concentrations were brought back to 1 per cent or somewhat more, with the exception of the fractions from the small γ_2 peaks.

The analysis obtained by this combination of methods is presented in qualitative form in Figs. 1 and 2. It is immediately apparent that there exists a much greater complexity of serum protein components than has previously been recognized. Albumin has been run off the Porath column and is not retained in the analysis. Four α components are recognized in the Porath scan, and three of these, α_{1a}, α_{1b} and α_{2b}, have been concentrated and run on starch. α_{2b} appears to be resolved scarcely from the β_1, yet the gel analysis shows a marked difference of composition between even these two closely adjacent fractions. Little slow α_{2b} macroglobulin, for example, is present in the β_1, and the heavily staining major β_1 component is only slightly represented in the α_{2b}.

Perhaps the most interesting finding lies in the demonstration that the leading slow α band is an α_{1b} and to a lesser extent an α_{1a} component. Here is a first example of an α_1 slow component, possibly macroglobulin, normally present in rabbit sera in our experience, though apparently not demonstrated by the older horizontal starch-gel technique. A component similar to the slow α_2 has been demonstrated to appear during pregnancy and certain tumour-bearing conditions in the rat[4]. We are investigating the presence of this component in other species.

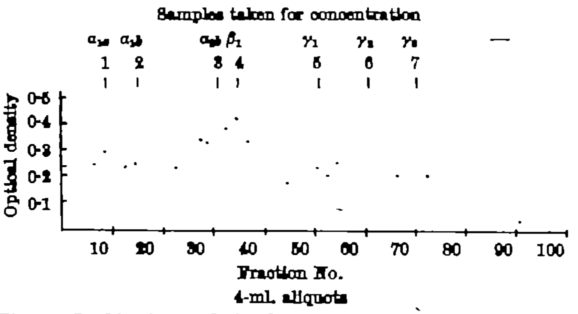

Fig. 1. Combination analysis of normal rabbit serum protein. First phase, Porath column electrophoresis showing fractions cut for reconcentration to 10 mg/ml. protein content

A further point of interest is that the γ_1 (or β_2) fraction gives a single rather diffuse zone which has in fact greater mobility than the slow α_1 and thus lies ahead of it in the unidimensional pattern. Most accounts in the literature fail to mention the presence of γ material so far ahead of the well. The resolution of the γ-globulins would thus appear to be much greater on starch than is generally supposed, although they do not form sharp bands. It is open to question whether this γ_1 zone includes the γ_1 macroglobulin, and work is in progress to investigate this point.

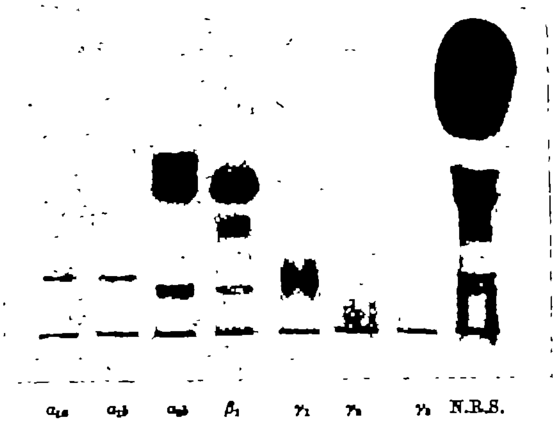

Fig. 2. Second phase. Vertical starch-gel electrophoresis of the series of concentrates derived from Fig. 1. N.R.S., Normal rabbit serum

The total number of components recognized as distinct by visual inspection of the original gel, and not shared by adjacent fractions, we record as 25 in this analysis. This compares with the previous 10–11 distinguished in this species by unidimensional starch-gel electrophoresis. Since several of the major zones, such as $f\alpha_{1a}$, $f\alpha_{1b}$ and γ_1, are diffuse, it may be that further refinements of technique will lead to sub-fractionation of some of these also. No attempts have yet been made to vary buffer conditions from those established by Smithies.

Zone electrophoresis was carried out by Porath's method[5] on a column kept at about 5° C, of dimensions 90 cm long and 2·5 cm diameter, on Munktell prepared cellulose, using veronal buffer pH 8·5, $i = 0{\cdot}05$.

The run was for 120 h at 1,000 V, 20 m.amp.: elution set at a flow-rate of about 16 ml./h. Aliquots of approximately 4 ml. were collected on a time-controlled 'Beaumaris' fraction collector working overnight. Albumin was run off the column, being collected in a dialysis sack tied over the outlet. Protein determinations were made on alternate samples, using the method of Lowry *et al.*[6]. Starch-gel electrophoresis was carried out by the vertical method of Smithies[7] using his buffer solutions.

Essential —SH Groups in Liver Ketohexokinase

PREPARATIONS of liver ketohexokinase (ATP: D-fructose 1-phosphotransferase) phosphorylating fructose at C-1 have been obtained mainly by Leuthardt and Testa[1,2], Staub and Vestling[3], Hers[4], Kuyper[5] and Parks[6]. Recently, Cadenas and Sols[7] obtained a preparation from intestinal mucosa. The importance of the —SH groups of the enzyme has not been investigated, except by Kuyper, whose results were rather negative[5].

Our ketohexokinase preparation was obtained from beef liver, according to Parks's method, omitting the second fractionation with methanol, introducing small modifications and lyophilizing for better conservation. This preparation phosphorylates 11 μmoles of fructose/mg protein nitrogen in 20 min, under the conditions set up by Hers[4]. It also phosphorylates sorbose at a velocity of 57 per cent of that of fructose. The Michaelis constant for fructose is $4{\cdot}6 \times 10^{-4}$ M.

With this preparation we have tested for —SH groups with four reagents.

The *p*-chloromercuribenzoate is a strong inhibitor of the ketohexokinase. At 8×10^{-5} M concentration, the whole enzymatic activity disappears. This inhibition is partially reverted by cysteine 2×10^{-4} M and the recuperation reaches up to 90 per cent with cysteine 2×10^{-3} M. If the unbound inhibitor is removed by dialysis, the same effect is observed.

N-ethylmaleimide, another effective —SH reagent, is also a powerful inhibitor of the enzyme, as is shown in Fig. 1.

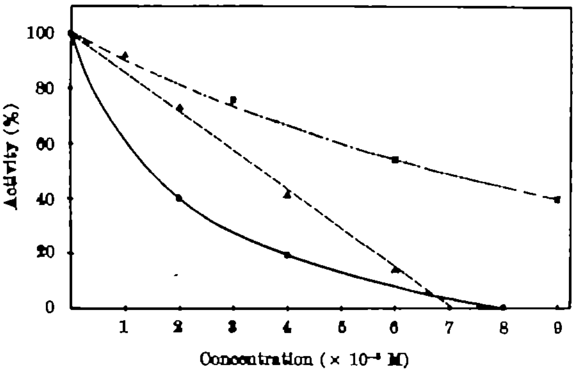

Fig. 1. Inhibition of ketohexokinase by *N*-ethylmaleimide, *o*-iodosobenzoate and *p*-chloromercuribenzoate. Reaction mixtures: 0·5 ml. enzyme solution with or without inhibitor, 0·1 ml. fructose 0·4 per cent, 0·1 ml. ATP 0·05 M, 0·1 ml. $MgAc_2$ 0·05 M, 0·3 ml. KAc 4 M, 0·1 ml. NaF 0·5 M, at 37° C, 20 min. ■, *o*-Iodosobenzoate; ▲, *N*-ethylmaleimide; ●, *p*-chloromercuribenzoate

o-Iodosobenzoate as well inhibits the enzyme. The inhibition is about 50 per cent at 6×10^{-5} M and reaches 100 per cent at $2{\cdot}5 \times 10^{-4}$ M. Cysteine does not produce reactivation even at a concentration of 10^{-3} M.

It has been reported[5] that iodoacetate does not inhibit ketohexokinase. However, if the enzyme solution is previously maintained in the presence of 0·02 M iodoacetate at 37° C for some time, the enzymatic activity becomes clearly inhibited. This inhibition increases with the time of previous incubation.

If iodoacetic acid is recrystallized several times, some diminution of the inhibitory effect is observed. However, the monoiodoacetate action cannot be attributed to the possible presence of iodine. In fact, iodine is an inhibitor of the enzyme, but only at concentrations higher than 10^{-5} N, which cannot be found when the recrystallized monoiodoacetic acid is used. The inhibitory effect of iodoacetic acid is not due to the possible decomposition products formed from it during the time of previous incubation, nor can it be attributed to a thermal inactivation of the enzyme. Neither is the *p*H appreciably modified during the previous incubation.

These results seem to offer sufficient evidence for the presence of essential —SH groups in the ketohexokinase. The behaviour with monoiodoacetate can be explained by a lower reactivity between the sulphidryl groups and this inhibitor.

Isolation of a Polar Aldosterone-like Substance from the Urine and Adrenal Incubates of Patients with Arterial Hypertension

A CONJECTURED role of disordered sodium-retaining function of the adrenal cortex in the genesis of essential hypertension has been largely founded on indirect evidence[1,2], including the rationale of low-sodium intake[3,4] and of naturetic agents[5,6] in therapy; and on direct steroid measurements[7,8]. These latter have shown hyper-excretion of the mineralocorticoid, aldosterone (11β,21-dihydroxy-20-oxo-pregn-4-ene-18-al), and its major metabolite, tetrahydroaldosterone (3α,11β,21-trihydroxy-20-oxo-5β-pregnane-18-al), in uncomplicated as well as complicated forms of this disease. These observations have favoured the hypothesis that essential hypertension may represent, in effect, a special form of hyperadrenocorticism. Correlation of normal aldosterone regulation with the renin-angiotensin mechanism in the kidney[9,10] has further focused attention on possible regulatory abnormalities of aldosterone in the pathogenesis of arterial hypertension.

Investigations here of mineralocorticoid function in essential hypertensives have led to the isolation from urine and adrenal incubates of an uncharacterized substance, designated as X_2, which may be chemically and physiologically related to aldosterone but differing from aldosterone in that it is chromatographically more highly polar (? hydroxylated) in character. The isolation of this substance, and of three other highly polar metabolites (X_1, THX_1 and THX_2), occurred fortuitously as a result of the application of reversed-phase partition chromatography[11] to the concurrent measurement of aldosterone and tetrahydroaldosterone in urine. This chromatographic modality has been considered of particular value for the separation of relatively polar C_{19} and C_{21} steroids which, because of retarded mobilities, are poorly resolved in conventional liquid–liquid systems. Our interest in this unknown substance was intensified by its absence in the urine of normal subjects under basal conditions. The results of our biosynthetic studies have also stimulated this research. An adrenal site of biogenesis of X_2 has been suggested by the incorporation of ^{14}C-acetate into this fraction during *in vitro* incubations of surviving adrenals surgically removed from one patient with essential hypertension (3·0 μg/g tissue/3 h) and from another patient with Cushing's syndrome due to adrenocortical hyperplasia (2·1 μg/g tissue/3 h). A relationship of the excretion of this metabolite to stress and to cardiovascular disease was early seen on its discovery in the urine of a subject who, while being studied by us during the course of intense psychological stress, developed sinus tachycardia, mild hypertension, and retinal hæmorrhages.

The mobilities of this metabolite isolated from the urine of hypertensives by reversed-phase partition chromatography, eluted and rechromatographed in two different systems as the acetylated derivative are shown in Table 1. Aldosterone and tetrahydroaldosterone were used as reference compounds. Inferences drawn from these studies were that X_2 is more polar than either of the foregoing and that it probably possesses four or five acetylable hydroxyl groups. From its solubility in organic solvents and its exhibition of a 239 mμ spectroscopic absorption maximum, we have assumed X_2 to be a Δ^4,3-ketonic steroid. Further semi-qualitative information derived from chromagen formation has shown a similarity of this substance to aldosterone with respect to the presence of an α-ketolic function at carbon 21 and has confirmed the absence of a 17α-hydroxyl substituent.

Table 1. CHROMATOGRAPHIC MOBILITIES

Hypomania †	1	14·6	609·0	109 2

* Standard recovery, 91 ± 8 per cent.

† ? Sodium intake; ? excessive sweating.

Investigations designed to demonstrate the possible physiological implications of X_2 have shown that its excretion could be induced by sodium deprivation and psychological stress, while exogenous corticotrophin appeared to be an ineffective stimulus (Table 2). Its maximal excretion during psychiatric hyperactivity will be noted.

A systematic study of mineralocorticoid excretion, including X_2 (measured as α-ketolic material), was undertaken in arterial hypertension. These results are shown in Table 3. It would seem that the excretion of X_2 described a provocative, if unknown, feature of essential hypertension and of hypertension associated with two hyperadrenocortical disease entities. None of this substance was found in the urine of patients with hypertension and hypokalæmic alkalosis due to unilateral renal disease. Of significance, it is believed, was the discernment of X_2 during each of the stages in the evolution of essential hypertension, including its earliest detectable expression in two genetically predisposed subjects.

Table 3. ARTERIAL HYPERTENSION* (URINARY EXCRETION, μG/24 H)

Ætiology of hypertension	No. of patients	Aldosterone	Tetrahydro-aldosterone	X
Essential, early	2	8·6	24·0	16 0
Essential, advanced	5	79·5	108·3	86·5
Essential, advanced with hypokalæmic alkalosis and mild azotæmia	2	321·3	328·0	64·1
Conn's syndrome	3	66·0	859·1	25·2
Cushing's syndrome	1	45·6	24·1	10·8
Unilateral renal disease	2	47·5	47·3	0

* Does not include patients with œdema, congestive heart disease, ascites, etc , or those on sodium restriction.

The implications of this work are that the unknown substance X_2, conceived at present as a Δ^4,3-ketonic steroid physiologically and chemically related to aldosterone. is a stress-directed biosynthetic product of the adrenal which may play a part in the pathogenesis of essential hypertension and in the hypertension of hyperadrenocorticism. Chemical and physiological characterization studies of this substance are now in progress.

We thank Dr. Horace Martin, of Monsanto Research Corporation, Everett, Mass., for his co-operation in the characterization studies and for doing the gas-chromatographic analyses. We also acknowledge the support of research grants Nos. *CA* 06745 and *HE* 07041 from the National Institutes of Health, Bethesda.

Solubility of Bean Leaf Protein in Ethanol

IT has been generally held that leaf proteins are insoluble in 80 per cent ethanol or similar solvents[1]. This belief has furnished a useful means of distinguishing two forms of nitrogen, 'soluble' (that is, amino-acids and peptides) and 'insoluble' (that is, proteins and nucleic acids). We became aware of a possible discrepancy in this logic when an alcohol-soluble 'peptide' fraction of bean leaf displayed an amino-acid composition indistinguishable from the bulk protein. Further tests, which included the biuret[2] and Folin[3] assays, trichloroacetic acid precipitability, and stainability with light green, indicated the protein-like nature of this 'peptide'. The recovery of such presumed protein from fresh bean leaves was about 1 per cent of

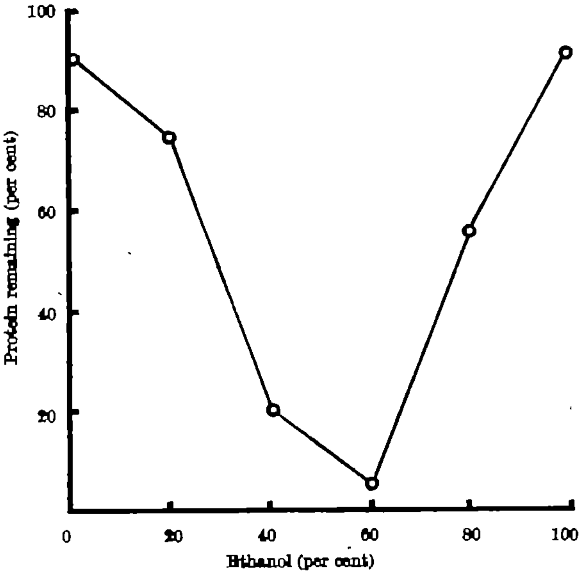

Fig. 1. Solubility of bean leaf protein, precipitated by trichloroacetic acid, in ethanol–water mixtures. The vertical axis shows the percentage protein which did not dissolve

the total protein. When examining peptide metabolism, this error would be more or less serious depending on the amount of peptide present. The amount usually present in bean leaves was quite low judging by paper chromatographic methods[4], hence the presence of ethanol-soluble protein was an unfortunate complication.

To establish the limits of bean leaf protein solubility in ethanol, freshly prepared protein solutions in buffer were treated with trichloroacetic acid and the resulting precipitates digested for 5 min with 4 ml. of varying concentrations of hot ethanol–water. The remaining precipitates were dissolved in 0·5 N sodium hydroxide and assayed with modified Folin reagent[3]. The results (Fig. 1) show that the protein was maximally soluble in 60 per cent ethanol. Experiments with protein precipitated by hydrochloric acid showed similar results. Likewise, other solvents such as acetone, methanol, and isopropanol had an equally great solvent action on the protein precipitates.

This anomalous behaviour had earlier been considered unique for insulin and serum albumin[5]. Whatever the cause of such solubility, we must re-evaluate the proposition that 80 per cent ethanol-extractable nitrogen does not contain protein. It seems possible that some leaf protein may be in the acid-denatured state either naturally (as a result of cellular senescence), or as an artefact of grinding which brings low *p*H materials into contact with native proteins.

Solubilization and Proteolytic Activation of Glucose-6-phosphatase from Microsomes of Bovine Livers

IN earlier publications[1,2] we described the preparation of soluble glucose-6-phosphatase (G6Pase) from microsomes of bovine liver. We always found that a combined treatment of the microsomes with sodium deoxycholate and digitonin leads to a reproducible solubilization of this enzyme. However, it was noted that G6Pase is very sensitive towards sodium deoxycholate and under the latter's influence activity is markedly diminished.

For this reason we looked for another possibility of treating microsomes with sodium deoxycholate in order to elucidate their structure. Heise and Kleitke[3] found that the fructose-1,6-diphosphatase is activated by trypsin in a proteolytic manner. Therefore, expecting a similar attack on the microsomes by trypsin we examined the influence of variable concentrations of trypsin and times of incubation on the disintegration of the structure of the resuspended microsomes. After discovering the best conditions of treatment with trypsin we examined the influence of the time of incubation with digitonin on the pretreated particles.

In order to prepare microsomes, bovine livers were minced mechanically and this was followed by homogenization of the liver in saline in Potter–Elvehjem-homogenizer with a 'Teflon' pestle for 90 sec. Undisrupted cells, nuclei and mitochondria were removed by centrifugation at 18,000*g*. By mixing the homogenate with 0·1 M citrate buffer *p*H 5·4 the microsomes were agglutinated and separated by centrifugation at 18,000*g* for 20 min.

Determination of activity was carried out by incubation of the samples with glucose-6-phosphate at 38° C (ref. 4). The liberated phosphate was measured by the method of Fiske and Subbarow[5]. Absolute activity was defined as µmoles liberated phosphate/h in 1-ml. sample; the specific activity as µmoles liberated phosphate/mg protein. Determinations of the protein were carried out by the biuret method and by the method of Lowry *et al.*[6] to reveal very small amounts of proteins.

We incubated the suspension of microsomes with trypsin at 40° C, the optimal temperature of this enzyme. Using 'Trasylol', a specific inhibitor of trypsin, we were able to prevent the action of the proteinase. 50 Kallikrein inactivator units of 'Trasylol' inhibit 100γ of crystalline trypsin ('Trasylol,' Trypsin-Kallikrein-Inaktivator: Bayer-Leverkusen). However, the amounts of 'Trasylol' necessary for the complete inhibition of trypsin needed for a successful treatment of the microsomes were too large for economic use. Therefore we prevented the action of trypsin by a rapid refrigeration of the samples in an ice-bath, washing the residue obtained by centrifugation.

To 1·0 ml. of suspended microsomes with 150 mg proteins, 2·5 ml. of solutions of trypsin of variable concen-

trations and 0·5 ml. 'Trasylol' or 0·5 ml. distilled water respectively were added to obtain a final volume of 4·0 ml. for incubation.

Four concentrations of trypsin (0·1, 0·3, 0·5 and 1·0 mg trypsin/ml. suspension) were applied. The influence of the time of incubation on the activity of the G6Pase was also examined. Alterations of enzymatic activity were expressed in per cent, taking the activity of the untreated microsomes as 100 per cent. According to Swanson[7] the activity of G6Pase is not proportional to dilution. However, our experiment showed that good proportionality exists up to a dilution 1 : 3.

The results obtained are illustrated in Figs. 1 and 2. Fig. 1 shows the influence of trypsin inhibited by 'Trasylol' on the activity of G6Pase; Fig. 2 shows the influence of trypsin without 'Trasylol' on the activity of the G6Pase. It can be seen that both methods alter the activity of G6Pase in the same manner. It was surprising that there were two peaks of enzymatic activity at 0·1 mg and at 0·5 mg trypsin. This fact can be explained either by assumption of two isoenzymes of the G6Pase or by the existence of two different activable centres in the same molecule of the enzyme. The lowered altitude of the second peak can be interpreted by assumption of a proteolytic activation of a G6Pase molecule, which is already damaged by trypsin.

It can be seen that incubation for 50 min at a concentration of 0·1 mg trypsin appeared to be the most favourable pretreatment of the microsomes for the preparation of soluble G6Pase.

Examining the influence of digitonin, the washed and centrifuged residue of the trypsin-treatment was mixed with the same amount of 2 per cent solution of digitonin and stirred at 0° C. After different times (5–120 min) aliquots of the mixture were removed, mixed with the same amount of 0·1 M citrate buffer *p*H 5·4 and centrifuged at 18,000*g*. Thereafter we determined the enzymatic activity in the supernatant and in the resuspended residue.

The results of these experiments are summarized in Table 1. It can be seen that the time of digitonin-action is without influence on the solubilization of the enzyme. For this reason we suppose that a 30-min action of digitonin is sufficient for loosening the G6Pase from trypsin-pretreated microsomes.

PHYSIOLOGY

A Linear Transfer Function underlying Impulse Frequency Modulation in a Cockroach Mechanoreceptor

Pringle and Wilson[1] have indicated the potential usefulness in neurophysiology of the linear transfer function concept of the engineering sciences[2], in their investigation of the dynamic behaviour of the mechanoreceptor of the large tactile spine on the femur of the cockroach *Periplaneta americana*. They have pointed out in particular that adaptation of impulse frequency following a step function stimulus (the step function transient response) and the responses to be expected from stimulation with sinusoidal forcing functions (the steady-state frequency response) are related through the transfer function, and that independent observations made with these two stimulus forms can therefore be compared to test the validity of proposed models of dynamic behaviour. In their work[1], these authors proposed that the present receptor adapts according to a time function containing three exponential terms. However, only a small range of forcing frequencies was available for their frequency response study, and their conclusion was based largely on an interpretation of the adaptation curve. Moreover, the close agreement of their sinusoidal data with this model is evidently due to a miscalculation of three coefficients in their equation (2).

In the investigation reported here we have extended this work, following essentially the same theoretical and experimental approach except in details of apparatus and methods of data analysis. In our preparation the isolated femur was mounted by insect pins, which also served as recording electrodes, on the armature of a strain gauge dynamometer (Statham *G*1-4-250), which recorded the tension applied to the spine by a servogalvanometer (Sanborn 171) driven with square or sine waves by an electronic function generator (Hewlett-Packard 202*A*).

In a study of more than 20 receptors, the discharge patterns (Fig. 1) were in general agreement with those of Pringle and Wilson[1]. With sinusoidal forcing, impulse frequency modulation usually occurred over a tension-dependent range of forcing frequencies lying between 0·01 and 100 c.p.s., with modulated impulse frequency approximating a clipped sine wave at the forcing frequency (Fig. 1, inset). Continuous firing throughout the forcing cycle was found on only one occasion. Usually with forcing frequencies below the frequency modulating range no discharge occurred, and above this range there was a single impulse per cycle, as with other mechanoreceptors under vibrational stimuli[1,3,4]. In analysing the clipped sinusoidal discharges we have computed the mean and fundamental terms of Fourier series of the impulse frequencies, using a digital computer. The result is a sine wave at the forcing frequency, fitting the data in the least squares sense, and filling in the silent part of the response cycle with fictitious negative impulse frequencies (Fig. 1, inset). These sine

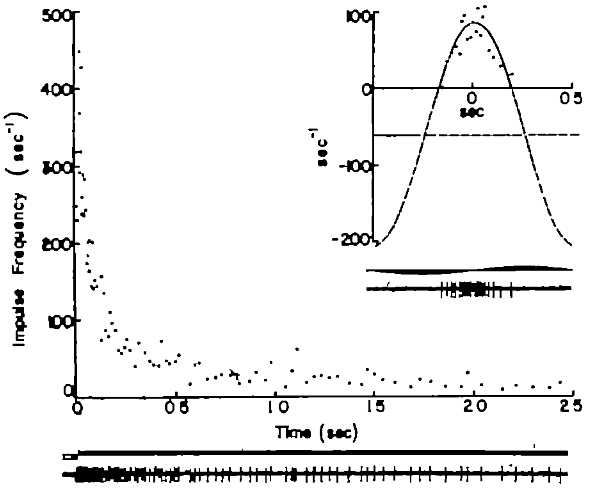

Fig. 1. Transient response to step function of applied tension (main graph) and steady state response to 1 c/s sinusoidal forcing function (inset). Tension applied 0·65 mm from base of spine; tension records above impulse discharge traces indicate range 0·8 – 2·4 kdynes increasing upward, and mean tension 1·6 kdynes in both cases. Spike amplitudes 100 μV. Sine wave through impulse frequency plot in inset is fundamental term of Fourier series of the discharge

waves were taken as the response in evaluating the frequency response function from sinusoidal stimulation data.

The step function transient responses of most of the receptors could be adequately described by a power relation of the form:

$$y = B\,t^{-k} \tag{1}$$

in which y = impulse frequency, t = time, and B and k are linear regression coefficients of log (y) on log (t) (Fig. 2). Thus B is related to sensitivity of the receptor and k to adaptation rate. Landgren[5] has reported a similar relationship for carotid sinus baroreceptors in the cat. The corresponding linear transfer function is given by the Laplace transform of equation (1) divided by that of the step function stimulus, as:

$$F(s) = B\ \Gamma(1-k)\ s^{k} \tag{2}$$

in which s is a complex variable (the 'complex frequency', p in the notation of ref. 1), $\Gamma(1-k)$ denotes the Γ function, and B and k are as in equation (1). The imaginary values of s correspond to the forcing frequencies of sinusoidal stimulation; substituting these into equation (1) yields the frequency response function:

$$F(j2\pi f) = B\ \Gamma(1-k)\ (2\pi f)^{k}\ \exp(jk\,\pi/2) \tag{3}$$

in which $j = (-1)^{1/2}$ and f = cyclic forcing frequency. Hence in this model the expected sinusoidal modulation leads the stimulus by a constant phase angle, $k\,\pi/2$ radians, and modulation sensitivity (response/stimulus amplitude ratio) increases as the k power of the forcing frequency. By contrast, a triple exponential adaptation model predicts in-phase modulation at low forcing frequencies, with increasing sensitivity and leading phase angles passing through one or more maxima at intermediate frequencies, terminating asymptotically in a greater in-phase sensitivity at higher frequencies[1].

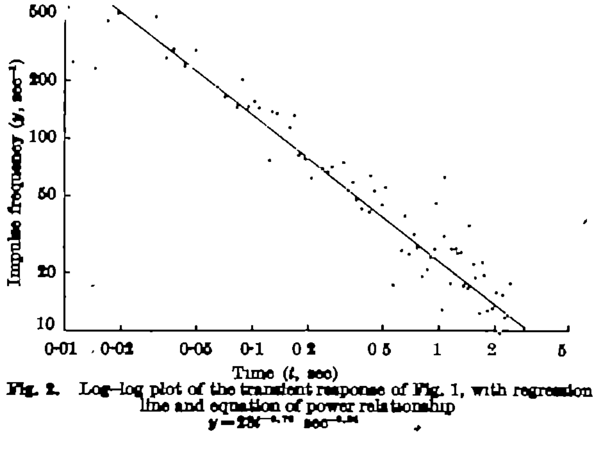

Fig. 2. Log–log plot of the transient response of Fig. 1, with regression line and equation of power relationship $y = 23t^{-0.76}$ sec$^{-0.24}$

In many but not in all of the receptors studied, frequency response functions determined with sinusoidal forcing agreed well with equation (3), with B and k evaluated from the transient response data (Fig. 3). We have not succeeded in fitting these data with exponentially adapting models, but the possibility that some of the underlying mechanisms are exponential in nature is not necessarily excluded.

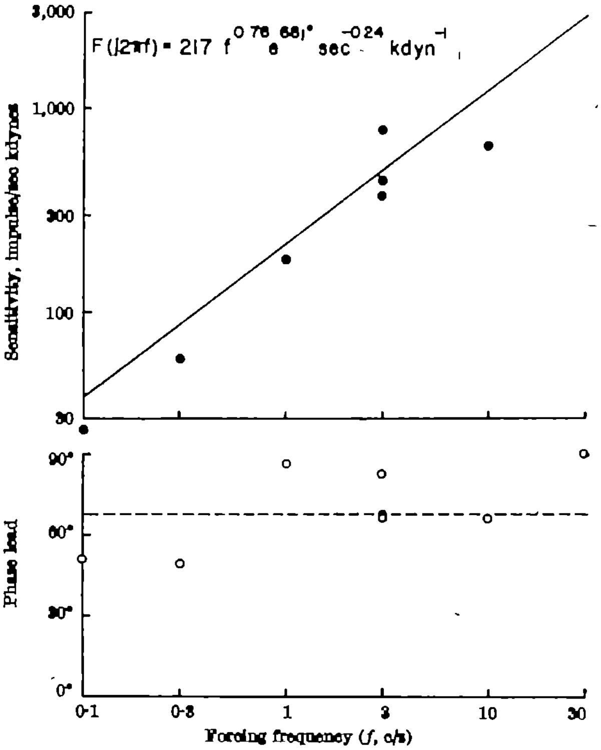

Fig. 3. Modulation sensitivity (solid circles and line) and phase lead (open circles, dashed line) plots of the frequency response function of the receptor of Fig. 1. Points were determined with sinusoidal stimulation, tensions as in Fig. 1, forcing frequencies over entire range for which impulse frequency modulation occurred (phase angle at 30 c.p.s. from single impulse per cycle). Lines and equation computed from transient response of Fig. 1, using equation (3), with B and k taken from Fig. 2

We conclude, therefore, that the time dependence of impulse frequency modulation in this cockroach mechanoreceptor arises in a dynamic biological process or set of processes for which a power law transfer function (equation 2) represents an important mode of behaviour. In view of the s^k factor in the transfer function, it is convenient to summarize the net mathematical behaviour of these processes as fractional (kth) order differentiation of the stimulus with respect to time. The relative contributions to these processes from tissue mechanics, generator mechanisms, impulse initiation phenomena, and all attendant non-linearities, remain to be demonstrated.

Evidence for 'Electrogenic' Active Sodium Transport in an Epithelial Membrane

In the course of active transport across the skin of a frog and the bladder of a toad, sodium moves against an electrical potential gradient both on entering and leaving the functional epithelial cell layer[1,2]. Transport in both tissues is dependent on the presence of potassium in the serosal medium[3-5].

To explain these findings in frog skin, Koefoed-Johnsen and Ussing have proposed a model which, as applied to the toad bladder, presumes passive entry of sodium through a selective permeability barrier at the mucosal surface, followed by active transport by a 'sodium pump' at the serosal surface[6]. Extrusion of sodium is thought to be coupled with active uptake of potassium, the latter leaking back out through the serosal surface, which is selectively permeable to potassium. Thus, according to this hypothesis, the sodium pump is not 'electrogenic', that is, it is not directly responsible for the separation of charge. Instead the potential steps are attributed to sodium and potassium diffusion potentials at the mucosal and serosal surfaces, respectively.

The characteristics of the mucosal surface of the toad bladder are consistent with this hypothesis[2,7]. The experiments recorded here examine the nature of the active transport process at the serosal boundary of the epithelial cell layer.

Ling-Gerard glass micropipettes were used to determine the polarity and magnitude of the serosal potential step. In 34 measurements in bladders exposed on the serosal surface to solutions of high potassium and low chloride concentration ($K^+ = 116$ m.equiv./l., $Cl^- = 3$ m.equiv./l.) the median value was 13 mV, with serosal surface positive to cell interior. Since the potassium concentration of whole bladder averages 111 m.equiv./l. of non-inulin space water[8], a potential of the observed magnitude and polarity is unlikely to be a potassium diffusion potential. With constant water content, and control cellular chloride concentration greater than 3 m.equiv./l., a chloride diffusion potential also is unlikely.

In order to examine the possibility of an anionic diffusion potential at the serosal surface due to the movement of any anion, net cation transport from mucosal to serosal surfaces was measured in the open-circuited bladder, exposed on the serosal side to sodium-free potassium Ringer's solution. Demonstration of net cation transport from mucosal to serosal surfaces in the absence of significant tissue swelling ruled out net movement of any anion from serosal medium into cell interior, and hence an anion diffusion potential, if anions move only passively across this boundary. The alternative to bidirectional passive anion movement across the serosal surface, an ion-pair transport mechanism, seems improbable[9].

A 150-fold change of serosal hydrogen ion concentration (pH 9·25–7·02) did not affect the spontaneous trans-bladder potential or net sodium transport. A coupling of hydrogen ion uptake with active extrusion of sodium, or a hydrogen ion diffusion potential, therefore seems unlikely.

Additional studies were performed to explain the dependence of sodium transport on the presence of potassium in the serosal medium. No direct coupling of sodium and potassium transport was demonstrable; uptake of potassium-42 from the serosal medium was independent of the rate of net sodium transport[10]. Instead, the influence of serosal potassium appeared to be mediated at the mucosal surface, by regulation of the permeability of this barrier to passive entry of sodium. With sodium Ringer's solution as serosal medium, removal of potassium resulted in a decrease of net sodium transport to 5 per cent of the control value, in association with significant alteration of tissue electrolyte content and diminution of tissue labelling with sodium-22 from the mucosal medium.

When choline replaced sodium in the serosal medium removal of potassium resulted in only slight alterations of electrolyte content and mucosal permeability, and net transport fell only to 56 per cent of the rate in control tissues. Although sodium moved down a chemical potential gradient in this situation, in separate experiments net transport of sodium was shown to occur even against an imposed electro-chemical potential gradient. Thus, active sodium transport persisted despite absence of potassium from the serosal medium, when removal of serosal sodium prevented marked depression of mucosal permeability.

The depression of active sodium transport resulting from removal of potassium from the bathing medium, a property common to many tissues, has been demonstrated here to be an indirect effect, a consequence of decreased availability of sodium at the site of active transport. The results indicate the necessity for critical evaluation of evidence for coupling in tissues having experimentally inaccessible permeability barriers. The results suggest also that the active transport mechanism in toad bladder involves movement of sodium across the serosal boundary without simultaneous and obligate movement of a diffusible anion in the same direction or a cation in the opposite direction. The transport of sodium gives rise to the serosal potential step directly, that is, the sodium pump is 'electrogenic'.

Formation of Histamine in Rat Tissues

It has recently been suggested by Kahlson *et al.* that the capacity of tissues to form histamine is related to the general process of growth, regeneration and repair[1-4]. Other workers have cast doubt on this theory, finding little or no histidine decarboxylase activity in various normal and malignant rapidly growing tissues[5-8]. Telford and West, finding that the optimal conditions for the determination of enzyme activity in the rat vary from tissue to tissue[8,9], and that the enzyme in different tissues behaves differently from drugs[10], suggested that in this species there may be several enzymes capable of forming histamine[8].

Recent experiments show that the methods at present being used for the determination of histidine decarboxylase activity do not give a true estimate of histamine-forming capacity. Using the optimal conditions for determination of enzyme activity as previously described[8,9], tissues were incubated with histidine for periods varying from 5 min to 5 h, and the amounts of histamine formed (μg/g) determined by biological assay. The results for adult liver are plotted in Fig. 1; similar curves were obtained for other tissues. In all tissues, maximum formation of

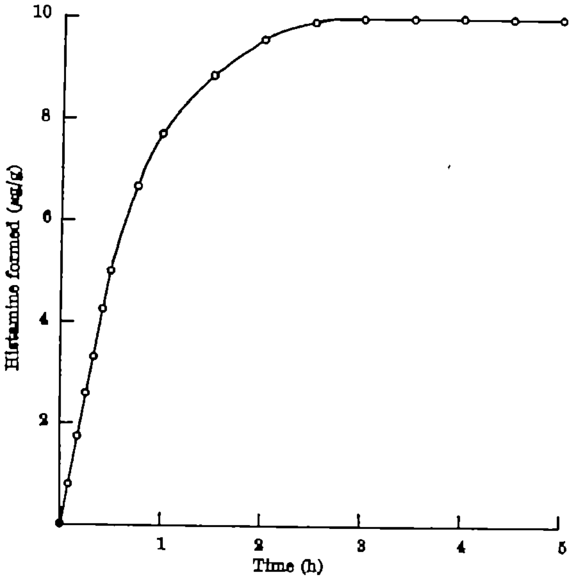

Fig. 1. Rate of histamine formation by adult rat liver *in vitro*. Incubation at 37° C under constant agitation, at pH 8·0, in presence of 20 mg/g benzene; 15 mg/g L-histidine as substrate

histamine occurred within an incubation period of 3 h. However, the rate of histamine formation was greatest during the first 30 min, up to 60 per cent of the total histamine production being formed within this time. During this early stage of the incubation period the relationship between histamine formed and time was linear, and it was thus possible to determine for each tissue the initial velocity of the reaction (µg histamine formed/g/min) by drawing a tangent to the origin of the curve.

Calculated in this way, the histamine-forming capacity of rat tissues *in vitro* is approximately three times higher than when calculated, as in previous work, from the total amount of amine formed after incubation for 3 h. For example, the adult liver forms 0·17 µg histamine/g/min. This represents 30·6 µg/g in 3 h (1·7 mg/tissue/day), as compared with only 10·0 µg/g in 3 h (0·6 mg/tissue/day) when estimated as total histamine production. The histamine-forming capacities of various rat tissues using the two methods of estimation are compared in Table 1; considerable quantities of histamine may also be formed by other tissues in which enzyme activity cannot be detected by the present method.

Table 1. Comparison of the histamine-forming capacities of rat tissues when estimated as the initial velocity of the enzyme reaction (µg histamine formed/g/min) and when estimated as total histamine production (µg histamine formed/g/3 h)

Tissue	Histamine-forming capacity: Estimated as initial velocity			Estimated as total production	
	µg/g/min	µg/g/3 h	µg/tissue/day	µg/g/3 h	µg/tissue/day
Fœtal liver (day 14)	46·1	8,298·0	331·9	2,534·6	101·5
Fœtal liver (day 21)	7·7	1,386·0	2,106·7	452·4	687·7
Whole fœtus (day 21)	0·13	23·4	1,609·9	8·0	550·4
Adult liver	0·17	30·6	1,713·6	10·0	560·0
Adult pyloric stomach	0·24	43·2	138·2	18·0	57·6
Adult duodenum	0·08	14·4	34·6	5·2	12·5
Adult kidneys	0·04	7·2	69·1	3·0	28·8

The progress curves of most enzymatic reactions are of the general form shown for rat liver histidine decarboxylase in Fig. 1, in which the velocity falls with time. Various factors may contribute to this fall in velocity, and they result in the curves not fitting the standard equations of homogeneous chemical reactions. It is only at the initial point that the conditions of the experiment are accurately known, and once the factors mentioned above have begun to operate the amount of histamine formed after a given time ceases to be a true measure of the rate of histamine formation. It is important, therefore, that histidine decarboxylase activity be measured from the initial velocity of the reaction. Measurements of changes in the histamine-forming capacities of tissues should include determination both of the initial velocity of the reaction and total histamine production, since it is possible that while the former may alter, the latter may not, and vice versa.

The initial velocity is similar in all tissues (range 0·15–0·19 µg histamine formed/g/min) when the amount of enzyme used for incubation is the same. Thus, different amounts of enzyme and different optimal conditions for enzyme activity do not reflect differences in the rate of the enzymatic reaction.

Summation of the amounts of histamine capable of being formed by the adult liver, pyloric stomach, duodenum and kidney shows that the adult rat is capable of forming as much as 2 mg of histamine a day. This is more than is capable of being formed by the rapidly growing fœtal rat, which on the 21st day of gestation when enzyme activity is highest is able to form 1·6 mg/day. However, it is worthy of note that at term a pregnant rat together with a litter of seven fœtuses has, by deduction, the ability to form more than 13 mg of histamine in 24 h. In comparison, the fœtal and adult guinea pig are probably capable of producing even larger amounts, histamine-forming capacities of a high order being recently reported in this species[8,11].

HISTOLOGY

Demonstration of Perineural Epithelium in Whale and Shark Peripheral Nerves

IT has been shown previously by us[1,2] that the peripheral nerve fasciculus in rat, cat, guinea pig and frog is surrounded by flat, stratified squamous epithelial layers, five in number in the sciatic nerves of the former three animals and only two-layered in the frog. The squamous cell layer surrounding the peripheral nerve fibre has also been shown by Key and Retzius[3], Krenjevic[4], Lehmann[5,6], and Rohlich and Weiss[7]. The cells of this squamous epithelium are uninucleated, the nucleus being very flat, and sex chromatin has been demonstrated in female cats and rats in these cells. In serial isolation of this epithelium we have demonstrated that the perineural epithelium represents a continuation of the pia-arachnoid membrane from the central nervous system. In a further investigation, we have been able to show[2] that the lamellated sheath of the Pacinian corpuscle is made up of the extended perineural epithelium, indicating that the pia-arachnoid not only covers the central nervous system but also covers the peripheral nervous system as a perineural epithelium extending up to and over the motor and sensory end organs.

In continuation of this work and in an attempt to demonstrate the universality of this membrane among vertebrates our work was extended to include marine vertebrates. The two animals discussed here represent

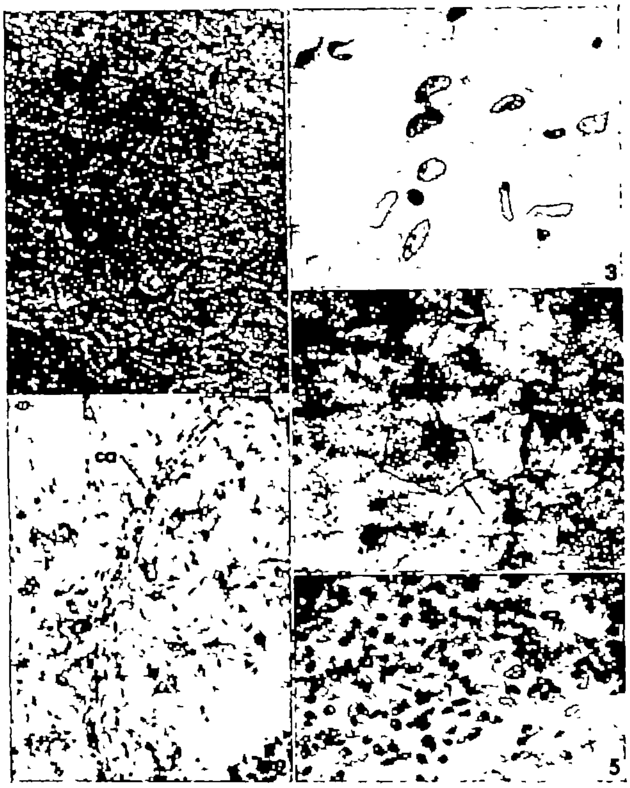

Fig. 1. Phase-contrast micrograph of formalin-fixed segmental nerve of shark, showing perineural epithelium, isolated under binocular dissection microscope, mounted in glycerine. Note clear-cut squamous epithelial layer with nuclei. Cell borders of some deeper layers are seen crossing underneath the superficial layer. (× 255)

Fig. 2. Formalin-fixed peripheral nerve of whale showing perineural epithelium, isolated under binocular dissection microscope, and four layers of the epithelium removed. Stained with cresyl violet. Note the capillary network (arrow *cs*) in the perineural epithelium. (× 68)

Fig. 3. Formalin-fixed shark segmental nerve showing isolated perineural epithelium stained by hæmatoxylin and eosin. Note cellular borders are not demonstrated by this method but nuclei are well stained. (× 660)

Fig. 4. Formalin-fixed whale peripheral nerve showing isolated perineural epithelium treated with 1 per cent aqueous silver nitrate (after repeated washing to remove formalin from tissue). Note cellular borders are clearly demonstrated (arrow), indicating the squamous nature of the cells. (× 255)

Fig. 5. Formalin-fixed whale peripheral nerve showing isolated perineural epithelium. Method same as Fig. 3. Multiplicity of nuclei overlapping each other indicates many layers of epithelial cells. (× 170)

groups low on the evolutionary scale (sharks) and those high on the scale (whales).

The material was collected from the waters around North Bimini in the Bahama Islands. Facilities were provided in Bimini by the Lerner Marine Biological Laboratories of the American Museum of Natural History.

A female nurse shark (*Ginglymostoma cirratum*), an elasmobranch, was anæsthetized and segmental nerves were removed and fixed in formalin. A female false killer whale (*Orca* sp.) was killed in the sea by a shot gun and the segmental and sympathetic chain nerves were removed and fixed in formalin. The formalin-fixed material was processed in our laboratory.

Isolation of the perineural epithelium was carried out under a stereo-binocular dissecting microscope as described previously[1]. Standard hæmatoxylin and eosin staining was applied to the isolated perineural epithelium. 0·5 per cent aqueous cresyl violet staining was used to demonstrate sex chromatin material. The cellular borders were visualized by washing the isolated epithelium repeatedly in distilled water to remove formalin from the tissues, and then treating with 1 per cent silver nitrate for 24 h in the dark, mounting in glycerine and then exposing to sunlight to demonstrate the cell borders. Some isolated tissue was mounted in glycerine directly for observation with the phase-contrast microscope.

During isolation of the perineural epithelium it was observed that the arrangement of the connective tissue components in both species of animals was the same as that of the peripheral nerves of rat, cat, guinea pig and frog. After removal of the epineurium, perineural connective tissue was seen. Meticulous clearing of incidental connective tissue components revealed a thin, glistening semi-transparent membrane under the perineurium which completely covered the entire nerve fasciculus. On silver nitrate impregnation it was seen that this semi-transparent membrane was made up of flat, stratified squamous epithelium arranged as a continuous sheet (Fig. 4). The formalin-fixed, glycerine-mounted tissue also demonstrated the presence of a squamous epithelium quite clearly under the phase-contrast microscope (Fig. 1). The epithelial layers were greater in number in the whale and it was possible, as in other mammals, to peel off up to five individual layers. The perineural epithelium of shark nerves, on the other hand, appeared to have three layers. The standard hæmatoxylin and eosin method does not demonstrate cell borders, but the nuclei were well stained and the cytoplasm pale (Figs. 3 and 5). Cresyl violet staining showed possible sex chromatin in the whale, planoconvex in shape, lying at the edge of the nuclear membrane. In shark nerves the perineural epithelium showed no evidence of sex chromatin. A capillary network was also identified in this epithelium (Fig. 2).

With these findings it becomes clear that, as in the other mammals and one amphibian examined, the pia-arachnoid membrane extends over the peripheral nerves as a perineural epithelium, following the nerves to their termination, in both shark and whale. The only difference between the perineural epithelium in peripheral nerves and the pia-arachnoid in the central nervous system is the absence of the sub-arachnoid space. According to Harvey and Burr[9] and Harvey *et al.*[10] the pia and arachnoid membranes are ectodermal in origin and it is highly probable that in whale, as in other mammals, they have the same origin. The origin of the membranes in fish, however, is uncertain but we feel they, too, are likely to be ectodermal in origin.

This communication thus demonstrates the peripheral nerves of whale and shark to be encased in an epithelial sheath which isolates them from the surrounding tissue fluids, maintaining them in an environment of their own which is akin to that of the central nervous system.

Further histological, histochemical and electron microscopical studies of peripheral nerves of various types of marine animals, vertebrate and invertebrate, are in progress in this laboratory.

This work was carried out in part with the aid of grant No. *B*–1914 of the National Institute of Neurological Diseases and Blindness and with funds from anatomy training grant No. *2G*–305 of the National Institutes of Health, Division of General Medical Sciences.

We thank Dr. Robert Mathewson, resident director, Lerner Marine Biological Laboratories, Bimini, Bahamas, and Dr. James Oliver, director, American Museum of Natural History, for providing the facilities to collect specimens.

IMMUNOLOGY

Electrophoretic Analysis of Serum and Pleuroperitoneal Fluid Proteins and Antibody from Guinea Pigs

INTRAPERITONEAL injection of Freund's adjuvant (with or without antigen) into mice induces the production of ascitic fluid[1-3]. Ascitic fluid contains γ-, β_2-, β_1-, α_2-, α_1-globulin and albumin determined by moving boundary electrophoresis[4,5]. Anti-bovine serum albumin precipitins in mouse ascitic fluid were identified as β_2-globulins[4,5]. This work has been extended to include the guinea pig. In many of the animals ascites formation was also associated with fluid accumulation in the thoracic cavity. Serum, pleural and peritoneal fluids were characterized by moving boundary electrophoresis. Preliminary evidence indicated little or no electrophoretic difference between pleural and peritoneal fluids. Since it is possible that pleural fluid accumulates as a result of ascites formation, these fluids collectively are referred to as pleuroperitoneal fluid.

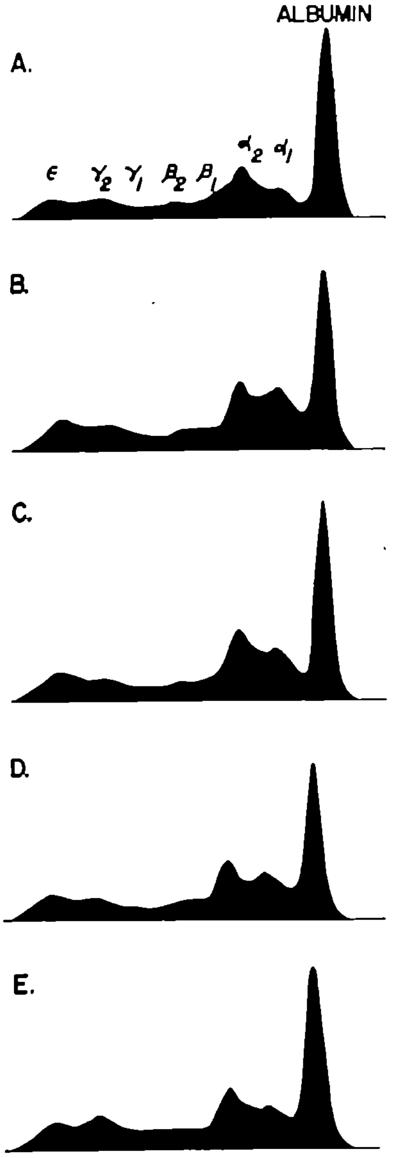

Fig. 1. Electrophoretic patterns of guinea pig sera and ascitic fluids. *A*, Serum from uninjected guinea pigs; *B*, serum from guinea pigs injected with Freund's adjuvant; *C*, serum from guinea pigs injected with Freund's adjuvant containing bovine serum albumin; *D*, ascitic fluid from guinea pigs injected with Freund's adjuvant; *E*, ascitic fluid from guinea pigs injected with Freund's adjuvant containing bovine serum albumin

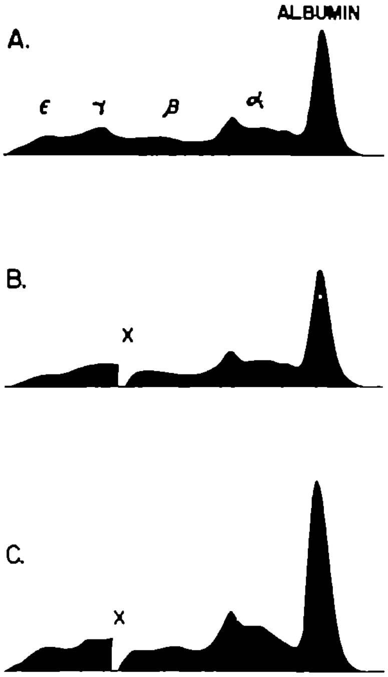

Fig. 2. Detection of anti-bovine serum albumin precipitins in guinea pig serum and ascitic fluid. *A*, Ascitic fluid from animals injected with Freund's adjuvant containing bovine serum albumin; *B*, a sample of the same ascitic fluid used in *A* with bovine serum albumin in the buffer; *C*, serum from animals injected with Freund's adjuvant containing bovine serum albumin with bovine serum albumin in the buffer

Random bred guinea pigs of both sexes were injected by the intraperitoneal route with Freund's adjuvant alone (85 parts 'Drakeol' mineral oil, 15 parts 'Arlacel *A*', 1 mg of *Mycobacterium butyricum*/ml.) or with Freund's adjuvant containing bovine serum albumin (4 mg/ml.). Each guinea pig received six 0·5 ml. injections of adjuvant over a period of three weeks. One week after the last injection pleural and peritoneal fluids were obtained by paracentesis and blood by cardiac puncture. Serum and pleuroperitoneal fluids were clarified by centrifugation. Moving boundary electrophoretic analyses were made in a Spinco model *H* instrument (barbital buffer: pH 8·6, $\mu = 0·1$; or glycine sodium hydroxide buffer: pH 10, $\mu = 0·1$). The electrophoretic component containing antibody was determined by the boundary disturbance test[6]. In this procedure antigen added to the buffer in the electrophoresis cell migrates into the antiserum and forms a specific precipitate with antibody. Location of the antigen–antibody reaction in the photographic record of the electrophoretic pattern is determined by a clear zone caused by interruption of light by the precipitate.

Electrophoretic patterns of serum from uninjected guinea pigs and serum and pleuroperitoneal fluid from animals injected with Freund's adjuvant alone or Freund's adjuvant containing bovine serum albumin are shown in Fig. 1. Seven components, γ_2-, γ_1-, β_2-, β_1-, α_2-, α_1-globulin and albumin, were resolved. In some samples only 5 components were resolved since γ_1-, β_2- and β_1-globulin could not be distinguished. Except for α_1-globulin, which is higher in the sera and pleuroperitoneal fluids of immunized animals, the relative concentrations of electrophoretic components of serum and pleuroperitoneal fluid were similar to the values determined for serum from uninjected animals.

To study the effect of pH on the electrophoretic resolution of guinea pig proteins experiments were also done at pH 10. All components migrated faster than at pH 8·6; however, the resolution of γ_1-, β_2-, and β_1-globulin components was not greatly improved.

Serum and pleuroperitoneal fluid from guinea pigs injected with bovine serum albumin in Freund's adjuvant contained anti-bovine serum albumin precipitins which were located in the γ_1-β_2-globulin region (*x*, Fig. 2) of serum and pleuroperitoneal fluid.

Although 7 components, γ_2, γ_1-, β_2-, β_1-, α_2-, α_1-globulin and albumin, could be resolved in guinea pig serum and pleuroperitoneal fluid, in some samples only 5 components were distinguished due to incomplete resolution of the γ_1-, β_2-, and β_1-globulins. Electrophoretic analysis at *p*H 10 did not significantly improve the separation of these proteins. The γ_1- β_2- β_1-globulin region probably consists of protein molecules differing progressively only slightly in charge.

Anti-bovine serum albumin precipitins of guinea pig serum and pleuroperitoneal fluid have the electrophoretic properties of γ_1- β_2-globulin. On the basis of these studies it is difficult to determine whether the precipitins are γ_1- or β_2-globulins or a mixture of both. Experiments to determine the properties of guinea pig precipitins in serum and pleuroperitoneal fluid are now in progress.

A New Allotypic Specificity in the Mouse (MuA2)

IMMUNOLOGICAL differences between γ-globulins of the same species have been demonstrated in man, rabbit, guinea pig, mouse and possibly baboon. In man and rabbit, these differences have been examined in great detail[1]. In the mouse, only one allotypic specificity has so far been described in a report by Kelus and Moor-Jankowski[2]. These authors elicited, in *C57BL* mice, an antibody to the γ-globulin of *BALB/c* mice. This antibody reacted with the γ-globulin of *BALB/c*, *C3H/He* and 'Champagne Glaxo' individuals. We have immunized *BALB/cJ* mice with the antigen obtained from *C3H/HeN* × *C57BL/6J* mice in two ways: (1) by injection with sera incorporated in Freund's adjuvant; (2) by injection with bacteria coated with antibody incorporated in Freund's adjuvant or suspended in 0·15 M sodium chloride[3].

In the first of these procedures, each mouse was given 12 subcutaneous injections with 0·1 ml. of emulsion; the total period of immunization was 8 months. On the 7th day after the last injection, animals were bled and the sera were pooled. A second group of *BALB/cJ* mice were immunized with *Proteus vulgaris* (*X*19) coated with antibody to the organism which had been raised in hybrid mice *C3H/HeN* × *C57BL/6J*. The mice were injected subcutaneously at weekly intervals; at first with the antigen in Freund's complete adjuvant, and later with the antigen suspended in 0·15 M sodium chloride. Seven days after the last injection, the animals were bled and the sera were pooled.

Both pools of immune sera reacted in an identical manner, giving one zone of precipitation in double diffusion with *C57BL/6J*, *C57BL/10J* and *SJL/J*. The antibody was shown by immunoelectrophoresis to react with γ-globulin. The allotype was found to be absent in *A/HeJ*, *A/J*, *AKR/J*, *BALB/cJ*, *CBA/J*, *C3H/HeJ*, *C57BR/cdJ*, *C57L/J*, *C58/J*, *DBA/1J*, *DBA/2J*, *RF/J*, *SWR/J*, 129/*J*, 2*BC3H* and 2*C3H*. A number of hybrid strains were also tested (*C3H/HeN* × *C57BL/6J*, *AKR/J* × *DBA/2J*, *C57BL/6J* × *A/J*, *C57BL/6J* × *DBA/2J*, *BALB/cJ* × *A/J*, *C57L/J* × *A/HeJ*, *C3H/HeJ* × *DBA/2J*) and it was found that all hybrids having in their ancestry one of the strains containing the allotypic specificity also possessed the allotypic specificity. In all cases, 5 or more males and 5 or more females were tested for the presence of the allotypic specificity, and in all cases, the distribution of the allotypic specificity in male and female animals was identical.

We also examined one strain of non-inbred 'Swiss' mice maintained at the Connaught Laboratories and found the allotypic character in 10 of the 21 animals tested.

In accordance with the agreed notation for rabbit allotypy[4], and after discussion with Dr. A. Kelus[5], we propose to call the allotypic specificity described here, MuA2. The allotypic specificity described by Kelus and Moor-Jankowski (γ^{BA}) will now, following Dr. Kelus's suggestion, be called MuA1.

Our allotypic specificity, MuA2, has been detected in three inbred strains of mice: *C57BL/6*, *C57BL/10* and *SJL*. The presence of the same allotype in *C57BL/6* and *C57BL/10* is not surprising since these two strains are very closely related[6]. It is, however, interesting to note that strain *SJL*, which does not have any known relation to *C57BL/6* and *C57BL/10* (refs. 6, 7) contains the same allotype. This observation could result from the fact that the mutation which led to the formation of the MuA2 allotypic specificity occurred before the aforementioned strains were bred. If this were the case, the allotype MuA2 should be present in some non-inbred strains. This assumption was supported by the finding of 10 MuA(2+) individuals among the 21 non-inbred 'Swiss' mice tested; this would indicate that this allotype may be present among non-inbred populations from which inbred strains have been derived.

Generally, allotypic antisera have been obtained by immunization with antigen–antibody complexes. Dray and Young[8] reported the successful production of allotypic antibodies in the rabbit by immunization with serum incorporated in Freund's adjuvant. In the hands of some other investigators, immunization with serum incorporated in Freund's adjuvant has not been equally successful. In our hands, and using the mouse strains described, immunization with serum in Freund's adjuvant has led to the production of an antibody of satisfactory potency and would seem to be, in this species, the method of choice.

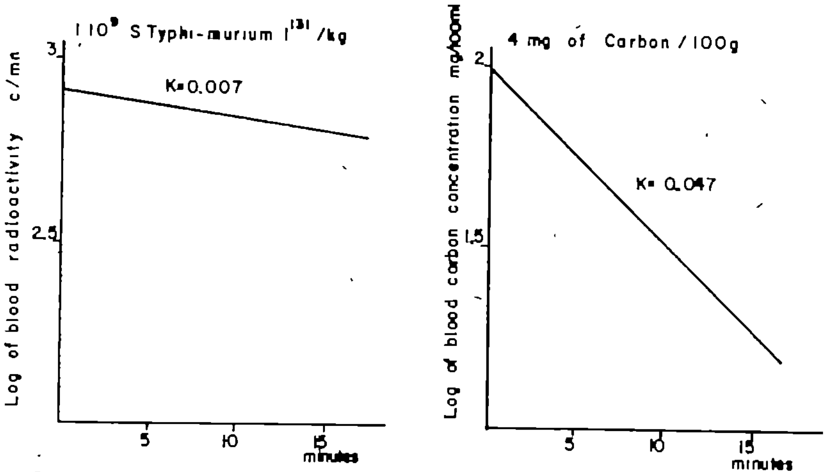
Phagocytosis of *Salmonellae* by Reticulo-endothelial Cells of New-born Piglets lacking Natural Antibody

It is a well-established fact that the uptake of bacteria by phagocytes is enhanced by serum factors (opsonins) acting on bacterial surface. The importance of serum opsonins in the phagocytosis of bacteria by fixed macrophages of the reticulo-endothelial system has been demonstrated by organ perfusion technique. It has been shown that serum factors playing a part in bacterial opsonization include immune or natural antibody, complement and possibly a third unidentified factor[1,2].



Organ distribution of Salmonellae I^{131}

	c/min/g	per cent of injected radioactivity
Liver	1,000	17
Spleen	80,000	44
Lungs	1,200	10
Kidneys	150	0.7

Fig. 1. Rate of blood clearance (*K*) and organs distribution of *S. typhimurium* labelled with iodine-131 and colloidal carbon in new-born piglets. The figures represent the mean value of three animals. The *K* value is determined by the formula: $K = \frac{\log C_t - \log C_{t'}}{t' - t}$. *C*, blood concentration; *t*, time expressed in min

The use of radiolabelled bacteria has made possible quantitative measurement of opsonins in the phagocytosis of bacteria by the reticulo-endothelial system *in vivo*[3-5]. The importance of antibody and complement in the phenomenon of bacterial opsonization has therefore been demonstrated in the intact animal[6,7]. It has also been suggested that the rate of phagocytosis of bacteria in different animal species was related to the amount of natural antibodies present in their serum[5]. In germ-free mice which are supposed to contain a lower amount of natural antibodies, the blood clearance of *E. coli* is slightly decreased. Nevertheless the bacterial repartition in the phagocytes of liver and spleen is similar in germ-free and control mice[8].

Recently, Šterzl *et al.* have shown that serum from new-born piglets deprived of colostrum was totally lacking in natural antibodies but contained 1–3 units of complement per ml.[9]. New-born piglets offer, therefore, an exceptional opportunity to investigate whether phagocytosis of bacteria by reticulo-endothelial cells *in vivo* occurs even in the absence of natural antibodies.

Investigation of phagocytosis of *S. typhimurium* by the reticulo-endothelial system in new-born piglets deprived of colostrum are reported here. These experiments were performed in fasting piglets 3–5 h after birth. The smooth phase of *S. typhimurium* 34/59 trace labelled with iodine-131 (ref. 4) was injected in an ear vein. The rate of blood clearance of labelled bacteria was established by measuring the radioactivity of blood samples removed from the opposite ear vein. When about 90 per cent of the radioactive bacteria were cleared from the blood the animals were killed and the radioactivity of different organs determined.

In another group of piglets the phagocytic activity of the reticulo-endothelial system was established by measuring the blood clearance and organ distribution of intravenously injected colloidal carbon using a technique previously described[10].

The results obtained in these experiments are summarized in Fig. 1.

It appears that *Salmonellae* are removed very slowly from the blood with a *K* value of 0·007. The distribution of the radioactivity in the organs shows that the majority of the bacteria are fixed in the spleen. The spleen, which weighed only about 1 g, accumulated 44 per cent of the injected bacteria while the whole liver (about 33 g) contained only 17 per cent. The number of bacteria per g of tissue was 80 times higher in the spleen than in the liver and this latter organ contained about the same amount of radioactivity as the lungs. It is important to note that the organ distribution of *Salmonellae* was very different in adult animals containing natural or immune antibodies. In adult animals the liver fixed 50–80 per cent and the spleen 5–25 per cent of the injected number of bacteria[3,4,7].

Examination of the phagocytic activity of the reticulo-endothelial cells with colloidal carbon in new-born piglets shows that the lack of bacterial fixation in the liver is not due to the inefficiency of the phagocytic function of the Kupffer's cells in the early stage of life, since these cells phagocytize 75 per cent of the injected amount of carbon. The phagocytic index *K* and the carbon distribution in the organs of new-born piglets are similar to those of adult animals[11]. Šterzl *et al.* have also shown that the reticulo-endothelial cells of new-born piglets deprived of colostrum phagocytize carbon particles at the same rate as piglets fed with colostrum[12].

These results indicate that, in new-born piglets, the absence of natural antibody inhibits the uptake of bacteria by Kupffer's cells, while the phagocytes of the spleen are capable of vigorous phagocytosis. It is interesting to emphasize the striking difference in the part played by opsonins in phagocytosis of bacteria by the Kupffer's cells and by the reticulo-endothelial cells of the spleen.

PATHOLOGY

Glycoprotein Excretion following the Injection of Papain into Rabbits

UNACTIVATED papain, injected intravenously into rabbits, passes from the blood to cartilage tissues where it is activated locally, causing ear collapse due to depolymerization of chondromucoprotein (chondroitin sulphate–protein complexes). The enzymatic products (for which the term 'chondromucopeptides' is proposed) leach out of the cartilage into the blood and are excreted in the urine[1].

In view, however, of the broad substrate specificity of papain[2], it would be surprising if papain attack *in vivo* was restricted to chondromucoprotein. Several glycoproteins (which contain sialic acid) act as papain substrates, while papain has been found to liberate glycoproteins from reticulum isolated from spleen[3]. Following injection of papain into rabbits increased levels of serum glycoproteins (seromucoid, protein-bound sialic acid) have been observed which were presumed to be liberated from ground substance components other than chondromucoprotein[4].

It therefore seemed of interest to know whether the increased mucopolysaccharide excretion observed following papain injection into rabbits was accompanied by an increase in urine glycoprotein components. The fraction investigated represents, in human beings, the major urinary glycoprotein component[5–7], the excretion of which is closely correlated with serum glycoprotein-levels[8].

The following method was adopted. Five rabbits were injected intravenously with crude papain (Messrs. A. M. Zimmerman, London) and the urines collected in 24-h periods. Their volumes were made up to 200 ml. with water and the samples stored at −10° until assayed. Aliquots (about 25 ml.) of each urine were incubated at 37° to re-dissolve any material that may have come out of solution during storage. After filtration, 20 ml. were taken, 20 ml. of water added and the mixture (at *p*H 8·5 ± 1·0) adjusted to *p*H 7 with hydrochloric acid using a *p*H meter. 2 M sodium benzoate (5 ml.) was added, followed by 2 N hydrochloric acid (4 ml.). The resulting *p*H was 4·1. After standing for 30 min at room temperature the precipitate of benzoic acid, containing adsorbed glycoprotein, was filtered off under suction and transferred quantitatively to a centrifuge tube (50 ml. capacity) with acetone. After the benzoic acid had dissolved, the glycoprotein residue was centrifuged down, washed once with acetone, suspended in water (2 ml.) and dissolved by the addition of 0·1 N sodium hydroxide (0·1 ml.). Glycoprotein was precipitated with acetone (18 ml.) followed by saturated aqueous sodium chloride (0·02 ml.). After the precipitate had flocculated it was centrifuged down, drained thoroughly, suspended in 0·1 N sulphuric acid (2 ml.) and heated (80°, 1 h) to liberate free sialic acid. Aliquots (0·2 ml.) of the hydrolysate were taken and sialic acid estimated by the thiobarbituric acid method of Warren[9]. The adsorption curve of the chromophore was identical to that produced by *N*-acetylneuraminic acid, indicating the absence of 2-deoxy-D-ribose and other interfering chromogens in the glycoprotein fraction. Results were expressed as mg sialic acid/24 h. Urine chondromucopeptide-levels, expressed as mg hexuronic acid/24 h, were determined by a method already described[10]. The results are summarized in Table 1.

Table 1. URINARY CHONDROMUCOPEPTIDE AND GLYCOPROTEIN EXCRETION FOLLOWING THE INJECTION OF RABBITS WITH PAPAIN

No.	Weight of rabbit (kg)	Amount of papain injected (mg) contained in 2·5 ml. physiological saline	Glycoprotein Excretion: mg Sialic acid/24 h Pre-injection level	Glycoprotein Excretion: mg Sialic acid/24 h Post-injection level	Glycoprotein Excretion: No. of days after injection to reach excretion peak	Glycoprotein Excretion: No. of days to reach pre-injection level	Chondromucopeptide Excretion: mg Hexuronic acid/24 h Pre-injection level	Chondromucopeptide Excretion: mg Hexuronic acid/24 h Post-injection level	Chondromucopeptide Excretion: No. of days after injection to reach excretion peak	Chondromucopeptide Excretion: No. of days to reach pre-injection level
1	1·0	40	0·76	1·48	1	7	1·6	5·0	1	2
2	1·5	60	0·85	1·88	3	8	2·2	4·4	2	3
3	2·1	100	1·30	2·30	2	4	1·1	5·8	2	3
4	1·1	40	0·88	2·05	1	4	5·1	9·7	1	2
5	2·2	100	1·70	2·25	4	6	1·5	7·1	1	2

The expected rise in chondromucopeptide was accompanied by increased excretion of glycoprotein material, the raised glycoprotein-level being maintained for longer periods than the chondromucopeptide-level. This finding correlates with the changes observed in serum[4], where glycoprotein and mucopolysaccharide-levels were maximal 2–5 days and 9–18 h respectively after papain injection.

Although some of the urine glycoprotein fraction measured here is derived from the urinary tract[11], plasma components entering the urine by glomerular filtration are also present. Part of the rise in urine glycoprotein following papain injection can be presumed due to release of cartilage chondromucoprotein, the protein moiety of which may be a sialoprotein[12], and also to the release of glycoprotein components from cartilage and perhaps other connective tissues.

Plasmin injected into rabbits causes a similar, although less dramatic, sequence of events so far as mucopolysaccharide liberation is concerned[10]. Whether or not plasmin liberates other tissue components leading to raised serum and urine glycoprotein-levels is under investigation, although the problem is rendered difficult since plasminogen, the precursor of plasmin, is itself a glycoprotein[13], preparations of human plasminogen used for injection, prepared from plasma fraction III by Kline's method[14], containing 75 μg sialic acid/ml.

Synthesis of Plasma Antihæmophilic Factor

IN *Nature* of May 12, 1962, L. I. Woolf offered an explanation of 'severe' and 'mild' *X*-linked hæmophilia *A* while discussing gene expression in heterozygotes. He proposed that the plasma-level of antihæmophilic globulin (*AHG*, *AHF*, Factor VIII) regulated its rate of synthesis, that is, that 'end-product (feedback) inhibition' controlled the synthetic rate. 'Feedback inhibition' is known to be a very important regulatory mechanism in biosynthetic pathways, producing small anabolites such as amino-acids, vitamins, etc.[1]. We can find no documented evidence, however, that 'feedback inhibition' is a controlling mechanism in protein synthesis. 'Feedback inhibition' should be sharply distinguished in this respect from 'feedback repression', which is recognized to be a highly important genetic mechanism concerned with regulating the synthesis of enzymes (proteins) in bacteria[1–4].

Woolf apparently has not considered the implications of the existence of another disorder in which there is *AHF* deficiency. This condition, von Willebrand's disease (*v.W.D.*), clearly results from a dominant mutation occurring on an autosomal chromosome, and its main features have been confirmed by many investigators[5–10]. The bleeding time is prolonged in *v.W.D.* but is normal in hæmophilia *A*. Thus, another plasma component, tentatively designated 'vascular factor' (*V.F.*), apparently controls the bleeding time and is reduced in *v.W.D.* along with *AHF*.

One of us pointed out several years ago that the occurrence of these two disorders of *AHF* synthesis clearly distinguishable on genetic grounds, one of which is dominantly inherited, makes it difficult to understand the regulation of the *AHF*-level[11]. It would appear that an explanation of *AHF* regulation must take into account that: (*a*) genes on at least 2 chromosomes are concerned; (*b*) at least two plasma factors are involved; (*c*) 'feedback inhibition' is almost certainly not the controlling mechanism.

Recently, French workers[8] have clearly documented an important earlier observation by a Swedish group[10]. When fresh plasma from persons with hæmophilia *A* (low *AHF*, normal *V.F.*) is transfused into persons with *v.W.D.* (low *AHF*, low *V.F.*), a remarkable result is obtained. Within a few minutes the bleeding time becomes normal as might have been expected; but there is also a progressive and completely unexpected increase in circulating *AHF*. The rising *AHF*-level may reach a peak as much as 24 h later and only slowly returns to the low, pre-transfusion level. This 'paradoxical' effect is observed neither when the plasmas are mixed *in vitro* nor when *v.W.D.* plasma is transfused into persons with hæmophilia *A*. The observations suggest that the low *AHF*-levels of hæmophilia *A* and *v.W.D.* are achieved by quite different biochemical mechanisms.

One explanatory model which comes to mind is one which might be called the 'activator' model. In this model an activator or co-factor of *AHF* is produced from information carried on the autosomal chromosome, while the structural information for a pro-*AHF* is coded on the *X*-chromosome. In *v.W.D.* the amount of activator is reduced and only a small quantity of the structurally and qualitatively normal *AHF* precursor becomes activated. When hæmophilia *A* plasma, rich in activator, is infused into a patient with *v.W.D.* the activator reaches the site where pro-*AHF* is activated. This is followed by a rising plasma *AHF*-level, until the activator becomes exhausted. When *v.W.D.* plasma, presumably containing normal pro-*AHF* molecules, is transfused into persons with hæmophilia *A*, only the expected rise in plasma *AHF* is observed, probably because the pro-*AHF* cannot reach the site where activation occurs.

To explain the dominance of the mutation this model assumes either that the genes normally producing activator are working at maximum speed and that one normal allele does not produce enough of the competent activator, or that the mutant activator substance acts as an inhibitor. It also assumes that the activator is a molecule which can enter and leave cells with ease, while pro-*AHF* is a molecule which is expelled from cells but does not enter them readily. The simplest situation would be one in which the *V.F.*, which is responsible for the normal bleeding time, is also the activator of the *AHF* system, but this is not essential. *V.F.* might be a product of an associated reaction.

The model described here is not without precedent. It has recently been observed that the activity of xanthine dehydrogenase in *Drosophila melanogaster* is controlled by two loci on different chromosomes (I and III). Mutation at either locus results in decreased xanthine dehydrogenase activity; however, *in vitro* mixture of extracts from the mutant flies results in return of enzymatic activity[12].

Another model can be imagined which operates in accordance with the system proposed by Monod and colleagues for regulating protein synthesis in bacteria[13]. In this 'inducer' model a dominant regulator gene mutation of the i^s type would explain *v.W.D.* The altered repressor substance produced by this autosomal gene would not be inactivated by its inducer, and its operon would always be repressed. Since this operon, which would ordinarily synthesize the inducer for the *X*-chromosomal *AHF* operon, is repressed, the plasma-level of *AHF* is reduced. This model also would be most elegant if the *V.F.* were also the inducer; but this is not essential. Here again the inducer would be required to be a small molecule because known inducers are small, and it is required to pass from blood of hæmophilia *A* into nuclei of persons with *v.W.D.* if *de novo* *AHF* synthesis is to occur.

The chemical nature of *V.F.* is unknown. It is interesting to note, however, that both models require a highly mobile molecule which probably implies small size. Coincidentally, several small molecular species are known to have striking physiological effects on blood vessel walls (serotonin, pitressin, adrenaline, acetylcholine). It is also of interest that *AHF*-levels in normal persons increase temporarily following adrenalin injections[14] or heavy exercise[15]. The presence of the inducer in Fraction I-0[10] may be explained by the occurrence of a protein carrier or by its particular solubility characteristics.

Sex-linked hæmophilia could be due to a structural mutation under either model. Severe sex-linked hæmophilia might result either from an operator mutation (0^c type) or a major change in the structural gene in the 'inducer' model. 'Mild' hæmophilia, on the other hand, might be a 'mis-sense' structural alteration with mild but not complete loss of the activity of the molecule.

It is difficult to imagine tests which could be carried out and lead to a decisive choice between these models. It is also possible that neither model is entirely correct; but we believe their heuristic value justifies their description.

This investigation was supported in part by research grant *H*-3140 from the U.S. Public Health Service.

RADIOBIOLOGY

Experimental Oxidation of Hæmoglobin: Effect of Repeated Whole-body γ-Radiation in Rats

WHEN washed suspensions of mammalian red cells are treated with isotonic solutions of nitrites, the iron of their contained hæmoglobin is oxidized to the ferric state with the formation of brown methæmoglobin. Using standard strength red cell suspensions and weak solutions of nitrite, the resistance (reaction time, Figs. 1–4) of the hæmoglobin to this change can readily be measured[1].

The increased sensitivity of cord and infant blood to oxidizing agents has long been known, but a similar increase in sensitivity of hæmoglobin to oxidation in the growing mammal, in the pregnant and in those bearing malignant tumours has only recently been reported[1,2]. The resistance of the hæmoglobin of rats to oxidation can also be decreased by starvation[1], by certain dyes and drugs[3] and by ionizing radiations. The exact effect of such radiation is dependent on the age of the animal at the time of irradiation[4] and on the dose administered.

In rats, 500 rads produce a rapid increase in the hæmoglobin sensitivity which persists for at least three months. With smaller doses (1/30–250 rads) in adult animals, the onset of the effect is somewhat delayed and recovery occurs in from 4–7 weeks (Figs. 1, 2 and 3). The hæmoglobin sensitivity of sham irradiated controls did not deviate from the normal value. Re-irradiation of the animals within one month of the return of their hæmoglobin sensitivity to normal produces an earlier change in their nitrite sensitivity and an earlier reversion. Subsequent doses of radiation at the same intervals produce a progressive acceleration of the phenomenon (Figs. 1, 2 and 3).

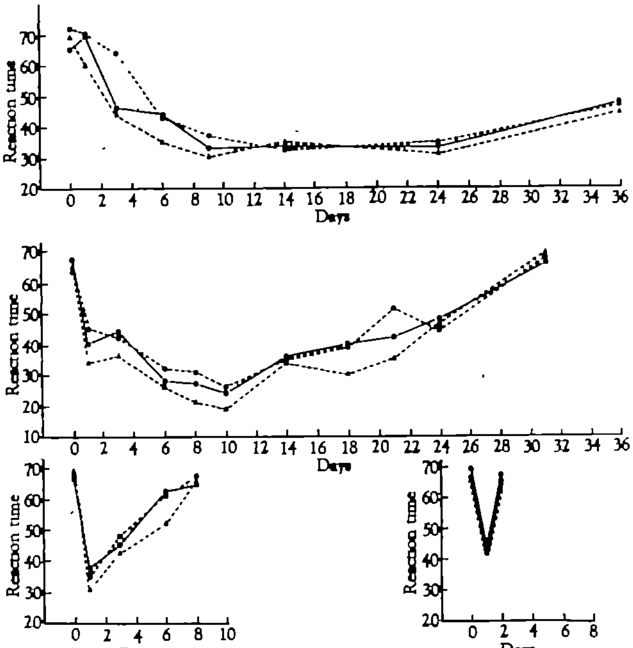

Fig. 1. Change in the reaction time (the time taken to convert the hæmoglobin of a standard saline red cell suspension to methæmoglobin using 0·1 per cent sodium nitrite *in vitro*) with differing and repeated doses of cobalt radiation. (The *S.D.* of any point is approximately 5 sec.) Upper, first dose; middle, second dose; lower left, third dose; lower right, fourth dose. ▲, 250 rads; ○, 125 rads; ●, 62·5 rads

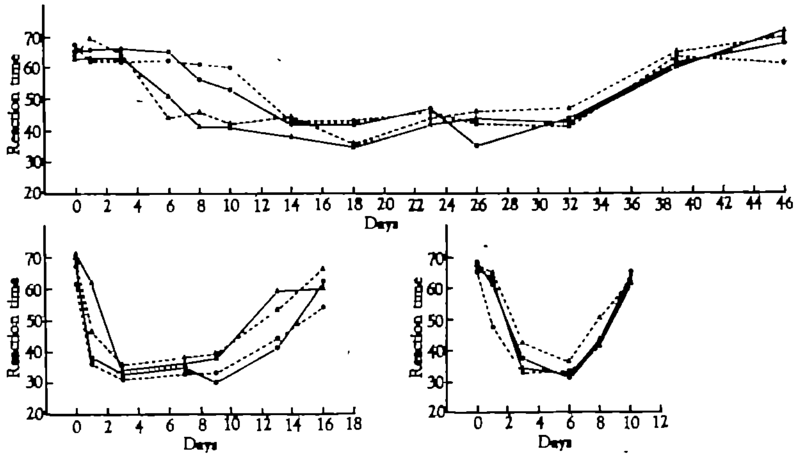

Fig. 2. As Fig. 1; the effect of much smaller doses. Upper, first dose; lower left, second dose; lower right; third dose. ●, 30 rads; ○, 15 rads; △, 6 rads; ▲, 3 rads

The mechanism of the change in sensitivity of the hæmoglobin is, as yet, completely unknown. However, since the increased sensitivity to nitrites of the young pregnant or starving animal is at least partially reversible by the administration of riboflavin and the increased sensitivity following 500 rads of γ-radiation is temporarily reversible by riboflavin plus adenosine triphosphate (although not by riboflavin alone)[1,4], it would appear that the flavoproteins may be involved in these phenomena. The latter observations would fit in with the increased ATPase activity and the disturbance in oxidative phosphorylation following radiation reported by several authors[5,6].

The possibility that the change in response with repeated doses of radiation is of an immunological nature is perhaps suggested by the finding that, while an initial series of T.A.B. injections caused a marked increase in the sensitivity of the hæmoglobin to oxidation, a second series of T.A.B. injections in the same animals 7 weeks later was completely without effect (Fig. 4). In the case of radiation, the antigenic stimulus would presumably be the products of tissue breakdown.

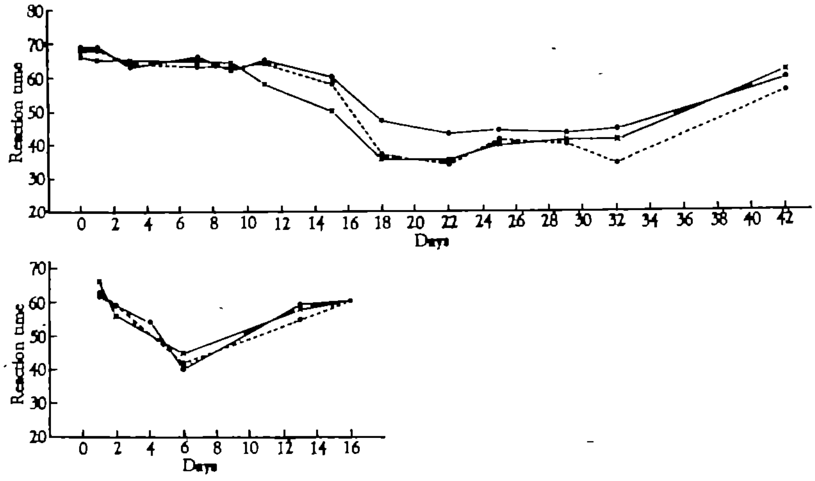

Fig. 3. As Fig. 1; the effect of doses in the maximum permissible dose range. Upper, first dose; lower, second dose. ○, 1/30 rad; ●, 1/10 rad; ×, 1/3 rad

A fuller discussion of the possible mechanism involved and of the experiments completed, in progress and planned, to elucidate the findings is beyond the scope of this communic-

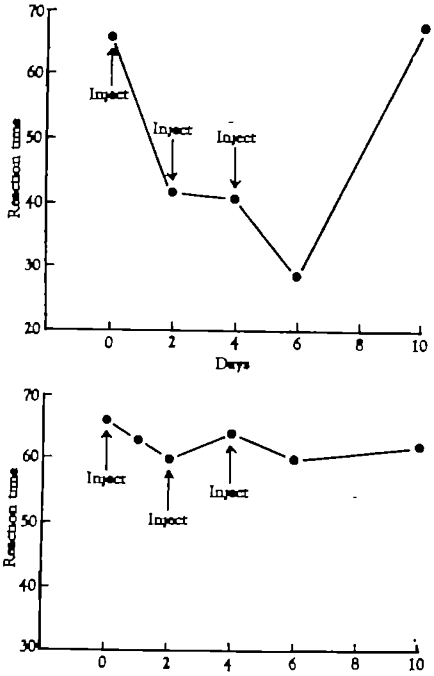

Fig. 4. Changes in the reaction time following two series of T.A.B. injections (250 × 10⁶ organisms) (separated by a 7-week interval). Upper, first series of injections; lower, second series of injections

ation, but the bulk of the evidence so far strongly implicates the involvement of the intracellular electron transfer systems and hence supports the views of Tahmisian[7] and many others that these systems are of paramount importance in the reaction of a tissue to radiation.

Binding of Strontium in Blood

WE have reported[1] that, following the ingestion of radioactive strontium by normal subjects, the specific activity in urine was appreciably greater than that in contemporary plasma. Consequently, we postulated that strontium existed in blood in two different chemical forms. We were unable, however, to find any difference in the specific activity of strontium in plasma ultrafiltrate compared with that of the non-dialysable fraction. This result prompted further experiments which have now revealed an artefact in the original measurements. Heparin, which is known to be a source of adventitious stable strontium[2], was used in the collection of the blood. An incorrect allowance for this gave us falsely low values for the specific activity of plasma. A complete re-estimation of the relative specific activities of strontium in urine and plasma has therefore been made. The results of these measurements are given in Table 1. The probability of the ratio being greater than unity is 32 per cent, the 95 per cent confidence limits 0·84 and 1·40.

Table 1. SPECIFIC ACTIVITY OF STRONTIUM IN URINE AND PLASMA

Subject	Specific activity of strontium (counts/min/μg)		Ratio specific activity urine/plasma
	Urine	Plasma	
R. H. M.	176	170	1·03
G. E. H.	208	145	1·43
A. J. P.	135	158	0·85
T. E. F. C.	240	192	1·25
P. W. B.	222	218	1·02
		Mean	1 1 ± 0 1

In some experiments already reported[1], and in others unreported, heparin (batch No. 64373) was added to the blood samples. This addition was 40 mg (equivalent to 4,800 units) to all blood samples of 100 ml. or more. As the strontium content of this amount of heparin is known, it was possible to correct these earlier determinations. The observed and corrected values for the specific activity of strontium in urine relative to that in plasma are given in Table 2. The mean corrected value of the ratio 0·98 ± 0·05 confirms the more recent values in Table 1.

Table 2. EFFECT OF HEPARIN ON THE OBSERVED RATIO OF SPECIFIC ACTIVITY OF STRONTIUM IN URINE RELATIVE TO PLASMA

Subject	Specific activity of strontium in urine relative to plasma	
	Observed	Corrected
A. J. P.	2·68	1·38
P. W. B.	1·70	0·67
,,	1·18	0·98
R. H. M.	1·70	0·81
,,	1·69	0·85
,,	1·80	1·10
,,	1·17	1·02
,,	1·01	0·80
,,	1·45	1·14
,,	1·49	1·02
F. S. W.	2·20	1·23
	Mean	0·98 ± 0·05

We conclude that the specific activities of strontium in plasma and urine are probably equal. It should be added that the same result has also been obtained for calcium by others[3,4]. There is, therefore, no experimental evidence to support the view that there are two different forms of strontium (or calcium) in blood which the kidney is able to differentiate.

A Multicomponent X-ray Survival Curve for Mouse Lymphosarcoma Cells Irradiated *in vivo*

NEARLY all investigations hitherto reported of the survival of animal cell populations exposed to single doses of ionizing radiations have yielded data which have been fitted by curves of the same general shape: a shoulder of varying size (which may be absent) followed by a region of exponential decrease. Only a single exponential component has been found even in those investigations in which survival was studied to fairly low levels (less than 10^{-3}), irrespective of whether survival was measured by colony formation *in vitro*[1-5], or *in vivo* by tumour induction[6,7]. These results have been obtained despite the fact: (*a*) that a given cell strain may be heterogeneous with respect to innate sensitivity[8]; (*b*) that cells may undergo marked fluctuations in radiation sensitivity during the division cycle[9]; (*c*) that inhomogeneities in degree of oxygenation might exist, particularly in a tumour cell population *in situ*[10]. It may be presumed, therefore, that one or more of the following has been pertinent in each study: (1) A particular population may be homogeneous with respect to inherent sensitivity, degree of oxygenation, and presence of protective agents or other modifiers of radiation response. (2) The overall sensitivity of cell populations heterogeneous with respect to radiation

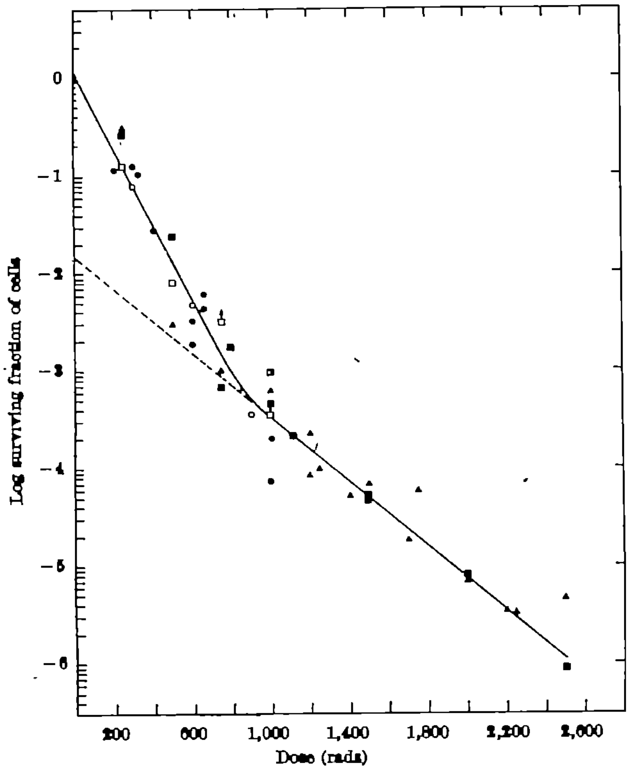

Fig. 1. Survival of *6C3HED* mouse lymphosarcoma cells irradiated *in vivo*. The curve has been fitted by eye. Each symbol refers to a separate experiment. Each point involved determination of the number of cells required to produce tumours in 50 per cent of 30 mice, using the end-point dilution method of Hewitt (ref. 14). This number for unirradiated cells was generally in the range 2–5 cells. The arrows indicate minimum values

response may, under certain conditions, exhibit relatively simple survival kinetics[9,11,12]. (3) A less-sensitive cell type may be present in amounts too small to be detected unless many decades of inactivation are effected[13]. (4) The precision of cell survival measurements, particularly those carried out *in vivo*, is limited.

We have observed a very different radiation response in the cell populations which constitute solid, subcutaneous *6C3HED* mouse lymphosarcomas, 1–2 cm in diameter, in *C3H* mice. When the viability of such cells is measured by Hewitt's method[14] immediately after total body exposures to graded doses of X-rays (220 kV C.P.; 0·5 mm copper + 1·0 mm aluminium added filtration; half-value layer 1·9 mm copper; 70–90 rads per min), survival is found to follow a multicomponent exponential curve, preceded by a small shoulder (Fig. 1). The results suggest that the survival kinetics are determined mainly by cells of only two sensitivities. The relative proportions of these remained essentially constant in four experiments. The initial exponential slope corresponds to a mean lethal dose (D_0) of 110 rads; its extrapolation number is about 1·2. The terminal slope indicates a D_0 of 260 rads, and extrapolates to about 0·01 on the ordinate. Neither the precision of the data nor the size of the resistant fraction warrants resolution of the measured survival curve into components for the sensitive and resistant fractions at doses less than 1,000 rads.

When tumours containing 10^8–10^9 cells (about 1 g) are irradiated with 3,000 rads, the surviving cells, which should be of the resistant type exclusively, give rise, on injection into new mice, to populations which exhibit a survival curve identical to that shown in Fig. 1. Hence, the resistant cells do not appear to constitute a sub-group the low sensitivity of which is inheritable.

The ratio of the exponential slopes, 2·3, is typical for oxygen enhancement of radiation sensitivity as observed in many studies[15], including those concerned with cytological damage[16] and survival[7,17,18] in tumour cells. It is proposed, therefore, that about 1 per cent of the cells of these tumours are anoxic and that the terminal slope characterizes their radiation sensitivity. The following preliminary results tend to support this hypothesis: (1) Irradiation in air of cells suspended in chilled foetal calf serum yields a survival curve which has only one exponential slope; the value of D_0 is close to that for the majority population irradiated *in vivo*. (2) Irradiation of cells *in situ* in mice killed by either cervical fracture[18] or asphyxiation in nitrogen, all of the tissues of which are presumably anoxic, yields a survival curve from which it is estimated that the fraction of radiation-resistant cells is about 10 times larger than in live mice. Further tests, both *in vitro* and *in vivo*, of the effects of oxygen and of anoxia on the radiation sensitivity of these tumour cell populations are under way.

The possibility that a given tumour cell population may be heterogeneous with respect to oxygenation has been considered previously[15,16], and the implications of the foregoing type of cell population response for the radiation therapy of tumours has been discussed theoretically by several authors[10,19,20]. Such discussions would now appear to rest on a much firmer foundation.

This investigation was supported by a grant (*CA* 05846) from the U.S. Public Health Service.

Carbohydrate Metabolism in the Sapwood of *Pinus radiata*

THE use of carbon-14 produced in nuclear bomb testing in biological investigation has been discussed in an earlier communication[1]. Since 1954 the specific activity of the carbon dioxide in the atmosphere over New Zealand has been increasing, as is shown in Fig. 1 [2]. We have used this effect to examine the carbohydrate metabolism of *Pinus radiata*.

Annual rings of a *Pinus radiata* tree felled in January 1960 in the Kaingaroa Forest were ground up and acetone extracted in a Soxhlet extractor. The ground rings were treated with steam in an autoclave and then exhaustively extracted with water. Cellulose was separated from the residue. The water-extracted material and the cellulose were converted to carbon dioxide and counted in the Institute of Nuclear Science low-level carbon-14 counter. The $^{13}C/^{12}C$ ratio of each sample was measured so that the results could be corrected for any isotope effect in

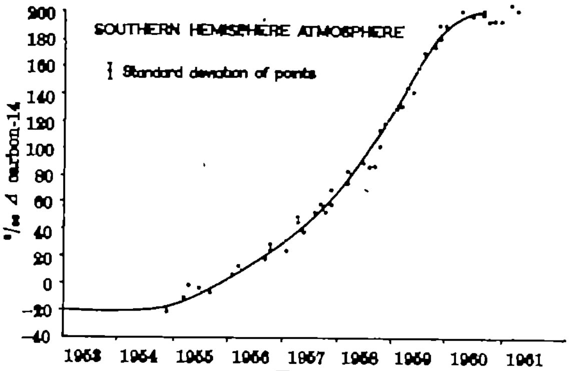

Fig. 1. Specific activity of southern hemisphere atmosphere, after Rafter (ref. 2). $\Delta^{14}C$ expressed as parts per thousand enrichment above 0·95 of National Bureau of Standards oxalic acid standard and normalized for isotopic fractionation to 0·975 of the P.B.D. Chicago belemnite standard

the metabolism of the tree or any possible fractionation in the laboratory procedure. The results are given in Table 1.

If the specific activity of the cellulose (Table 1) is compared with that of the atmosphere (Fig. 1) it is seen that the cellulose activity corresponds to that of the atmosphere when its ring was the outside of the tree. Thus the cellulose is not in dynamic equilibrium with the metabolism of the tree and, once synthesized, remains fixed. This result is not altogether unexpected and has long been assumed by those engaged in the carbon-14 age dating. The cellulose was included in these experiments as an internal standard.

The activity of the water-soluble carbohydrate (Table 1) is considerably lower than that of the atmosphere at the time of felling the tree. Thus the soluble carbohydrates in the inside rings of sapwood of *Pinus radiata* are not in dynamic equilibrium with the metabolism of the tree. These carbohydrates, therefore, are not analogous to the fat reserves of an animal.

Table 1. PARTS PER THOUSAND Δ CARBON-14 VALUES FOR CHEMICAL FRACTIONS OF ANNUAL RINGS OF *Pinus radiata*

Annual ring	Cellulose	Water-soluble (soluble carbohydrate)
1953/54 + 1954/55	− 20 0	+ 8·0
	σ = 4·0	σ = 4·9
1955/56 + 1956/57	− 14 8	+ 7·8
	σ = 2·3	σ = 4·4

Atmosphere at time tree felled (January 1960) = + 200.

* Δ Carbon-14 expressed as parts per thousand enrichment above 0 95 of National Bureau of Standards oxalic acid standard and normalized for isotope fractionation to 0 975 of the P.B.D. Chicago Belemnite Standard. σ = standard deviation of counting.

It should be pointed out, however, that a small amount of 'bomb carbon-14' has been incorporated into the water extractives since they are significantly higher than the cellulose. This might be due to the metabolism of some of the parenchyma cells in the medullary rays. This casts doubt on the practice of attempting to determine the specific activity of the atmospheric carbon dioxide at times in the past by accurate counting of the wood in the rings of trees[3], and suggests that a better procedure might be to do a chemical separation and to count only the cellulose.

We thank the Forest Research Institute, Rotorua, who kindly felled the tree and separated the rings, the Institute of Nuclear Science for counting the samples, and the New Zealand University Grants Committee for financial support.

BIOLOGY

Use of Spleen-slice Homografts in the Study of Graft-versus-Host Reactions

PRESENT knowledge concerning the graft-versus-host reaction has been derived chiefly from examination of the consequences of injecting homologous adult lymphoid cell suspensions into tolerant hosts[1–4]. We have attempted further investigation of this phenomenon in so far as it may occur when morphologically intact lymphoid tissue is transplanted.

In earlier work[5], a technique was developed for transplanting slices of renal tissue from parental strain mice on to the kidney of F_1 hybrid recipients. Homografts between such strain combinations are of particular interest since genetically they are capable of inducing a graft-versus-host response without a concomitant host-versus-graft response. These kidney slice grafts failed to exhibit any evidence of a graft-versus-host response, presumably because the kidney lacks cells capable of proliferating in response to homologous antigens. In the experiments recorded here, slices of an immunologically competent organ, the spleen, were transplanted in a similar fashion. On microscopic examination of these spleen slice grafts, changes indicative of a graft-versus-host reaction were observed.

Adult male mice weighing 20–24 g were used. The parental strain was $C_{57}Bl_6$, and the F_1 hybrid strain was $B_6AF_1/J(C_{57}Bl_6$ ♀ × A/J ♂). The mice were obtained from Jackson Memorial Laboratories, Bar Harbor, Maine.

Mice were anaesthetized by the intraperitoneal injection of pentobarbital and the left kidney was exposed through a flank incision. A small atraumatic vascular clamp (bulldog) was placed across the renal pedicle to prevent subsequent bleeding. A thin slice of renal cortex was shaved off the convex surface of the kidney with a sharp scalpel in order to provide a bed for the new spleen graft. The graft was taken from the spleen of the donor with fine

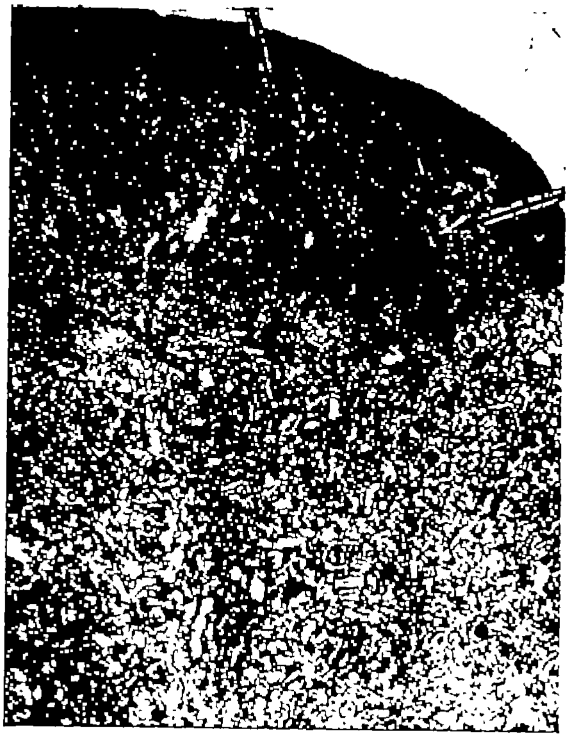

Fig. 1 Parental line spleen slice on F_1 hybrid kidney seven days after grafting. Arrows point to one of the hyperplastic follicles present in the graft. The preservation of the follicular component and the red pulp are evidence of the integrity of the splenic architecture (× c. 93, haematoxylin and eosin)

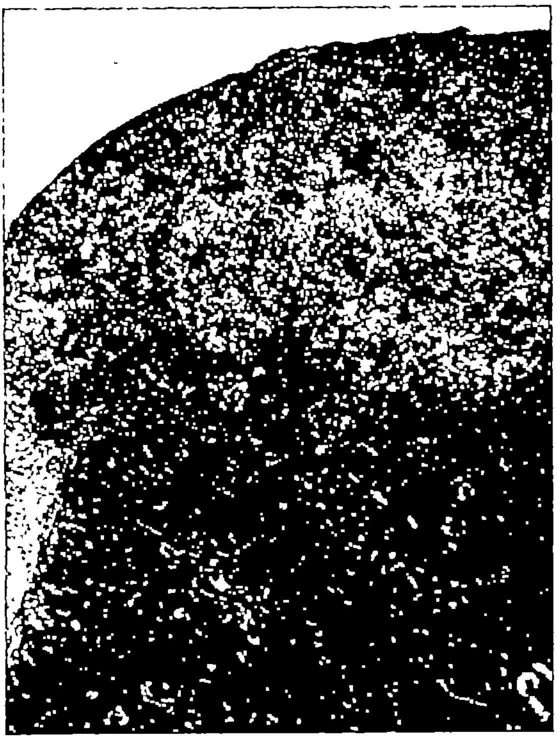

Fig. 2. F_1 hybrid spleen slice on parental line kidney seven days after grafting. Follicular architecture has been destroyed. Not evident at this magnification are the focal areas of necrosis in the graft. The mononuclear cells at the base of the graft infiltrate the interstitium of the kidney (× c. 98, hæmatoxylin and eosin)

scissors, excising from the convex surface a disk of tissue measuring about 4 by 3 by 1 mm. The cut surface of the graft was then placed on the renal bed and pressed down gently. The vascular clamp was released and the abdominal wound closed. Seven days later the kidney with its splenic graft was excised and sectioned transversely. Blocks were fixed in 10 per cent formalin and sections stained with hæmatoxylin and eosin. Adjacent blocks were fixed in absolute methyl alcohol and stained with methyl green-pyronin and with hæmatoxylin and eosin.

Each experimental group was composed of at least 20 animals. During the week following transplantation there was no mortality, and no systemic manifestations of runt disease were observed.

On gross examination at seven days, the control parental isografts ($P \rightarrow P$) and F_1 hybrid isografts ($F_1 \rightarrow F_1$) were reddish-purple, firm disks resembling normal spleen and measuring 1·0–3·5 mm in greatest dimension. Follicles were frequently apparent on the cut surface. Homografts of $P \rightarrow F_1$ were also reddish-purple, but were larger than the isografts and on sectioning were seen to contain larger, grey follicles. Homografts of $F_1 \rightarrow P$ were swollen, soft, and reddish-brown. Greyish-yellow foci of necrosis were present on cut section. No follicles were seen.

In histological sections, characteristic splenic architecture, including lymphoid follicles, was observed in the isografts. Homografts of $P \rightarrow F_1$ were distinguishable from the isografts by the presence of larger follicles (Fig. 1) and of numerous large immature cells of the lympho-reticular series. These cells had prominent pyroninophilic cytoplasm and were most numerous in the lymphoid follicles. They appeared similar to those cells described by Fagraeus as transitional cells[6] and by Scothorne[7] as large lymphoid cells. Grafts of $F_1 \rightarrow P$ were enlarged to nearly twice the size of the $F_1 \rightarrow F_1$ controls and were heavily infiltrated by macrophages, small lymphocytes and immature cells of the lymphocytic and/or plasmacytic series. The graft bed was heavily infiltrated by similar immature cells and by small lymphocytes. Areas of necrosis were observed in the grafts and follicular architecture was completely obliterated (Fig. 2).

This technique of spleen-slice transplantation permits direct observation of the histological changes occurring after transplantation of immunologically competent tissue. The hyperplasia of immature lymphoid cells with enlargement of the splenic follicle in the $P \rightarrow F_1$ graft is interpreted as a proliferative response of the surviving cells in the graft to host antigens. In the $F_1 \rightarrow P$ grafts the focal necrosis, loss of lymphoid follicles, and cellular infiltration of graft bed are interpreted as manifestations of the reaction of the host against the graft. The proportion of donor and recipient lymphoid cells surviving in such grafts and the functional capabilities of the cells of the graft are under investigation.

This work was supported in part by the Veterans Administration and in part by a grant from the National Heart Institute, *H*–1771 and an Army medical contract, *M.D.* 2061.

Use of *Cyclo*phosphamide in an Attempt to modify the Canine Renal Homograft Response

In view of the prolongation of skin homografts in mice as a result of administering cyclophosphamide as reported by Sutton, Griffith and Preston[1], with the finding that the same drug used as a preconditioning agent permitted an increased survival of tumour transplants in rats by Henegar, Jackson and Preston[2], it was felt that this drug might be of use in prolonging canine renal homografts in line with previous investigations using other metabolites such as those of Calne[3]; Pierce, Varco and Good[4]; and Zukoski, Lee and Hume[5].

A comparative examination was made to evaluate this possibility. Twelve mongrel dogs were used in the control series. They underwent bilateral nephrectomies and were recipients of a renal homograft from a similar type unrelated dog of the same sex. The renal artery and vein of the donor kidney were anastomosed end-to-end to the iliac artery and vein of the recipient and the ureter was anastomosed to the bladder. Eleven dogs survived the operative procedure and lived for a period averaging twelve days with a range between seven and fifteen days. The blood urea nitrogen (BUN) increased precipitously about the seventh day and serial needle biopsies showed an intense cellular infiltration of lymphocytes, plasma cells and macrophages beginning at this time. The white blood count and hæmatocrit remained at almost the pre-operative level until this time and then fell.

In the *cyclo*phosphamide-treated group, 5 mg/kg of the drug was given intravenously at the time of surgery and 10 mg/kg of body-weight was given orally every other day beginning on the first post-operative day and continuing until their death. In this group there was one immediate post-operative death with the other animals living an average of twelve days but ranging from 4–23 days. There were three animals who exceeded the range of the control group, living 17, 21 and 23 days with two animals expiring before the control group at four days showing signs of drug toxicity. Outside of the last two, autopsy findings were similar in all cases with the kidneys markedly swollen and hæmorrhagic. Microscopically, they showed the intense cellular infiltration mentioned above. The onset of this cellular infiltration and rising BUN appeared approximately four days prior to the animal's death. The white counts post-operatively were depressed to about one-third of the pre-operative level with the hæmoglobin showing an approximate 30 per cent depression. Both these findings occurred during the first few days and remained generally at this level.

In conclusion, it was felt that *cyclo*phosphamide in the dosage and method used for administration in this series had little over-all effect in prolonging the survival time although further study will be necessary to evaluate the response in the two that did survive beyond twenty days.

Effect of Light on the Oxidation of Reduced Nicotinamide-Adenine Dinucleotide Phosphate in Animal Tissues

DURING the course of experiments on glucose-6-phosphate : NADP and phosphogluconate : NADP dehydrogenases it was noted that the reduction of methylene blue occurred much faster in the light than in the dark. Subsequent experiments showed that this effect also occurred with isocitrate : NADP dehydrogenase but only to a slight extent with malate : NAD and succinate dehydrogenases.

The rate of reduction of methylene blue was determined by the Thunberg method. The following reagents were used: dye, 0·267 mM methylene blue; buffer, M *tris*-hydrochloric acid, *p*H 7·5; substrates mM, glucose-6-phosphate (disodium salt); 0·02 M (±)-isocitrate trisodium salt; 0·01 M sodium malate; 0·01 M sodium succinate; coenzymes, 0·05 mM NADP (sodium salt); 0·2 mM NAD; enzyme preparations. (*a*) Hæmolysate of human red blood corpuscles. 5 ml. of heparinized venous blood was centrifuged for 10 min at 2,500 r.p.m., the supernatant plasma withdrawn, the corpuscles washed twice with 0·9 per cent sodium chloride, and the volume finally made up to 5 ml. with distilled water. A 1-in-20 dilution of this hæmolysate in distilled water was used for the experiments on glucose-6-phosphate and phosphogluconate dehydrogenases. (*b*) Homogenate of mouse heart. A mouse heart was homogenized in 2 ml. of distilled water and the homogenate diluted with distilled water to contain 10 mg heart tissue/ml. for the experiments on isocitrate dehydrogenase and 20 mg/ml. for the experiments on malate and succinate dehydrogenases.

For the experiments on the red blood cell dehydrogenases 0·5 ml. each of the dye, buffer and diluted hæmolysate and a drop of octanol were placed in the Thunberg tube and 0·5 ml. each of glucose-6-phosphate and NADP in the hollow stopper. The tube was evacuated for 5 min to ensure the complete deoxygenation of oxyhæmoglobin. For the experiments with heart homogenate 0·5 ml. each of the dye, buffer, substrate and coenzyme were placed in the tube and 0·5 ml. of the diluted homogenate and a drop of octanol in the hollow stopper. The tube was evacuated for 3 min.

After evacuation, the tube was placed in a beaker of 1 l. capacity about three-quarters filled with water at 37° and allowed to equilibrate for 5–7 min, after which the reaction was started by mixing the tube and stopper contents. The tube was then either replaced in the beaker of water and illuminated with a 150-W frosted bulb or placed in the dark in a beaker of water at 37° in an incubator. In the former case, the tube was placed in the water-bath in a sloping position with the reaction mixture nearest the observer and 12 cm in a horizontal line from the rounded end of the bulb.

The time taken for the methylene blue to become reduced by 70 per cent, as estimated by comparison with a standard tube, was recorded as the reduction time. For the experiments on red blood corpuscles the standard tube contained 1·5 ml. buffer, 0·5 ml. diluted hæmolysate and 0·5 ml. methylene blue 30 per cent the concentration used in the reaction mixture. The tube was evacuated for 5 min. The standard tube for the experiments with heart homogenate contained 1·5 ml. buffer, 0·5 ml. diluted homogenate and 0·5 ml. methylene blue 30 per cent the concentration used in the reaction mixture.

At a certain time, when it was learnt by experience that the end-point had almost been reached, the tube in the dark was removed from the incubator, examined in daylight, and immediately replaced in the incubator. This procedure was repeated at 1–2 min intervals until the end-point was reached.

The concentration of the enzyme preparations used was chosen so as to give reduction times of 3–6 min in the light.

Typical results are shown in Table 1.

Table 1. METHYLENE BLUE REDUCTION TIMES AND DARK/LIGHT RATIOS

Dehydrogenase system	Dark (min)	Light (min)	Dark/light ratio
Glucose-6-phosphate : NADP and phosphogluconate : NADP (human red blood corpuscles)	41·0	4·5	9·1
Isocitrate : NADP (mouse heart)	84·0	8·3	10·2
Malate : NAD (mouse heart)	6·0	4·2	1·4
Succinate (mouse heart)	8·8	5·9	1·5

In a further experiment with isocitrate : NADP dehydrogenase a reaction mixture incubated in the dark for 10 min and then exposed to the light (150-W bulb) took 50 sec to reach the end-point.

The results show that light has a striking effect on the reduction time of methylene blue in systems in which NADP is the coenzyme. Since the reduction of methylene blue involves the oxidation of reduced coenzymes it can be concluded that light exerts a major stimulating effect on the rate of oxidation of $NADPH_2$.

Size and Feeding of Different Types of Fishes

THE pelagic, predatory, marine fishes are a remarkable group, containing many species of great importance for both commercial and game fisheries. Some examples are the mackerel (*Scomber scomber*), the Thunnidae, the spear-fishes (*Makaira* sp.) and *Tarpon atlanticus*.

As these fishes are both fast swimmers and pursue their prey persistently, they may be defined as 'stayers', that is, fish capable of maintaining a high speed over a period of time. The 'stayers' are characterized by a body-musculature with a comparatively high amount of red muscle tissue, consisting of fibres of the thin red type. Thin red muscle fibres are characterized by the presence of myohæmoglobin, coupled with a good vascularization[1,2] and an aerobic metabolism, in which not only glycogen but also probably fat may be used for the production of energy. The alternative, broad white fibres have a completely different complex of metabolic enzymes[2-4]. They have an anaerobic action, using glycogen exclusively for energy production, and have a faster contraction than the narrow red fibres with a greater number of sarcomeres. The slower narrow red fibres are suited for prolonged action. Consequently, a large amount of red muscle tissue in the body musculature enables the fish to cover long distances at a relatively high cruising speed. It is, however, an expensive ability, which demands a good supply of both calories and oxygen to function efficiently. A 'stayer' like the trout has a higher basal metabolism and food-coefficient than other types of fish[6,7].

The drag on the surface of moving fish is correlated with the surface areas of its body, which is in turn proportional to the cross-section of the musculature. This cross-section estimates the power of the muscle. As the fish grows, the increase of the swimming speed is only slight[8]; but the possibilities for fuel storage increase with the contents in the third degree of the proportions, much faster than the drag on the surface.

In this connexion it is interesting that the biggest representatives of this group of typical 'stayers' occur in oligotrophic seas. Representatives of this group in the eutrophic North Sea are: *Scomber scomber* (mackerel), *Trachurus trachurus* (horse mackerel) and *Belone belone* (garfish), all small fishes with a maximum weight of 1–3 lb.[9].

On the contrary, in oligotrophic tropical seas, a considerable number of pelagic predators with a length of more than 50 cm are found, especially in the family Carangidae, and also a number of real giants with a maximum weight of 100–1,500 lb., with a maximum length varying from 1·5 to 5 m. The latter belong to the families Histiophoridae, Xiphiidae, Scomberomoridae, Thunnidae, Coryphaenidae, Rachycentridae, Elophidae and Carangidae[10,14].

The more favourable relation between fuel-storage and drag on the surface gives the bigger fish a larger action radius. The migration of big pelagic fish-eating species is often remarkable. For the albacore (*Germo alalunga*) migrations of 4,724 miles in 324 days and 3,166 miles in 176 days have been recorded[11]. These big species can thus search huge areas for food, which is an obvious advantage if food is scarce.

An additional advantage the larger predatory fish has over a smaller species is the greater variation in the size of the potential prey. The huge swordfish and spearfishes also feed on very small prey[12,13]. If food is scarce and heterogeneously dispersed, we may conclude that an increase of size is a favourable factor in the struggle for life of this type of fish.

If food is abundant and more or less homogeneously dispersed, the greater possibilities for fuel storage of the bigger species are not important.

In flat-fishes, range and normal swimming speed are not important, but time is the main factor which determines the quantity of food captured by the fish. Flat-fishes obtain the biggest part of their food (worms, lamellibranchs, crustaceans) by careful search of the bottom, which has to be done at a low speed: so that these fishes do not need a large amount of red muscle tissue which makes a high main speed possible. In order to escape from their enemies and to catch a moving prey, the ability to sprint fast is very favourable. As one might expect the body-musculature of flat-fishes consists mainly of broad white muscle fibres with low sarcomeres. This is well suited for the sprint.

In eutrophic boreal seas flat-fishes are, in the main, much bigger than their relatives in oligotrophic tropical seas. The maximum length of flat-fishes from Ceylon varies from 9 to 62 cm with an average of 20 cm. In the Norwegian and North Sea the corresponding variation is 12–200 cm with an average of 55 cm[9,10].

The Gadoid fishes form another group of bottom-dwelling 'sprinters' which mainly live in the open sea. They are very common in eutrophic boreal seas but even there concentrated on spots abounding with food. They are almost absent from tropical waters.

In tropical seas, fish-eating 'sprinters' are concentrated on coral reefs. Here they find quiet water, where their lack of stamina is of no importance, and hiding places, which increase their chances of seizing prey.

A relatively large stock of small fishes feeding on the corals and other invertebrates, and extremely clear water, are advantages to fishes who have to find prey by the eye. Fishes of this type are the baracuda (*Sphyraena baracuda*), which reaches a weight of 100 lb., and the groupers (Serranidae), some of them reaching a weight of 1,000 lb.[14].

On the shores of boreal seas, conditions are not so well suited for 'sprinters'. There is not such a concentration of small fish, the water is much less clear and, in most cases, moving strongly. The genera *Gobius* (gobies) and *Cottus* (sea-scorpions) are good representatives of the small coast-dwelling 'sprinters' in the North Sea and the Atlantic.

Endocrinology of Reproduction in the River Lamprey

EXISTING literature on endocrine aspects of reproduction in cyclostomes has recently been reviewed[1,2] and we have already reported the results of a preliminary investigation on controlling mechanisms in the reproductive physiology of the river lamprey, *Lampetra fluviatilis*[3]. The present communication records the results of more extensive work.

The experimental animals were obtained from the River Severn and kept in well-aerated running tap-water. Hypophysectomy was carried out as previously described[3] on a large number of individually marked lampreys, biopsy specimens of gonad from both hypophysectomized and sham-operated control animals being examined at the time of operation and at intervals afterwards. Ten lampreys were gonadectomized. Survival of all operated animals was excellent.

When male lampreys of this particular population begin their anadromous migration in late September, the testis contains only spermatogonia, and mitotic divisions are numerous. Between October and December the germ cells enter the prophase of meiosis, and this stage lasts until mid-February when metaphase plates first become evident. From the beginning of March the testis contains an increasing number of spermatozoa and progressively fewer earlier stages. Maturation is complete and spawning occurs in early April. The development of the germ cells is approximately synchronous within an individual testis and throughout a particular population, though this is not absolute. Secondary sexual characters become evident during March and are usually fully developed by early or mid-April.

Eighty lampreys were hypophysectomized between early October and early March, and in all cases of complete hypophysectomy secondary sexual characters failed to develop.

Examination in April of biopsy samples from the testes of lampreys hypophysectomized in October revealed the presence of primary spermatocytes in late prophase, together with meiotic metaphases, secondary spermatocytes, spermatids and, rarely, spermatozoa. Several of these animals survived until the end of June when their testes were again examined by biopsy. In every case the testis contained spermatozoa, occasionally accompanied by late spermatids. These spermatozoa were never whorled within the lobule, with their heads grouped together, as in the normal mature testis, and their appearance in sectioned testicular tissue suggested that they were incompletely developed.

When examined in April, the testes of lampreys hypophysectomized in November and December contained all stages of spermiogenesis from early spermatids to spermatozoa, the latter being loosely scattered, similar to the June configuration of the October-hypophysectomized testis. The testes of lampreys hypophysectomized in January and later, when examined in April, contained only spermatozoa, the degree of whorling being greater in the later-operated animals.

From the foregoing results it appears that removal of the pituitary, even when the germ-cells are only at the spermatogonial stage, is not an insuperable barrier to the progress of spermatogenesis and spermiogenesis, though under these conditions spermatozoa are formed approximately two months later than in normal animals. Hypophysectomy performed when the germ-cells are in early prophase of the first meiotic division (in November and December) causes less delay in sperm formation, and when performed during the later stages of prophase (January and February) there is little, if any, disturbance of the timing of sperm maturation and the nuclear events which precede it.

These results suggest that spermatogenesis and spermiogenesis in lampreys, unlike other vertebrates, are autonomous processes though they are appreciably catalysed by the pituitary, the absence of which from October onwards delays the appearance of sperm by some ten weeks. Moreover, in animals maintained for this length of time after the normal population has spawned, the sperms are loosely distributed in the lobules and appear incompletely developed though, because no normal females are available at this time, their capacity for fertilization has not been tested. It may be noted in this context that a virtually normal testis picture could be obtained if hypophysectomy is carried out at such a time that it does not unduly delay the development of the spermatozoa. This would appear to suggest that it is a time factor, rather than absence of the pituitary, which is responsible for the somewhat abnormal appearance of the testis of animals hypophysectomized in October and examined late in the following June.

In female lampreys, hypophysectomy abolishes the normal increase in size and dry-weight of the eggs which occurs between January and April. After hypophysectomy the ovary remains small and compact and the eggs are not released into the body cavity, whereas in the control animals they are ovulated by the beginning of April. However, no signs of atresia were observed, and this is a point of considerable interest since, so far as is known, atresia of yolk-containing eggs invariably follows hypophysectomy in other female vertebrates.

The effects of replacement therapy using lamprey pituitary extracts, mammalian gonadotrophins of extra-pituitary origin, and steroids, have also been investigated. Of two groups of hypophysectomized lampreys, one was injected with a suspension of lamprey pituitary material at a dose level of three glands per animal in 0·1 ml. saline, and the other with a mixture of 200 I.U. pregnant mares' serum and 300 I.U. chorionic gonadotrophin in 0·1 ml. saline, at approximately fortnightly intervals between December and April. The animals displayed secondary sexual characters in April and sperm was present in the testes, in most cases whorled within the lobules as in intact mature lampreys. Ovulation occurred in the females. These changes were more marked in the case of the pregnant mares' serum—chorionic gonadotrophin injections, in which the dose was evidently more suitable. Control animals injected with saline retained the immature status of hypophysectomized lampreys.

Intact lampreys of both sexes were also injected with pregnant mares' serum and chorionic gonadotrophin at the same dose-level and at similar intervals between November and early March. Stimulation of both primary and secondary sexual characters was obtained. Secondary sexual characters first appeared during February, though the injections started in November. This suggests that the tissues concerned are insensitive to hormonal stimulation until shortly before the time at which the secondary sexual characters normally develop.

Intraperitoneal implantation of a 25-mg pellet of testosterone into hypophysectomized male lampreys in December or February caused the development of secondary sexual characters in early May. Implantation of a 12·5-mg pellet had only a slight effect. Intact and hypophysectomized female lampreys implanted each with a 25-mg pellet of testosterone failed to develop the characteristic female post-anal fin, but developed an enlarged urinogenital papilla similar to that of a mature male. Thus, the nature of the secondary sexual characters appears to depend on the type of steroid hormone administered.

Three lampreys gonadectomized in November and seven gonadectomized in February survived until mid-April. None showed any sign of secondary sexual characters. It therefore appears likely that the relationship between gonad and secondary sexual characters, well established in other vertebrates, holds also in cyclostomes.

Unequal Weighting in Numerical Taxonomy

IN the Fungi Imperfecti, the system of classification which has evolved over the past 150 years involves the recognition of 'form species' and 'form genera' which lack any established genetic basis. Thus it is possible to speak of 'similarity' but not of 'relationship'. This system, though admittedly artificial, is at present essential to sorting and identification procedures.

As no more natural scheme is yet in prospect, any consistent and reasonably objective way of placing an unknown or undescribed fungus within the existing framework would be useful both to the non-taxonomist attempting identifications, and to the scientific historian trying to explain the rationale of the present system.

We have accordingly attempted to apply the numerical approach to taxonomy within the existing scheme, as a first step toward making mathematics an operational tool in the taxonomy of the Fungi Imperfecti.

The method originally tested was that described by Sneath[1] in which coefficients of similarity are formed between pairs of organisms or taxa by the comparison of large numbers (at least 40 and preferably more than 60) of equally weighted qualitative and quantitative characters. Our initial work used a small group of Fungi Imperfecti comprising the genera *Haplobasidion*, *Lacellin-*

opsis and *Lacellina*, each with three species. The data were derived from a taxonomic treatment by Ellis[4], a list of 70 features being compiled for use in the numerical scheme.

When Sneath's method was followed, it was found that similarity coefficients between 'form species' from different existing 'form genera' were in some cases higher than those between 'form species' now considered congeneric (Table 1), and no acceptable alternative classification could be visualized. Consequently, it was felt that the method in its original form was unsuitable for this application.

In most discussions of numerical taxonomy[1–3] equal weighting of all characters has been a prerequisite, because of the difficulty of devising any rational criteria for differential weighting.

Table 1. SIMILARITY COEFFICIENTS WITH EQUAL WEIGHTING

Table 2. SIMILARITY COEFFICIENTS WITH DIFFERENTIAL WEIGHTING

Species	1*b*	1*c*	2*a*	2*b*	2*c*	3*a*	3*b*	3*c*
1*a*	78	78	73	71	69	50	54	57
1*b*		83	67	68	71	53	53	54
1*c*			75	72	69	56	54	56
2*a*				86	85	74	76	75
2*b*					84	71	70	72
2*c*						71	68	71
3*a*							96	88
3*b*								88

Key to species: 1*a*, *b*, *c*, *Haplobasidion thalictri*, *H. lelebae*, *H. musae*. 2*a*, *b*, *c*, *Lacellinopsis sacchari*, *L. levispora*, *L. spiralis*. 3*a*, *b*, *c*, *Lacellina graminicola*, *L. macrospora*, *L. leonensis*.

The principal differences between *Haplobasidion*, *Lacellinopsis* and *Lacellina* are that only the first two possess swollen sporiferous vesicles at the apex of the conidiophore, and only the last two possess setae. In organisms like the Fungi Imperfecti, which are described largely in morphological terms, those terms may conveniently be divided into primary and secondary characters. Primary characters are those organs (setae, vesicles, conidia) which require further characterization or description. This is supplied by a variable number of secondary descriptive features (width, septation, pigmentation). Differences in secondary characters will naturally lower the similarity coefficient, and since secondary characters considerably outnumber primary characters, such differences can sometimes outweigh similarities in primary characters. Where a species lacks a primary character, the associated secondary characters are not considered when making comparisons with other species and hence do not affect the similarity coefficients. It seems unsatisfactory that it is possible for two species, both possessing a given primary character, to appear less similar to each other than to a third species lacking the primary character entirely, because of differences in secondary features of that character. This anomalous situation seems, in fact, to have arisen in the Fungi Imperfecti, although it has not apparently been encountered in other groups to which the method has been applied.

To obtain more realistic coefficients of similarity in the Fungi Imperfecti, an amended scoring system was devised. To each primary character was added a weighting of unity for each secondary character needed to describe it. The primary character 'setae present' is described by a maximum of eight secondary characters in any individual. In *Lacellinopsis sacchari*, for example, these are as follows: (1) simple, (2) straight, (3) subulate, (4) thick-walled, (5) pigmented, (6) septate, (7) 400–700μ long (max.), (8) 7–9μ thick (max.).

Under the modified scheme, the presence of setae in *Lacellinopsis* and their absence from *Haplobasidion* was now scored as nine character differences.

When this weighting system was used, the classification obtained was in accordance with present-day practice, the 'form genera' being clearly delimited (Table 2). While this was to be expected, since the weighting system was devised for this particular group of organisms, a more recent and larger analysis (which will be discussed in detail elsewhere), involving intraspecific as well as interspecific and intergeneric comparisons, has confirmed the usefulness of the modified method in the Fungi Imperfecti.

Germination of Basidiospores and Production of Fructifications of Members of the Agaric Family Bolbitiaceae using Herbarium Material

DURING the taxonomic examination of the Bolbitiaceae it has been necessary, in order to carry out mating determinations, to germinate the basidiospores of numerous collections. The source of the spores has included not only fresh spore prints but also spores from dried fruit bodies and from spore prints accompanying herbarium material.

Fresh turgid spores, collected from a mature sporophore and immediately plated out on 5 per cent malt extract agar, have germinated after a 48-h period in the dark at 25° C. On dung agar the germination vesicles, typical apparently of this family, and especially pronounced in the genus *Conocybe*, have been produced within a similar period of time. Spores of dried material, however, have not germinated satisfactorily, even during a 28-day period. Out of almost eighty collections, only in three have one or two spores been observed to develop vesicles and germ tubes. The subsequent growth of these germ tubes has been poor, and the vesicles have soon collapsed. No increase in germination has been noted if the spores from the herbarium were agitated in sterile distilled water for ½, 1, 2, 3, 4 h or longer periods of time. This suggests that the lack of germination is not due to the activity of a simple water soluble and leachable inhibitor. Sterile dilute aqueous solutions of organic acid and/or mineral nutrients have had no stimulatory effects.

Spores from herbarium material, however, germinate if they are incubated in a saturated atmosphere overnight, transferred to a phial of sterile distilled water, dispersed by agitation in a micro-shaker and plated out.

The incubation was carried out by placing the dry spores in a welled slide mounted on glass disks in a sterile Petri dish and surrounded by 5 mm of sterile water. This was left overnight in a darkened incubator at 27° C, the latter being the most favourable temperature.

By this simple technique basidiospores of the type material of *Conocybe percincta*, after two years in the dry conditions of a herbarium, have been induced to germinate. The viability of collections varies according to the way the herbarium material has been dried. Herbarium material treated with insecticides has not germinated by this method.

A few collections, approximately three years old, of *Bolbitius vitellinus*, *Conocybe subpubescens* and *Agrocybe semi-orbicularis*, have germinated after the foregoing treatment, but normally after two years the spores have completely dried out and the protoplast has become disorganized.

Scarth[1] has shown that after freezing plant tissue in micro-cold chambers and suddenly thawing under constant observation there is a flooding of the intercellular spaces, rupturing of the protoplast, and consequently a low survival of the cells constituting the tissue. If gradual thawing is allowed there is no such tearing of the cell wall away from the protoplast and the organization seems to be retained or not drastically disorganized as with a violent deplasmolysis.

A similar mechanism may explain the results with agaric basidiospores. If water molecules gradually diffuse into the internal parts of the spore the survival rate is considerably higher than if the spores are swamped with excess free water. Using the dried herbarium material and incubating the spores in a saturated atmosphere, water is gradually imbibed by the viable spores present in the spore deposit. The colloidal components are allowed slowly to absorb sufficient water for reorientation over a twelve-hour period and are not disorganized by flooding.

The spores so treated are in a suitable state to be agitated in either sterile distilled water or aqueous mineral solutions without further injury to the protoplast. A suspension of them in sterile distilled water was sprayed on nutrient agar, supplemented with 10 per cent dung extract. Agar disks with germination vesicles and germ tubes were cut out with a flamed cork borer and transferred to sterile half-pint milk bottles. In the bottles was placed a pad of shredded block paper pulp, 10 cm in depth, soaked in water, partially squeezed dry and covered with nutrient agar. The bottles were kept on the laboratory window sill at 20° C.

Sufficient of the nutrient agar, made up according to Lange's formula[2] plus 0·5 per cent malt extract, was added to form a 1–2 cm-layer at the bottom of each bottle and a thin coat over the paper pulp. The alveolate nature of the pulp presents a larger aerated surface for fungal colonization.

After about 50 days under the foregoing conditions primordia appear and within 60 days mature fruit bodies bearing normal basidia, basidiospores, cheilocystidia and dermatocystidia are formed. The spores produced by these fructifications are quite viable and fresh inoculations have been made from them. Some cultures, however, take longer to produce primordia or once they are formed do not develop further. Favourable growth and the production of sporophores in these cultures can be induced by covering the paper pulp pad with a layer of a sterile sand and soil mixture.

Incorporation of Hydrocyanic Acid labelled with Carbon-14 into Asparagine in Seedlings

In the course of work on the biosynthesis of cyanoglucosides in plants, it was observed in feeding experiments that young seedlings of a number of plant species incorporate radioactivity from $H^{14}CN$ into asparagine to a considerable extent.

Sorghum vulgare, var. Honey Drip, was used in most of the experiments. Seeds were germinated and grown in the dark for 4 days at 29 ± 1° C. Twenty seedlings were selected for uniformity and placed in a 10-ml. beaker containing 5 ml. distilled water. This beaker and a vessel containing 1 μM $Na^{14}CN$ (3·48 μc.) in 0·17 ml. 0·1 N sodium hydroxide were placed in a 2·5-l. desiccator which was closed immediately after addition of a slight excess of mineral acid to release $H^{14}CN$. The seedlings were maintained in continuous light under incandescent lamps for 40 h, during which period they appeared to grow normally. The plants were then collected, weighed, frozen in liquid nitrogen, ground and extracted with 100 volumes of boiling 80 per cent (v/v) aqueous ethanol for 5 min. The solvent was evaporated *in vacuo* and the residue extracted with 2 ml. of 10 per cent (v/v) aqueous isopropanol. The extract was clarified by centrifugation if necessary and suitable aliquots were used for paper chromatography. Similar feeding experiments were also carried out with barley (*Hordeum vulgare*, var. California Mariout), pea (*Pisum sativum*, var. Alaska), flax (*Linum usitatissimum*, var. Imperial), red clover (*Trifolium pratense*, var. Medium) and white clover (*Trifolium repens*, varieties Ladino and New Zealand Certified).

Two-dimensional chromatograms were prepared on Whatman No. 1 paper in phenol/water (80 : 20 w/v) followed by butanol/acetic acid/water (120 : 30 : 50 v/v), using the descending technique[1]. Autoradiographs were made using Kodak 'No-screen' X-ray film with exposure times of 1–2 weeks. In all cases, a very intense spot was observed on the autoradiographs, which superimposed exactly with the characteristic brown spot for asparagine observed on spraying the chromatograms with ninhydrin reagent and developing at room temperature. Percentage recoveries of carbon-14 in the suspected asparagine were determined by eluting the radioactive zones from one-dimensional chromatograms run in butanol/acetic acid/water and counting suitable aliquots at infinite thinness in a gas-flow counter (Nuclear-Chicago model 181*B*). Recoveries in two experiments with sorghum were 14 and 17 per cent.

Some less-intense spots were also observed on the autoradiographs, the pattern varying with different species. In several instances a spot was observed in the position where sucrose would be expected, corresponding exactly with a positive reaction to aniline phthallate reagent[1] on the chromatograms. A tracing of a typical

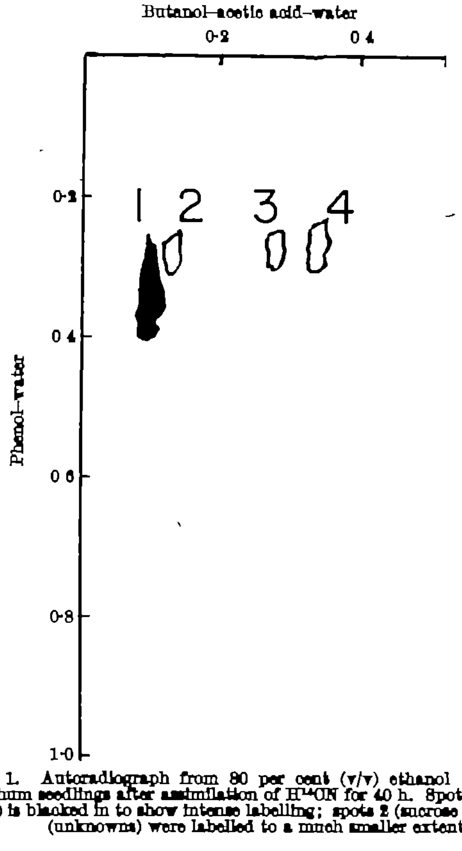

Fig. 1. Autoradiograph from 80 per cent (v/v) ethanol extract of sorghum seedlings after assimilation of $H^{14}CN$ for 40 h. Spot 1 (asparagine) is blacked in to show intense labelling; spots 2 (sucrose ?), 3 and 4 (unknowns) were labelled to a much smaller extent

autoradiograph from the experiments with sorghum is shown in Fig. 1.

The identity of the most heavily labelled compound as asparagine was established conclusively for all the species studied. Aliquots of the extracts were chromatographed in one dimension on Whatman No. 1 paper in each of the 4 following solvent systems: methanol/water/pyridine (160 : 40 : 8 v/v), ethanol/water/ammonia (180 : 10 : 10 v/v), methyl ethyl ketone/acetone/water (30 : 10 : 6 v/v), ethanol/*tert*-butanol/water/ammonia (60 : 20 : 15 : 5 v/v). The distribution of radioactivity was determined using a chromatogram strip scanner (Nuclear Chicago model *R*1000). In all cases the major radioactive peak was found to correspond with DL-asparagine marker. A superposition test with authentic L-asparagine using methyl ethyl ketone–acetone–water as solvent was positive. Exact correspondence was also obtained when an aliquot was run on DEAE paper in 0·02 M phosphate buffer, *p*H 4·7 (ref. 3).

Formation of aspartic acid was demonstrated by enzymatic hydrolysis with a *Pseudomonas* enzyme which exhibits both glutaminase and asparaginase activity[4]. Prof. D. M. Greenberg and Dr. M. E. Ramadan, University of California Medical School, San Francisco, kindly supplied an enzyme preparation of activity 200 enzyme units per ml. (1 unit is defined as liberation of 1 μM ammonia per 15 min). Radioactive asparagine in the extracts was separated from glutamine by paper chromatography in butanol–acetic acid–water. Suitable aliquots of the eluates were incubated for 15 min at 37° with constant shaking with 0·1 ml. enzyme in the presence of 0·09 M sodium veronal buffer, *p*H 8·2, and 0·023 M potassium cyanide in a total volume of 1·1 ml. Chromatograms were then run in butanol–acetic acid–water, scanned for radioactivity and sprayed with ninhydrin. A single radioactive peak was observed to correspond with aspartic acid in marker strips and no radioactivity was detected at the asparagine position.

In a preliminary assessment of the distribution of carbon-14 in the asparagine, chromatograms of the partially purified asparagine-^{14}C and of aspartic acid-^{14}C derived by enzymatic hydrolysis were sprayed with ninhydrin, dried for 5 min at 100° and scanned a second time in the strip counter. Whereas there was no reduction in radioactivity in the case of asparagine, all the radioactivity was lost from the aspartic acid by decarboxylation after spraying twice with ninhydrin. This suggested that the label was present solely in the β-carboxyl carbon atom of aspartic acid, or the amide carbon atom of asparagine[5].

The distribution of carbon-14 in the carboxyl- and amide-carbon atoms of asparagine was determined more precisely by the decarboxylation of asparagine-^{14}C and aspartic acid-^{14}C with *N*-bromosuccinimide[6]. The $^{14}CO_2$ evolved was collected in 1 ml. *M* potassium hydroxide in the centre-well of Warburg vessels and determined by a modification[7] of the scintillation counting method of Gordon and Wolfe[8]. Whereas 100 per cent of the carbon-14 of aspartic acid was recovered as $^{14}CO_2$, only 1·6 per cent of the carbon-14 of asparagine was thus recovered.

These experiments show that the carbon atom of hydrocyanic acid is incorporated in relatively large amounts into the amide-carbon atom of asparagine in seedlings of 6 species. It appears likely that asparagine can be synthesized in these species by 3-carbon plus 1-carbon condensation, where the 1-carbon fragment is hydrocyanic acid or a related compound such as formamide. In similar feeding experiments with $^{14}CO_2$ a much wider distribution of the label was found, showing that the observed results with $H^{14}CN$ were not due to conversion to $^{14}CO_2$. Preliminary experiments with serine-^{14}C support the hypothesis that serine or a related metabolite could be the 3-carbon unit.

It will be noted that hydrocyanic acid was incorporated into asparagine both in seedlings of species which contain relatively large amounts of cyano-glucosides (flax, sorghum and white clover)[9], and in seedlings which contain very small amounts, if any, of organic nitriles.

These results may also be of interest with respect to the use of cyanide as an inhibitor in experiments with plant tissues, since the level of inhibitor might change during an experiment due to metabolism of hydrocyanic acid in the manner described here.

Efficiency of Infective Propagules of *Rhizoctonia solani* in reducing Vigour of Strawberry Plants

WE have found that the number of strawberry plants produced by the end of the season is inversely related to the number of mycelial fragments of *Rhizoctonia solani* adhering to small roots of strawberries at mid-season.

On May 2, 1961, four different soil treatments were disked into the upper 3–5 in. of 7 × 10 ft. plots. The treatments, plus untreated control plots, were replicated four times. Six days later, Midway variety strawberry plants, naturally infested with *R. solani*, were set out. There were ten plants per plot. On August 28, samples of roots, 1 mm in diameter or less, were taken from the plants. Soil particles were shaken from the roots. The latter were dipped in lactophenol, drained, and mounted in lactophenol for examination under the microscope. The average number of mycelial fragments of *R. solani* adhering to a 5-cm length of root was determined. The total number of strawberry plants—original plus all runner plants—were counted at the end of the season.

Fig. 1 shows the highly significant negative correlation between root infestation by *R. solani* and the final numbers of plants. The data fit both an arithmetic and a logarithmic regression equally well. Any essential differences between the two regressions is evident only above or below our range of observations as shown in Table 1. If the relation between cause and effect is arithmetic, then reducing the number of mycelial fragments from 10 to 1 per 5 cm of root could increase the expected number of plants by less than 10 per cent. A logarithmic relation, however, implies that such a reduction in mycelial fragments would about double the number of expected plants, if there were no other limiting factors. At the other end of the scale, an arithmetic relation would predict a complete loss of plants if there were more than 70 fragments

Table 1. EFFECT OF NUMBER OF *R. solani* MYCELIAL FRAGMENTS ON THE FINAL NUMBER OF STRAWBERRY PLANTS. COMPARISON OF AN ARITHMETIC WITH A LOGARITHMIC RELATION

Mycelial fragments per 5 cm of root	Expected No. of plants at end of season	
	Arithmetic	Logarithmic
1	49	87
5	46	58
10	43	40
25	33	30
50	16	17
7	0	10
100	0	5

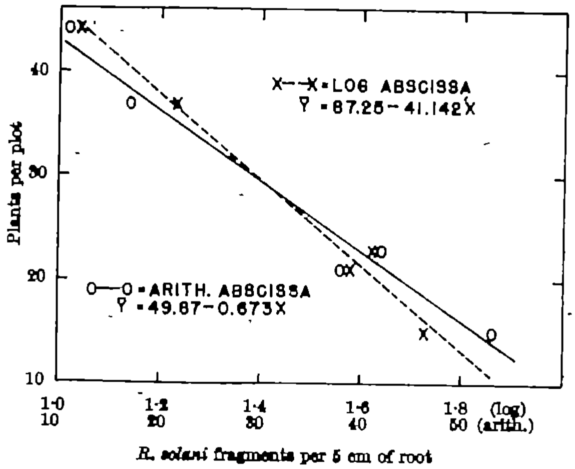

Fig. 1. Relation between number of *R. solani* mycelial fragments per 5 cm of root and final number of strawberry plants per plot. The regression coefficients obtained with either the logarithmic or arithmetic abscissae are both significant well beyond the 1 per cent level

per 5 cm of root. The logarithmic relationship would predict that more than 100 fragments would be needed to reduce the number of plants to one.

Regardless of which relation applies, *R. solani* must be reducing the vigour of strawberries in Connecticut where this fungus is omnipresent. As biological cause–effect relations are usually logarithmic, the reduction in vigour must be appreciable. In addition, the logarithmic relation accounts for why *R. solani* of itself rarely causes complete failure of plantings.

Correlated Seed and Tuber Dormancy in Potatoes

The seeds of temperate-zone wild plants are usually dormant at maturity and germinate only after a lapse of time and/or the application of certain more or less specific dormancy-breaking conditions. By contrast, the seeds of cultivated plants are commonly non-dormant, and this must usually represent a response to human selection; loss of dormancy has thus been a significant episode in the evolution of many cultivated plants. Since few genetical investigations of dormancy in crop plants have been reported, an investigation of the cultivated potatoes was begun in 1959; the finding that, in this group, seed and tuber dormancy are correlated, an observation of some general and practical interest, prompts a brief description of the leading results so far obtained.

An inverse measure of seed dormancy may be obtained by counting germination of freshly gathered seed four weeks after being set out in the Petri dish and this method has been adopted as routine[1]. Tuber dormancy is estimated by the mean time to appearance of shoots from tubers buried in moist peat in the glasshouse.

One set of experiments started from highly heterogeneous (open pollinated) bulks of seed[1] derived from field plantings of cultivated diploid potatoes ($2n = 24$) and Andigena Group tetraploids ($2n = 48$) (ref. 2). The material all came from the Commonwealth Potato Collection. Fresh seed was laid out in trays on moist filter paper and selection for early and late germination was carried out: this was, effectively, selection for low and high dormancy. Of the four resulting lines, the two diploid (which were self-incompatible[2]) were carried on by sib-crossing, the two tetraploid by sib-crossing and selfing. Responses were striking: the two low-dormancy lines both gave more than 90 per cent germination in three generations; the high-dormancy lines dropped to 40 per cent germination in two generations for the diploids and to about 1 per cent in three generations for the tetraploids Thus selection for and against seed dormancy was effective Moreover, tuber dormancy showed a parallel response to the same selection: thus the low-dormant lines bear tubers that sprout in about 2–3 weeks (diploids) or 4–5 weeks (tetraploids); and the high-dormant lines, by contrast, bear dormant tubers, sprouting in about 8–9 weeks (diploids) and in over 12 weeks (tetraploids).

Change in tuber behaviour therefore occurs as a correlated response to seed selection. The converse is also true: seed derived from plants selected for different levels of tuber dormancy responds with a parallel shift in seed dormancy. Among the edible diploids, the Stenotomum Group (*stn*) have, in general, dormant tubers while the Phureja Group (*phu*) have non-dormant ones and this difference represents a response to human selection for different agronomic conditions in South America[2]. Fig. 1 shows a comparison of mixed lots of Phureja and Stenotomum seed. It was six months old when tested, so some natural dormancy decline had certainly occurred[1]; nevertheless, the difference is striking. The subject has been further investigated by means of diallel crossings of *stn* and *phu* clones, and the results reveal significant clonal and reciprocal effects. The work is yet incomplete, but one experiment gave a mean seed germination of 74 per cent for *phu* crosses, 39 per cent for *phu*/*stn* hybrids and 27 per cent for *stn* crosses. The corresponding figures for tuber dormancy are 2–3 weeks, 4–8 weeks and 10–12 weeks or more. Once again, therefore, the two dormancies are correlated.

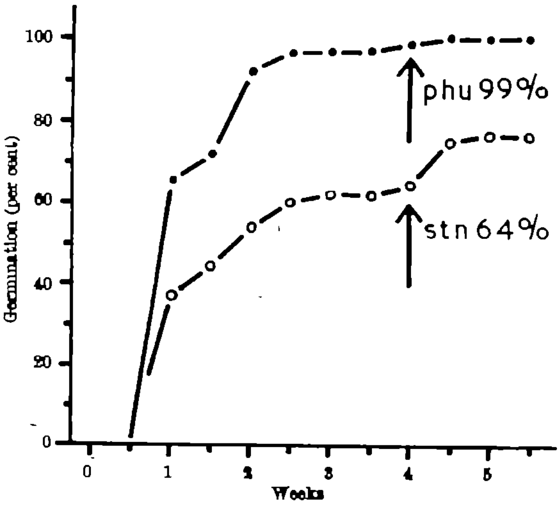

Fig. 1. Seed germination curves of diploid potatoes, Groups Phureja (*phu*) and Stenotomum (*stn*). Five replicate plates of 50 seeds each

The implications of these results are: first, that seed and tuber dormancy are under a common biochemical control; and, secondly, that selection at the seed-level is of potential practical importance. Thus the potato breeder could select for early sprouting tubers by picking the first germinators in dormant seed lots; and the breeder who needs slow sprouting ('good keeping quality') could advance his selection by picking the slowest germinators. Emilsson[3] has shown that European selection generally favours a rest period of 9–11 weeks (roughly equivalent to the same period of dormancy in my test though measured quite differently), so the lower extreme displayed by the South American cultivars is largely eliminated. But other cultivations, in warmer countries, need lower dormancy to permit frequent replanting, just as low dormancy has been selected in the Phureja Group in South America[2]. Examples are Israel[4] and Japan[5]. Seedling selection could be a useful adjunct to potato breeding in these circumstances.

ENTOMOLOGY

Influence of Relative Humidity on the Uptake of Insecticides from Residual Films

It is now well known that the effectiveness of insecticides absorbed by certain soils is much greater at high than at low humidity. Analytical results[1–3] have shown that this is not due to an increase in concentration of the toxicant in the superficial layers of the soil.

It has been suggested[1,2] that water is adsorbed preferentially on the soil particles, with consequent displacement of the insecticide molecules and increase in their mobility. Under these conditions the toxicant was thought to be more readily available to the insect.

The increased availability of dieldrin in humid conditions has now been confirmed by the direct determination of toxicant pick-up by insects from residual films on glass.

Insects were exposed in glass tubes, the inner surface of which (200 cm^2) had been treated with dieldrin labelled with carbon-14. A gentle flow of air was led through the tubes during exposure to prevent accumulation of insecticide vapour and condensation of insecticide directly on to the insects[4]. Pick-up of toxicant by the insects was thus achieved mainly by contact with the treated surface. The relative humidity was varied by feeding either dried or humidified air into the exposure tubes (relative humidity < 10 or > 90 per cent respectively). The exposure tests were carried out using dieldrin-resistant strains of *Musca domestica* and *Anopheles gambiae*, and a normal susceptible strain of *Aedes aegypti*.

After exposure, extracts of both the insects and the remaining insecticide residue on the glass were examined by a liquid scintillation counting technique. The total recovery of radioactive material, in terms of dosage applied, amounted to 95 per cent.

Table 1 shows that uptake of insecticide was always higher under humid than under dry conditions, and provides a quantitative confirmation of previous findings, indicating a greater availability of toxicant at higher relative humidity.

Table 1. UPTAKE OF ^{14}C-DIELDRIN UNDER DRY AND HUMID CONDITIONS

Species	No. of insects	Residue (µg)	Exposure time (h)	Insecticide recovered from insects (µg)		Ratio of uptake humid/dry
				Dry	Humid	
Musca domestica	10	1	24	0·480	0·769	1·6
Aedes aegypti	20	0·1	17	0·022	0·069	3·1
Anopheles gambiae	30	1	15	0·067	0·606	9·0

It is interesting to note that the influence of humidity on the uptake of dieldrin is least with *Musca domestica*, which walks the most actively during exposure, and most pronounced with *Anopheles gambiae*, which seldom walks at all. *Aedes aegypti* is intermediate in both respects.

The most likely explanation for this inverse relationship is that insects walking over the treated surface pick up the insecticide mechanically from a large area compared with that contacted by the stationary insects. The rate of pick-up by the stationary insects would depend largely on the mobility of the insecticide molecules in the residual film, and under these conditions the greater influence of relative humidity would be expected.

The results obtained with residual films on glass were confirmed in further exposure tests on dieldrin-impregnated filter paper, which showed that the uptake of toxicant by *Anopheles gambiae* was 2·2 times higher under humid than under dry conditions. It seems likely, therefore, that the effect of humidity is not restricted to specific substrates. Furthermore, similar observations have been made with γ-BHC and with DDT on dried soils, and it would appear that we are dealing with a fairly general phenomenon. The influence of relative humidity should, therefore, receive careful consideration in the interpretation of bioassay tests of the kind described here.

MICROBIOLOGY

Endotoxoid Preparations

The methods which are used for the preparation of non-toxic but highly antigenic toxoids from Gram-positive bacterial toxins could not be applied to the detoxification of toxic *O*-antigens of Gram-negative micro-organisms.

During investigation of the relationship between chemical structure and various biological properties of Gram-negative bacterial *O*-antigens, it was found possible to abolish selectively one or more biological activities by a variety of chemical treatments[1]. Endotoxic *O*-antigens soluble in trichloroacetic acid were isolated from *Serratia marcescens* cultivated on beef infusion broth. The lyophilized preparations were purified by extraction with methanol, a procedure which removes inert impurities but does not influence the biological properties of the endotoxins[2]. The purified materials were then subjected to chemical procedures. Those treatments which diminished the mouse lethal toxicity while retaining the reactivity with homologous rabbit *O*-antiserum were further investigated. Three methods were found to be especially effective.

(1) 100 mg of the foregoing endotoxin refluxed for 60 min with 10 ml. of 2 per cent boron trifluoride in anhydrous methanol resulted in the almost complete dissolution of the material in this solvent. When the reaction mixture was diluted with 4 volumes of water and dialysed against distilled water for 48 h, the material showed less than one-tenth of the original lethal toxicity.

(2) 100 mg toxic *O*-antigen preparation was refluxed for 60 min with 20 ml. of 0·02 M potassium methylate in anhydrous methanol. The insoluble residue was filtered on a glass filter, washed with methanol and dried in a vacuum desiccator. This preparation was practically free from any toxic properties.

(3) Our earlier observation showed that the use of a powerful dissociating agent formed by concentrated pyridine and formic acid in a 2 : 1 ratio dissolves bacterial glycolipids at boiling water bath temperature without altering their mouse lethal toxicity. A 10 per cent aqueous solution of the same reagent under identical conditions in 60 min not only dissolved the *O*-antigen preparation but detoxified it as well. 100 mg endotoxin and 10 ml. of concentrated pyridine and formic acid in a 2 : 1 ratio were first stirred in a boiling water bath. After 15 min 90 ml.

Table 1. TOXICITY AND ANTIGENICITY OF THE PREPARATIONS

water was added and stirring was continued at the same bath temperature for 60 more minutes. The *O*-antigen was then precipitated in the cold with 4 volumes of methanol, washed with 80 per cent methanol, dissolved in 50 volumes of water and lyophilized.

Some immunobiological properties of the preparations were investigated. The results are summarized in Table 1. The mouse LD_{50} of the materials was determined following intraperitoneal injections. The results of quantitative precipitin tests revealed that while the treatment with boron trifluoride diminished the reactivity with homologous *O*-antiserum, the second and third detoxification procedures approximately doubled the amount of protein nitrogen precipitable by these modified *O*-antigens. The *O*-antiserum was obtained by injecting rabbits with a heat-killed suspension of *Serratia marcescens* cells. Immunization of rabbits with the detoxified preparations produced in all cases a potent antiserum; however, the first procedure reduced the antigenic character of the endotoxin.

It was found, in co-operation with other groups, that the endotoxoids greatly increased the non-specific resistance of mice and rabbits against experimental infections[1]. Preparation obtained by the second procedure causes marked hyperplasia of granulocytes in the bone marrow 7 days after injection[2]. The same preparation gave 100 per cent protection against total-body 700-r. irradiation in mice when injected 24–72 h before irradiation[4]. Detailed reports of these results will be published separately.

Quantitative analyses revealed certain changes in the composition of the preparation. Table 2 presents some of the results of chemical analyses. Evaluation of these results and clarification of the changes in the structure due to detoxification are under further investigation.

Accumulation of Free Proline during Yeast Sporogenesis

ALTHOUGH the composition of the pool of free amino-acids in the yeast cell has been much investigated, this has been done using commercially supplied yeast[1,2] or vegetative cells from growth cultures[3,4]. No work has been reported on the amino-acid content of sporulated cells. We have undertaken to compare vegetative, sporulating and sporulated cells in respect of their content of free amino-acids.

Culture methods were essentially those of an earlier investigation[5]. 100-ml. volumes of pre-sporulation growth medium in 200-ml. round-bottomed flasks were inoculated from 2-day cultures on stock culture medium. The cells from a given pre-sporulation flask were collected by centrifugation, washed twice in distilled water, and suspended in 100-ml. of sporulation medium (0·1 M *p*H 5·0 phthalate buffer with addition of 1 per cent sodium acetate), and aerated in a 200-ml. flask at 27° C. For determination of amino-acid content the cells in a given flask were separated from the medium by centrifugation, washed twice in distilled water, and suspended in 80 per cent ethanol for at least 12 h. They were then removed by filtration and dried for weight determination. The filtrate was evaporated to dryness in a hot water bath. The residue was added to 1 ml. of distilled water and centrifuged to remove water-insoluble material. The supernatant, preserved by addition of a small crystal of thymol, was subjected to a quantitative chromatographic procedure[6-8].

Fig. 1 summarizes in part the results obtained with a strain of *Saccharomyces cerevisiae* used in earlier sporulation work[5]. Spores were not present in the vegetative cultures and began to appear after about 24 h in the sporulation environment. Frequency of cells containing spores at successive times were: 24 h, 3 per cent: 48 h, 40 per cent; 72 h, 55 per cent; 96 h, 60 per cent; 120 h, 70 per cent; 144 h, 80 per cent. Twelve amino-acids and glutathione were detected. After six days in sporulation medium the total content of these substances was less than in vegetative cells, largely in consequence of a marked diminution in amount of glutathione, glutamic acid, lysine and glycine, which were initially the most abundant (at least 1,000 μg/g). It is of interest that proline increased from minute amounts in vegetative cells to become the most abundant free amino-acid in 6-day sporulated cells. The increase began, moreover, long before spores could be seen. It also preceded the meiotic nuclear divisions, which commence in cells of this yeast

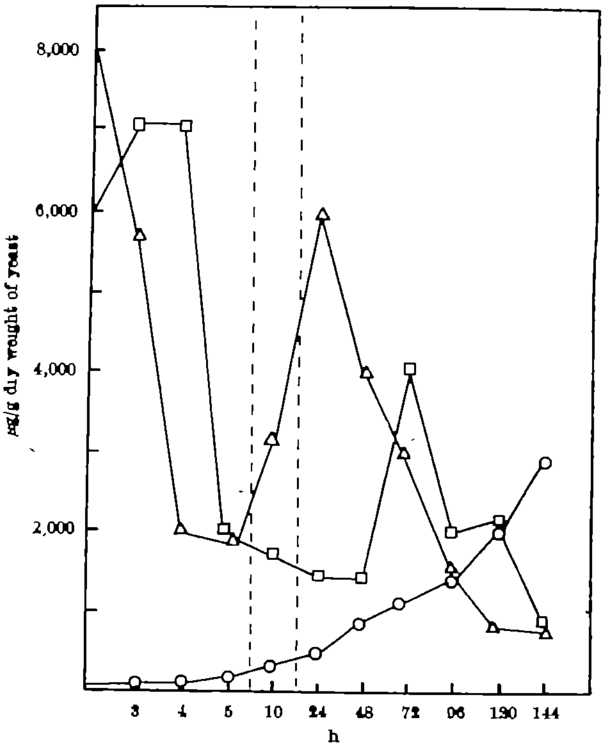

Fig. 1 Changes in content of proline, glutamic acid, and glutathione in cells of *Saccharomyces cerevisiae* during six days of incubation in sporulation medium. △, Glutathione; □, glutamic acid; ○, proline

strain under equivalent cultural conditions about 15 h after transfer to sporulation medium[8].

The procedures were done twice with both vegetative and 6-day sporulated cultures of *Saccharomyces oleaceus* Santa Maria and *S. mellis* (Fabian and Quinet) Lodder and Kreger-van Rij. Proline was not detected in the vegetative cells of either yeast; but it was prominent among the amino-acids in sporulated cells. However, no proline was found in four experiments using vegetative and sporulated cells of *Schizosaccharomyces pombe* Lindner, nor in an experiment with *Torulopsis famata* (Harrison) Lodder.

Changes in amino-acid content after transfer of 6-day sporulated cells of *S. cerevisiae* to fresh growth medium were also followed. In about 4 h the spores were distinctly swollen. A day later most had germinated, and growth was in progress. Whereas most amino-acids gave evidence of increase during two days in growth medium, proline diminished to 200 μg/g.

It would have been preferable to use for these experiments large volumes of sporulation medium, taking successive samples during six days, instead of running each chromatogram with an individual 100-ml. culture. But as sporulation was poor in large sporulation cultures, the less-accurate method had to be used, and this may account in part for the fluctuations in amount of glutamic acid and glutathione indicated by successive determinations. But as each point is based on at least four, and in many cases ten, experiments it is possible that marked changes occur in the content of these substances during active sporogenesis.

We thank the National Research Council of Canada for the award to one of us (C. R.) of a postdoctorate fellowship.

Stimulation of Sporulation in *Penicillium* by Anhydroglucose

In submerged shaken cultivation in a synthetic medium containing potassium nitrate, potassium dihydrogen phosphate, and magnesium sulphate, trace elements and pure (analytical reagent) glucose, *Penicillium griseofulvum* Dierckx (Strain *ARL*. 375) grows vegetatively but does not sporulate even when it has used up all the available nitrogen. Abundant sporulation at a relatively early, exponential, stage of growth was observed when pure glucose was replaced by a crude commercial glucose derived from maize starch by acid hydrolysis[1]. Crude glucose was also found to stimulate submerged sporulation in 5 other species of *Penicillium* out of a further 21 species which were tested. The nature of the sporing factors in crude glucose was therefore investigated.

It was found that the sporing stimulus depended on the simultaneous presence of two substances, of which the first proved to be calcium (Ca^{++}), occurring in amounts sufficient to give a level of approximately 5×10^{-4} M in a medium containing 5 g/l. crude glucose. Calcium was already known to induce submerged sporulation of *Penicillium griseofulvum*, but only at levels above 5×10^{-3} M, and then only at a late, post-exponential stage of growth when the nitrogen in the medium is either exhausted or nearing exhaustion. The amount of calcium present in the crude glucose added to our standard medium does not, however, normally induce sporulation, except in the presence of a second substance occurring in crude glucose. This was found to be a neutral organic heat-stable compound which appeared to be an acid reversion product of glucose. In fact variable amounts of a similarly active substance were found to be produced by autoclaving pure glucose with acid. The substance was separated from crude glucose by adsorption on charcoal and elution with ethanol, and the active fraction was identified as a 1,6-anhydroglucose by preparative paper chromatography. When this fraction, together with 1×10^{-4} M Ca^{++}, was added to a submerged culture of *P. griseofulvum* in a medium containing pure glucose, abundant sporulation was induced early in the exponential phase of growth, although neither Ca^{++} nor the anhydroglucose fraction produced this sporing effect alone.

The nature of the organic sporing factor was confirmed by synthesizing 1,6-anhydro-β-D-glucopyranose by alkali treatment of β-phenylglucoside[2]. This substance gave the characteristic induction of sporulation in *P. griseofulvum* when added, with 1×10^{-4} M Ca^{++}, to a culture growing in medium containing pure glucose. Maximal sporulation occurred when the anhydroglucose concentration was between 2×10^{-4} and 6×10^{-4} M and was not increased at higher concentrations. No sporulation occurred in the absence of added Ca^{++} even with very high concentrations of anhydroglucose in the usual growing medium. When the potassium nitrate was replaced by ammonium succinate, however, very high concentrations of anhydroglucose did induce (late) sporing without added Ca^{++}. This does not seem to be due to traces of Ca^{++} already present, and it indicates, as do certain accompanying morphological changes, that anhydroglucose may have specific biological effects apart from its interaction with Ca^{++}. A mixture of the pyranose and furanose forms of 1,6-anhydro-D-glucose, produced by the pyrolytic distillation of starch[3], proved to have the same sporulation-inducing effect as the pure pyranose form, when tested (with Ca^{++}) in the same conditions. Smaller but significant inductions of sporulation were also given in the presence of Ca^{++} by 1,6-anhydro-β-D-galactopyranose and by 1,6-anhydro-α-D-galactofuranose.

These observations show that the stimulus to sporulation of *P. griseofulvum* (and probably of other species of *Penicillium*) caused by crude glucose is due to the presence of anhydroglucose and traces of Ca^{++}. Further confirmation is provided by the absence of any sporing effect from crude glucose produced by enzyme hydrolysis instead of by acid hydrolysis of starch. Studies of the effects of anhydroglucose and related compounds on metabolism and sporulation of fungi are now in progress. The ability of 1,6-anhydro-β-D-glucopyranose to increase so powerfully the spore-inductive effect of Ca^{++} provides another example of a biological effect elicited by carbohydrate reversion products[4,5]. Interactions between Ca^{++} and hexose phosphates have been observed in the stimulation of perithecia formation in *Chaetomium*[6].

VIROLOGY

Two-sided Effect of Steroids on Interferon in Tissue Culture

In the course of an investigation of interferon production in a line of rat tumour cells (*DE7R* cells), infected with Sindbis virus Δ′,17α-methyltestosterone ('Dianabol', Ciba), an androgenic steroid known to increase protein synthesis in rats[1] was added to the virus-cell system, in the hope of obtaining higher interferon yields. The effect of 'Cortisol' was evaluated at the same time in order to compare the action of a glucocorticoid known to decrease protein anabolism *in vivo*[2] with that of an androgen. The methods used for preparing the interferon and to test for its activity have been previously described in detail[3].

'Cortisol' and 'Dianabol' were obtained in pure crystalline form. Each steroid was dissolved in ethanol at a high concentration and kept at −10° C for a maximum of 30 days. Final dilutions in culture medium were carried out before each experiment. The final ethanol concentration varied between 2×10^{-4} and 5×10^{-5}. Care was taken to have the same amount of ethanol in the control fluids. Two concentrations of each steroid were tested: 'Dianabol' was used at 2 γ/ml. and 0·2 γ/ml. (7×10^{-6} M and 7×10^{-7} M respectively), and 'Cortisol' was used at 0·25 γ/ml. and 0·025 γ/ml. (7×10^{-7} M and 7×10^{-8} M respectively). These concentrations had previously been shown to have no toxic effect on rat cells *in vitro* by comparing growth curves of rat embryo fibroblasts with and without the steroids.

Cultures of *DE7R* cells were infected with Sindbis virus at a multiplicity of 0·1. The steroids tested were added to the culture after virus adsorption had occurred. Culture fluids were collected 3 days after onset of infection for determination of virus and interferon production. At this time the cytopathological effect (CPE) of the virus was 75–100 per cent; there was no difference in degree of cytopathological effect between control and steroid-treated cultures. The infectious virus was destroyed by overnight dialysis against Sörensen glycine buffer at *p*H 2, followed by two consecutive 4 h dialyses against phosphate-buffered saline at *p*H 7. Preliminary studies with tritiated 'Cortisol' had shown that about 10 per cent of the steroid was not removed after this procedure. The dialysed fluids were examined for interferon activity in secondary cultures of rat embryonic cells, using Sindbis virus as a challenge. The results of such an experiment are shown in Table 1.

Table 1. Influence of 'Dianabol' and 'Cortisol' on Interferon Production by Sindbis Virus in *DE7R* Cells

	Interferon titre	Infectious virus produced
Control medium	1/80	$10^{4.75}$ $TCID_{50}$/ml.
'Dianabol' 0·2 γ/ml.	1/40	$10^{3.75}$
2 γ/ml.	0	$10^{4.75}$
'Cortisol' 0·025 γ/ml.	1/20	$10^{4.50}$
0·25 γ/ml.	1/10	$10^{4.75}$

It can be seen that, at concentrations which alter neither cellular nor virus growth, both 'Cortisol' and Δ′,17α-methyltestosterone strongly decrease final yields of interferon in tissue culture. A similar effect has been previously described by Kilbourne with the diethylaminoacetate hydrochloride of 'Cortisol' and 17α-ethyl-19-nortestosterone ('Nilevar' Searle) in chick embryo membranes[4]. This inhibitory effect on interferon synthesis could possibly be related to the capacity of steroids to release latent ATPase activity of rat tissue mitochondria, as shown by White *et al.*[5]. It is interesting to speculate whether a similar mechanism might explain the partial inhibitory effect of bicarbonate on interferon synthesis in rat cells, earlier described by us[3]. Wright *et al.*[6] have indeed shown that bicarbonate has an inhibitory effect on ATP-levels in rat liver homogenates. Experiments are planned to investigate this possibility.

The influence of 'Dianabol' and 'Cortisol' on the action of interferon was examined using the same steroid concentrations as in the previous experiments. Under certain conditions the presence of the steroid enhanced the viral inhibitory activity of the interferon, the effect being most pronounced with 'Dianabol'. This increase of interferon activity was observed either after overnight incubation of the cells with the steroid and interferon, followed by addition of the challenge virus in the morning, or after overnight incubation with the steroid alone, and removal of the steroid containing culture medium before subsequent incubation with interferon. No increase in interferon activity could be obtained when the cultures were incubated with the interferon first, and the steroid added after removal of the interferon. Similarly, overnight incubation with the steroids and interferon gave no enhancement of interferon activity if the cultures were washed and fresh medium added before addition of the challenge virus. Thus the continuous presence of interferon in the culture fluid seemed to be essential in order to obtain the enhancing effect of the steroids. No enhancement, but no clear cut decrease of activity either, was found when the experiments were performed in the conditions reported by Kilbourne[4], that is, short incubation of 2 h with the steroid, and removal of the steroid before addition of interferon. Table 2 summarizes the result of an experiment in which secondary rat embryo cell cultures were incubated with two-fold interferon dilutions in the presence of 'Dianabol' at 2 γ/ml. Sixteen hours later, 1,000 $TCID_{50}$ of Sindbis virus were added to each culture. The cytopathological effect was recorded 72 h after addition of the challenge virus, and the cultures were then put at −20° C for determination of virus development at each interferon dilution with and without the steroid.

The enhancement of activity of interferon under the conditions described here could be explained by an alteration of the cell membrane permeability, which would facilitate the uptake of new interferon after inactivation of the intra-cellular one.

It is of interest that 'Cortisol', a glucocorticoid, and Δ′,17α-methyltestosterone, a synthetic androgen, had similar actions at cellular levels. The inhibition of interferon synthesis, on one hand, and the enhancement of interferon activity, on the other hand, are suggestive for a double mechanism of steroidal action in the cell. Interferon may reveal itself to be an interesting tool for dissociating steroidal effect on specific protein synthesis and on cell membrane permeability.

We thank Dr. P. Osinski for providing us with tritiated 'Cortisol'. 'Dianabol' was generously supplied by Ciba,

GENETICS

Interchromosome Effects of Chiasmata and Crossing-over

The significance of chiasmata in relation to crossing-over inferred by Janssens was more fully recognized with the development of the partial chiasmatypy theory by Darlington[1]. Although in recent years mechanisms of crossing-over, very different from that based on the breakage and reunion hypothesis, have been proposed, a direct relationship between chiasmata and genetic recombination of the reciprocal type characteristic of most organisms has continued to be valid. Thus, as indicated by Pritchard[2], chiasma formation would be expected to occur regularly even on the copying-choice model of Lederberg[3] so long as the two copies are synchronized in their switching from one template to another, as they are expected to be, in the case of reciprocal exchanges. Whatever may be the mechanism of crossing-over—and it is widely recognized that the copy choice model as well as the mechanism proposed by Belling, though attractive, present considerable difficulties with regard to their wider applicability[4,5]—further evidence, briefly described here, has become available in recent years which either shows a direct correlation between chiasma formation and chromatid exchange or indicates in other ways a parallelism between chiasmata and crossing-over.

A one-to-one relation between chiasma formation and chromatid exchange has been demonstrated by Brown and Zohary[6] following their observations on heteromorphic bivalents and their anaphase separation in the pollen mother cells of *Lilium*. Further evidence which indicates a correspondence between chiasmata and genetic recombination is provided by studies on interchromosome effects in relation to these cytological and genetical events although the two types of observations have not so far been made on the same organism.

Interchromosome correlations for genetic recombination in *Drosophila* have been reported by a number of authors, more particularly by Schultz and Redfield[7], who have made a detailed analysis of this effect. The main findings, based primarily on the work of these authors, are that in structural homozygotes negative correlation of recombination in given regions of non-homologous chromosomes may occur, giving evidence of interchromosome interference. In structural heterozygotes the presence of inversions increases crossing-over in other chromosomes. Numerical changes in chromosomes such as those in triploids have effects on crossing-over identical with those of inversions and provide similar evidence of interchromosome influences. In the case of plants, compensatory increase in genetic recombination has mostly been demonstrated at intrachromosomal level[8].

Interchromosome effects in relation to chiasma distribution have been described by several authors[9], and more recently evidence has become available which indicates the factors controlling this distribution[10]. A particularly detailed analysis has been carried out on *Delphinium*, a favourable material for investigations of this type. Of the eight chromosome pairs in *Delphinium ajacis* var. Comet. two are considerably larger than the other six, and two groups of chromosomes can, thus, be easily recognized. There is good evidence to show that chiasma frequencies in these two groups of chromosomes are negatively correlated in most plants. The evidence for such a correlation was first obtained from observation on five plants[10]. This analysis has now been extended to another group of 25 plants all of which were found to show similar negative correlations.

The *Delphinium* material also offers an opportunity to examine interchromosome effects for chiasma distribution under conditions of structural heterozygosity corresponding to those in the inversion heterozygotes of *Drosophila*. This can be done if a large population of plants is raised from X-irradiated seeds. Several of these X_1 plants carry randomly induced structural changes in a number of their chromosomes as a result of which their meiotic pairing is affected and chiasma formation suppressed partly or completely. There was evidence that experimental reduction of chiasmata in some of the chromosomes in this way leads to increased chiasma formation in others[11]. This interchromosome effect in structurally heterozygous X_1 plants has now been systematically analysed, using for the purpose of comparison univalent carrying and normal pollen mother cells of the same plant, as shown in Table 1.

The foregoing observations make it clear that following the failure of one or two chromosome pairs to form chiasmata the other chromosome pairs, particularly the large ones, show a distinct tendency for increased chiasma formation. A statistical analysis of these observations confirmed that the mean chiasmata per bivalent in all the plants with one exception is significantly more ($P < 0.05$) in those groups of cells which carry univalents.

A further correspondence between interchromosome effects for genetic recombination and chiasma distribution is indicated by the observation that both are rather variable and not always manifested. In the case of

**L*, per large bivalent
†*S*, per small bivalent.

chiasma distribution, some of the factors accounting for this variability have been indicated by the analysis of *Delphinium*[10] and other plants[9]. An interesting observation in this connexion is that not always the presence of univalents elicits a response from the bivalents in the pollen mother cells. Inbreeding was found to be an effective method for inducing univalent formation in the pollen mother cells of *Delphinium*; when such plants were analysed, there was no evidence of compensatory increase in chiasma frequency as in the material from X-ray-treated seeds. Obviously a genotypically determined decline in chiasma frequency operates at the level of the nucleus as a whole, leaving little scope for interchromosome effects. Finally, while no triploids of *Delphinium* were available for observation, it is well known that chiasma frequency in such organisms registers an increase over the corresponding diploid as shown by Darlington[12].

The observations described above thus show that the 'Schultz–Redfield' effect operates for interchromosome distribution of chiasmata also. The observations reported here in a way supplement the earlier analysis of White and Morley[13], who found that pericentric arrangements of chromosomes in grasshoppers lead to compensatory formation of chiasmata at intrachromosome-level. These findings and the observations of Brown and Zohary referred to earlier provide additional support for interpreting chiasmata as being associated with genetic recombination.

We thank Dr. B. P. Pal and Dr. M. S. Swaminathan for their interest in this work.

PSYCHOLOGY

Information Load and Discriminability

It is clear that subjects take longer to differentiate between two stimuli if they are closely similar than if they are widely separated along some continuum of difference[1,2]. Conditions such as poor contrast or dim illumination which tend to obscure differences between complex stimuli may be expected to have the same effect. Recent models for discrimination and recognition[2,3] entail the assumption of some interaction between a factor of discriminability and the number of items to be differentiated. While data on reading-speed for various English vocabulary-sizes under dim illumination[4] may be taken as support for this, a situation in which subjects make responses to complex stimuli presented one at a time has not been manipulated to demonstrate directly such an interaction. The two experiments summarized here show such interactions between size of stimuli, illumination-level, and the number of items between which discriminations are made.

(1) *Size and information load.* Four packs of forty white playing card blanks were made up. Each card bore a single letter of the alphabet stencilled in indian ink as follows: pack *2S*, the letters *A* or *Z* appeared in equal numbers in a face 3 mm high; pack *2L*, the same, in letters 22 mm high; pack *8S*, the letters *A*, *B*, *C*, *D*, *E*, *F*, *G* and *H* appeared in equal numbers in a face 3 mm high; pack *8L*, the same, in letters 22 mm high.

Twenty subjects with 20/20 uncorrected vision (Royal Navy ratings aged 18–32 years, mean 23·7) were trained to sort these packs into piles according to the letters stencilled on the cards. Packs *2S* and *2L* were sorted into two piles and packs *8S* and *8L* into eight piles. Subjects held the packs face-downward in their non-dominant hands and turned cards over singly, dealing them on to the appropriate piles as quickly as possible. The overall sorting time for each pack was taken with a stopwatch. Subjects sorted the packs in random order, each man sorting each pack fifteen times over three experimental sessions. Results presented in Table 1 are derived from the mean sorting times for the last five trials on each pack.

Table 1. Mean Sorting Times (sec) for Two-Choice and Eight-Choice Packs with Large or Small Type-Face

Two-choice large type	38·7
Two-choice small type	39·5
Eight-choice large type	56·0
Eight-choice small type	60·6

An analysis of variance shows the interaction between type size and information load to be significant ($P < 0{\cdot}001$). It is thus apparent that a reduction in size of the symbols used affects performance more in the eight-choice than in the two-choice situation.

(2) *Level of illumination and information load.* The *2S* and *8S* packs described here were sorted by a second group of subjects also having 20/20 uncorrected vision (undergraduates aged 19–23, mean 21·3) under two conditions of illumination. Cards were sorted either in normal daylight illumination, or in dim illumination. In the latter condition subjects sorted cards after forty minutes' adaptation in a lightproof cubical illuminated by a dimmed tungsten lamp allowing 0·1 ft.-lamberts to be reflected from the surface of each card. This measurement was carried out with an *S.E.I.* photometer in the absence of a subject.

Ten trials were given on each pack under each of the conditions described, nine subjects beginning in the dim, and nine in the normal condition. Conditions were tested in separate experimental sessions. The results described in Table 2 are again based on the means for the last five trials on each pack.

Table 2. Mean Sorting-Times (sec) for Two-Choice and Eight-Choice Packs in Normal and Dim Illumination

Two-choice in normal illumination	37·4
Two-choice in dim illumination	40·5
Eight-choice in normal illumination	58·9
Eight-choice in dim illumination	65·3

An analysis of variance performed on the data shows that both two-choice and eight-choice packs take longer to sort in dim than in normal illumination ($P < 0{\cdot}001$). The interaction between illumination and information load is significant ($P < 0{\cdot}01$).

It must be concluded that dim illumination reduces efficiency more in the eight-choice than in the two-choice situation.

The extremes of choice between theoretical models for decision processes of this type are taciturnity on problems of discriminability[5] and an attribution of the entire effects of information load to problems of discrimination as the number of items to be distinguished increases[2]. The present results may further a more decent eclecticism. It is at least satisfactory that their practical implications are important and obvious.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, February 18

Society of Chemical Industry, Pesticide Group (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. K. S. Hocking: "The Work of the Tropical Pesticides Research Institute, Arusha".

Institution of Mechanical Engineers, Education and Training Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Should an Undergraduate Mechanical Engineering Course Include Production Engineering ?"

Institute of Metal Finishing (at the Northampton College of Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. R. W. Beattie and Mr. N. Fairweather: "Electroplating and Inspection of Electrical Contacts".

Tuesday, February 19

British Computer Society (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 4 p.m.—Mr. P. G. Lowe: "The Matrix Exponential Function with an Application to Structural Engineering".

University of London (at the Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. C. W. Jones: "Applied Mathematics in the Context of Engineering" (Inaugural Lecture).

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. I. Oswald: "Physiology of Sleep Accompanying Dreaming".* (Last of twelve lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Some Problems in Metal Box Production".

Royal Institute of Chemistry, London Section (at Norwood Technical College, Knight's Hill, London, S.E.27), at 7 p.m.—Dr. S. A. Miller: "The Liquefaction of Gases".

Wednesday, February 20

Royal Statistical Society (at the Piccadilly Hotel, London, W.1), from 10 a.m. to 4.30 p.m.—Productivity Conference. Morning Session, Opening address by Sir Robert Shone. Papers by Mr. W. B. Reddaway, Mr. C. T. Saunders, Prof. J. Johnston and Prof. H. D. Dickinson. Afternoon Session, Introduction by Dr. J. O. Irwin. Papers by Prof. G. A. Barnard, Mr. P. A. Dainley, Mr. L. H. C. Tippett and Mr. G. W. Sears.

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Prof. L. Doniach: "Pathology of Thyroid Carcinoma".*

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. A. J. Dyer: "Measurements of Evaporation and Heat Transfer in the Lower Atmosphere by an Automatic Eddy-Correlation Technique"; Mr. J. L. Monteith and Mr. G. Szeicz: "The Radiative Balance of Bare Soil and Vegetation"; and "Radiative Temperature in the Heat Balance of Natural Surfaces".

Institution of Electrical Engineers, Electronics Division (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. H. Page: "U.H.F. Television Broadcasting: Planning the Transmitting Equipment".

Royal Microscopical Society (at Tavistock House, South, Tavistock Square, London, W.C.1), at 5.30 p.m.—Dr. F. J. Jackson: "Problems of Extra-Terrestrial Microbiology".

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. S. Young: "Nuclear Power".

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. D. H. Chaddock: "The Development of High-Speed Automatic Loading Mechanisms for Heavy Anti-Aircraft Artillery".

Oil and Colour Chemists' Association (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mrs. S. M. Rybicka: "The Versatility of Chromatographic Methods in Paint Research".

Thursday, February 21

Parliamentary and Scientific Committee (in the River Room, Savoy Hotel, London, W.C.2), at 11.30 a.m.—Annual General Meeting.

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. R. P. Miller, Miss Elizabeth Napier, Mr. R. A. Wells, Dr. A. Audsley and Mr. G. R. Daborn: "Natural Leaching of Uranium Ores"; Dr. D. A. O. Morgan: "Some Economic Aspects of Mineral Exploration".

Linnean Society of London (at Burlington House, Piccadilly, London W.1), at 5 p.m.—Scientific Papers.

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. D. R. Hughes: "Geometry and Division Rings".

Institution of Electrical Engineers, Science and General Division P.G.S2 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Ferromagnetic Films" opened by Mr. C. E. Fuller.

University of London (at the Institute of Archæology, 31–34 Gordon Square, London, W.C.1), at 5.30 p.m.—Prof. J. M. C. Toynbee: "Early Christian Art and Græco-Roman Symbols".*

Institution of Mechanical Engineers, Steam Plant Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Performance Testing of Modern Large Steam Turbo-Alternators".

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Meeting on "Chemicals for the Control of Vegetation on Roads and Airfields".

Royal Institute of Chemistry, London Section (joint meeting with the Borough Polytechnic Chemical Society, at the Borough Polytechnic, Borough Road, London, S.E.1), at 7 p.m.—Prof. R. S. Nyholm, F.R.S.: "Higher Co-ordination Numbers of the Transition Metals".

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Dr. D. C. Gajdusek: "Kuru".

Thursday, February 21—Friday, February 22

Royal Society (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m. daily—Discussion Meeting on "Recent European Contributions to the Development of the Physics of Elementary Particles", organized by Prof. C. F. Powell, F.R.S.

Friday, February 22

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on "The Upper Mantle". Chairman: Sir Edward Bullard, F.R.S.

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. R. J. Harrison. "Bones, Teeth and Identification".

Saturday, February 23

Association of Clinical Biochemists, Southern Region (at Lewisham Hospital, London, S.E.13), at 2.45 p.m.—Scientific Papers and Demonstrations.

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Anthony Christie: "Looking at Oriental Art".*

Monday, February 25

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. B. Ackner: "Stress and Psychosomatic Disorders".*

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Dr. F. N. L. Poynter: "On Collecting Books for a Library of the History of Medicine".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. George Pendle: "Latin American Culture". (Second of three Cantor Lectures on "Latin America—World of Tomorrow".)

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.15 p.m.—Prof. D. B. DeLoach (California): "Agricultural Technology and the Management of Surpluses".* (Fifth of eight lectures on "The United States of America".)

Institut Français du Royaume-Uni (at Queensberry Place, London, S.W.7), at 8.15 p.m.—French Scientific Films.

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. W. W. Herbert: "In the Footsteps of Roald Amundsen".

Monday, February 25—Tuesday, February 26

Institution of Electrical Engineers, Power Division (at Savoy Place, London, W.C.2)—Symposium on "Transient, Fluctuating and Distorting Loads and their Effect on Power Systems and Communications".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Geology—The Registrar, The University, Leicester (February 23).

Assistant Lecturer in Zoology—The Registrar, The University, Leicester (February 23).

Assistant Lecturer (with special interests in palæontology and stratigraphy) in Geology—The Registrar, The University, Sheffield (February 23).

Chair of Theoretical Physics—The Secretary, The University, Exeter (February 23).

Lecturer or Assistant Lecturer in Pure Mathematics—The Registrar, University College, Singleton Park, Swansea (February 23).

Hospital Biochemist (Senior Grade), to work in the Department of Clinical Pathology—The Superintendent, Guy's Hospital, London Bridge, S.E.1 (February 25).

Lecturer in Biochemistry in the Department of Physiology and Pharmacology—Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (February 25).

Lecturer or Assistant Lecturer in Philosophy; and an Assistant Lecturer in Moral and Political Philosophy—The Registrar, The University, Keele, Staffs (February 25).

Postgraduate Research Student in Land Use Studies in the Department of Geography—The Registrar, University College of Swansea, Singleton Park, Swansea (February 28).

Research Assistant in Plant Biochemistry in the Department of Botany, to work on enzymes in isolated chloroplasts under the direction of Dr. J. Friend—The Registrar, The University, Hull (February 28).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Chemical Oceanography, Engineering or Physics—The Secretary and Registrar, The University, Southampton (February 28).

Research Assistant (with good qualifications in mathematics, and preferably a knowledge of numerical analysis and computing methods) to Prof. A. T. Price, to work on the analysis of magnetic observations made during the I.G.Y.—The Secretary, The University, Northcote House, Exeter, Devon (February 28).

Research Fellow (graduate in animal husbandry, science, veterinary science or agricultural science) in the Department of Physiology, University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 28).

COLLEGE LECTURER IN PURE MATHEMATICS—The Master, Emmanuel College, Cambridge (March 1).

READER or SENIOR LECTURER IN CLINICAL BACTERIOLOGY, for duties mainly concerned with the clinical bacteriological services of the Manchester Royal Infirmary—The Registrar, The University, Manchester 13 (March 1).

LECTURER or ASSISTANT LECTURER IN APPLIED MATHEMATICS—The Registrar, The University, Sheffield (March 2).

ASSISTANT LECTURER (with a good honours degree and some special knowledge of soils or practical experience in soil survey) IN GEOGRAPHY; and an ASSISTANT LECTURER or DEMONSTRATOR (with a good honours degree and some research experience in one of the branches of the subject) IN GEOGRAPHY—The Registrar, The University, Hull (March 4).

SENIOR LECTURER/LECTURER (graduate in anatomy or physiology or psychology, and some research and/or teaching experience relevant to ergonomics) IN ERGONOMICS—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 3/G (March 7).

LECTURER (with an interest in experimental taxonomy and cytology) IN THE DEPARTMENT OF BOTANY—The Secretary, University College, Gower Street, London, W.C.1 (March 8).

UNIVERSITY DEMONSTRATOR IN BIOCHEMISTRY—The Administrator, Department of Biochemistry, The University, South Parks Road, Oxford (March 8).

DEMONSTRATORS (with good honours degrees and approximately one year's research experience) IN CHEMISTRY—The Registrar, University College of Wales, Aberystwyth (March 9).

LECTURER IN ZOOLOGY—The Secretary, The University, Aberdeen (March 9).

PURDIE CHAIR OF CHEMISTRY (preferably organic chemist)—The Secretary, The University, College Gate, St. Andrews (March 9).

CHAIR OF METALLURGY in the University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, March 15).

CHAIR OF BIOCHEMISTRY—The Registrar, The University, Sheffield (March 16).

POSTDOCTORAL FELLOW IN ORGANIC CHEMISTRY, to carry out researches into the behaviour of olefinic acids in strong acid media in collaboration with Dr. M. F. Ansell—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (March 18).

LIBRARIAN—The Secretary of the Executive Council for the University of Lancaster, P.O. Box 78, County Hall, Preston, Lancashire (March 22).

LECTURER (with special interests and qualifications in mineralogy and petrology) IN GEOLOGY in the Faculty of Science—The Registrar, The University, Manchester 13 (March 23).

SENIOR LECTURER or LECTURER IN ZOOLOGY at the Australian National University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 25).

TECHNICAL OFFICER (with a degree or comparable qualifications in physics or electrical engineering, and preferably experience in the field of high frequency techniques) IN THE ELECTRONICS SECTION OF THE DEPARTMENT OF PHYSICS—The Secretary, Department of Physics, Cavendish Laboratory, Free School Lane, Cambridge (March 25).

CHAIR OF AGRICULTURE in the University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Malaya and London, March 28).

READER IN PHYSICAL ANTHROPOLOGY—The Registrar, University Registry, Oxford (March 28).

PRINCIPAL LECTURER and a SENIOR LECTURER (with good academic qualifications and research experience, and preferably teaching experience) IN THE DEPARTMENT OF PURE AND APPLIED MATHEMATICS—The Secretary, Royal College of Advanced Technology, Salford 5, quoting Ref. No. P/11 (March 29).

CHAIR OF PATHOLOGY in the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, March 31).

LECTURER IN MICROBIOLOGY at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W.1 (Australia and London, March 31).

ASSISTANT CONSERVATOR OF FORESTS (under 40, with a degree in forestry) in the Ministry of Tourism, Forests and Wild Life, Kenya, for work in connexion with the administration and technical direction of a Forest Division—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. T/R.C.324/80/02.

ASSISTANT (with a degree in physics, with some medical physics or other appropriate experience) IN THE PHYSICS DEPARTMENT—The Deputy Secretary, St. George's Hospital, Hyde Park Corner, London, S.W.1.

LECTURER or SENIOR LECTURER (with good academic qualifications and preferably research experience to doctorate level) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING—Dr. J. H. Calderwood, Royal College of Advanced Technology, Salford, Lancs

MASTER TO TEACH PHYSICS to "A" level—The Headmaster, Berkhamsted School, Herts.

SCIENTIFIC RESEARCH AND THE INDEPENDENT INSTITUTION

SIR HENRY TIZARD often viewed with some concern any tendency to look to Government institutions to undertake the risks which properly belong to private enterprise, and was wont to quote with approval a remark of Lord Rutherford: "We haven't any money; we've got to think". Dr. Caryl Haskins's latest presidential address to the Carnegie Institution of Washington* brings to mind that remark if in the context of bounty rather than of scarcity. Looking back over the sixty years in which the Institution has now been operating—the first of its kind in America to be devoted entirely to the ideal of research scholarship over wide fronts of science in its broadest, most unfettered, most completely uncommitted aspect—Dr. Haskins looks afresh at the place of the independent research institution in the world of to-day. This he does in the light of present experience of different forms of organization, of the present scale of research and the disposition of the resources made available for research, and of some of the results achieved.

His survey is wide, his analysis searching and cogent. He looks at those problems of Government support of science which arise inevitably out of the dependence of some 65 per cent of research in the United States on Federal funds. This is natural enough when the National Science Foundation alone in 1963 has a budget of 165 million dollars for scientific research, when the Department of Defence is spending about 7,000 million dollars on research and development, the National Aeronautics and Space Administration another 2,500 millions, and the Atomic Energy Commission some 1,500 millions—compared with a total Federal research programme of 100 million dollars twenty years ago. Without following Prof. J. S. Dupré and S. A. Lakoff into the examination, in their recent book, of *Science and the Nation: Policy and Politics*, he touches on the fundamental issues involved in deciding on forms of organization and administration. In a report which in cogency, insight and distinction fully maintains the high standard he has already established for himself, Dr. Haskins provides a brilliant and stimulating vindication of the place in this technological society of the gifted, unorthodox and unfettered individual.

Dr. Haskins begins by noting that within four years of its foundation the Institution had been organized into some fourteen departments, representing as many subjects. However, during the next five years of experiment and trial it was decided to concentrate the resources of the Institution primarily on its own research, making it an operating, rather than a grant-making, institution. By 1911 its departments were firmly established and reduced to ten, and the Institution had assumed essentially the form of organization that characterizes it to-day. The number of departments has indeed been further reduced to five, and whole fields included in 1911 have been discarded as the resources of the nation in these areas have strengthened, while others on the frontiers of research, like embryology, molecular and cellular biology, the study of the mechanism of photosynthesis, have been included. Through the years the major philosophies of the Institution have stood constant, and with them the decision made at the outset that flexibility and effectiveness in the kind of research to which the Institution is dedicated can best be achieved through a series of rather small unit laboratories. Each of these units, being mobile and relatively independent, is able to seize the initiative in new and appropriate fields as they appear, yet as a whole remain sufficiently connected so that they may be of mutual assistance as the needs arise.

That decision was remarkable at the time for its uniqueness and vision, but naturally over the decades many other experiments in organization have been tried. In the meantime, it is undoubtedly true that some of the most modern thought and experiment in this field, both in the United States and elsewhere, has returned to this pattern as one of the most effective in exploring the dynamic frontiers of scientific knowledge. Dr. Haskins's report owes some of its value and inspiration as a contribution to thought on the organization and administration of research from the fact that he is prepared to re-examine impartially the question of the place and value of the small and mobile group. May it not be true to-day that major advances in new knowledge, the setting of radically new scientific directions, can be achieved in the environment of great and highly organized research teams, that in practice such environments are essential, or at least the most favourable to the process? Is it possible that we are witnessing a profound revolution in the very character of research itself? Is it possible that small and mobile groups, which in the past characteristically had an influence on scientific progress out of all proportion to their numbers or their social cost, can no longer provide such significant approaches to the unknown?

To ask such questions is to challenge the underlying philosophy—developed in the days of scarcity in science—that envisages the environment of brilliant original unfettered individual research as the *milieu* in which the great new directions of scientific thought were born and nourished. Now we live and work in a world committed to an unparalleled rate of growth in the material resources for research, in a world in which perhaps 80 per cent of all the scientists who have ever lived are our contemporaries. Is it indeed now true that research is, after all, essentially a matter of adequate resources and organization, that quantity rather than quality comes first?

Rightly and wisely, Dr. Haskins goes back to the philosophy that inaugurated the Carnegie Institution and has remained unchanged through the years: the philosophy that all its resources and all its deepest purposes are centred in the creative individual whatever his field, that in the truest sense he is the uncommitted investigator, suitably endowed and protected, whose time, quite literally, is bought by the Institution, and then returned as unconstrained endowment. Equally deep-seated and important is the philosophy that this freedom from fixed commitment applies to fields of endeavour as well as to men. High mobility within specific fields, the unfettered crossing of fields, and the fashioning of unconventionally wide-ranging programmes, are subject only to the limitations imposed by Nature and by the judgment of gifted and discriminating investigators. Making this mobility and this flexibility possible has been, and is, a principal objective of the Institution.

---

* Report of the President of the Carnegie Institution of Washington, 1961–1962. Pp. 112+xi. (Washington, D.C.: Carnegie Institution of Washington 1962.)

The practical success that has attended the pursuit of programmes inspired by this philosophy does not inhibit Dr. Haskins from re-examining its basis, or from recognizing that new and important problems of organization now confront the Institution in the context of the changed situation in national scientific and technical development. It is because of this and because of the recognition also of the temptations to-day to imagine and to expect: (1) that cost and magnitude themselves may provide an important index of scientific significance; (2) that the speed and effectiveness with which new scientific frontiers are breached may be a simple function of numbers of men and rates of expenditure; (3) that the attainment of new scientific vision in an area of basic research may be accelerated in direct proportion to the size of teams and the amounts of money committed, that Dr. Haskins's survey is so stimulating and suggestive in the present discussion of the organization and administration of research and development in Britain.

It is not only in the United States that this pragmatic philosophy finds support, and the distinction between the contribution of the gifted individual and of the massive research team with its powerful new tools is made less clear than is desirable. It is as easy as it is dangerous to assume that great teams and high costs are prerequisites for setting new directions in scientific thought, rather than the means by which intelligent planning and concerted effort achieve the possibilities disclosed by the search of gifted individuals in new fields, seeking knowledge for its own sake and yielding unexpected and radically new ideas about Nature. The confusion is evident, for example, in some of the present criticism of support of research into kidney graft surgery in Britain; wise decisions as to the magnitude or administration of grants for research cannot be taken when such a philosophy persists.

The Carnegie Institution of Washington is deeply committed to the belief that the distinguished, unfettered individual can bring unique gifts to his society, and to belief also in the uniqueness and the importance of the influence which a community of independent scholars can exercise on scientific progress. Dr. Haskins examines three outstanding advances marking the technical and scientific progress of the past three years, all three of which he finds justify the belief that the basic contributions of small and mobile groups retain their old significance. Moreover, he points out that recent great advances in our knowledge of the universe and of our own more immediate environment—the original ideas of scientific stature achieved in the past few years, which promise to open truly novel avenues of thought—have not been necessarily, or even primarily, associated with the massive programmes of great teams. His first example is the immense complex of research and development dedicated to the placing of man in outer space; the second, an achievement in astronomy of the past year, is the identification of what has proved to be by far the most remote celestial object ever discovered in the heavens and the measurement of the red shift of its spectrum; and the third, the establishment beyond reasonable doubt that the information governing the inheritance of all the qualities of living things is structurally graven on the chromosomes within their germ cells in the form of a genuine code.

All these advances have won important and striking new knowledge. All have involved a variety of scientific disciplines apparently far removed from the main concern. All three, and especially the third, have resulted in profoundly new directions of thought. All three, Dr. Haskins observes, are characteristic of their age and could not have been achieved with the tools of any other era. Equally, he maintains, they demonstrate that the magnitude and organization of a research effort may be the least significant of parameters in any fundamental and enduring sense. The essential qualities and requirements of inquiry at the very frontiers of man's knowledge of his universe do not now, and in all probability will not in the foreseeable future, differ significantly from those of our classical scientific past.

Scientific inquiry will then continue to bear the unmistakable stamp of the gifted and untrammelled individual, whatever the scale of resources, in knowledge, in tools, in human and material support, which he may require. We may regard the large and the small research enterprises in our society as essentially symbiotic, each fulfilling its specific role. But on the small and mobile group rests, above all, the heavy responsibility of maintaining the vision of the creating individual—a responsibility that may well become wider and more challenging. Dr. Haskins, discussing the implications of the needs for the integration of knowledge and the demands made by the processes of research, points out that there can be no more urgent imperative than the creation of opportunity for individuals to address themselves once again to wholly new fields of inquiry. This, he feels, lies peculiarly in the domain of the small and mobile and basically highly uncommitted research groups.

Dr. Haskins concludes his survey with a notable tribute to the value and intrinsic importance of the individual in the society of to-day. The future of that society depends above all on the continued integrity and freedom of small and mobile enclaves of thoughtful and imaginative men and women. Their persistence alone can effectively preserve the conditions which have nurtured the rich sources of greatness, for it is the gifted unorthodox individual who has always brought, and will continue to bring, all the basic resources by which we live.

Dr. Haskins's address is fundamentally a summons to guard and honour and implement the position of the gifted individual with every resource that we can muster, because he is irreplaceable. However, beyond this his address is full of implications for all who are considering the scale and organization of research in Britain, the relations between research institutions and Government. Lord Hailsham has repeatedly shown that he is well aware of the importance of these fundamental aspects of effective research which Dr. Haskins emphasizes, and that he appreciates that if money spent on research is not to be wasted it must go to the support of first-class men with first-class ideas. The problem lies, of course, in the assessment of the men and of the ideas. More than this, it is important to ensure that the men supported are given the freedom and the conditions in which they can give of their creative best, and that so far as possible no first-class men with first-class ideas are hampered by lack of support.

Taking into account all that is involved in respect of organization as well as of manpower and resources, including that of securing effective use of the large and costly equipment often needed, all this would seem to be a full-time occupation for the Minister for Science. Quite apart from recent suggestions that his Office requires a considerably stronger staff of high competence, the appointment of Lord Hailsham to fresh responsibilities for unemployment in the North East can scarcely fail to raise misgivings as to whether these responsibilities as Minister for Science will receive adequate attention. It is not, indeed, as if the present administrative arrangements for the control and stimulation of research could be regarded as static or ideal. The Zuckerman Report alone has shown how much room there is for further critical inquiry and constructive thinking. Nor should it be thought that this is solely the responsibility of the Minister for Science and his Advisory Council for Scientific Policy. There is far too much shallow, if not politically biased, criticism of the scale of research expenditure as well as of its organization. The Minister for Science is entitled to expect from scientists and technologists generally a level of informed and constructive criticism which should materially facilitate the development of a pattern of organization appropriate to the nation's needs and resources for research. He can also expect their co-operation in the vitally important task of educating public opinion as to the necessary scale of that effort and its implications, whether in economies elsewhere or in the training or deployment of manpower.

TECHNICAL CO-OPERATION AND SERVICES OVERSEAS

THE Queen's speech at the opening of the present session of Parliament referred specifically to the Government's citation to encourage men and women from Britain to offer their services for work in developing countries overseas, whether in the service of the other Governments concerned, as specialist advisers, or under schemes of voluntary recruitment. This matter was discussed in the House of Commons on December 12, when a motion urging the Government to give every assistance to ensure the expansion and development of voluntary service in the under-developed countries was agreed without a division, although the attendance at the debate was disappointingly small. The public interest in this field, however, is far from being represented by this debate. It was no less manifest in the debate on the Commonwealth Scholarships (Amendment) Bill which received its second reading in the House of Commons on November 19, and it is equally apparent in the recently published second annual report of the Commonwealth Scholarship and Fellowship Plan for the period ending March 31, 1962[*].

This latter report shows that the Plan is fast becoming an established feature in the educational life of the Commonwealth, and during the period 729 scholars and Fellows held awards in thirteen different countries. During the year, Cyprus accepted an invitation to participate and is instituting three scholarships tenable at the Cyprus Forestry College. Sierra Leone has also instituted awards, and others were taken up for the first time in India, Pakistan, Ceylon, Nigeria, the Federation of Rhodesia and Nyasaland, and Malta. The target of a thousand current awards was expected to be achieved during 1962. The most important difficulty which arose in operating the Plan was that experienced by the nominating agencies in submitting nominations at different times of the year. This was fully discussed by a Working Party of the second Commonwealth Education Conference at New Delhi in January 1962, in the light of differences in the academic year in the northern and southern hemispheres; it was recommended that two common closing dates should be established, on December 31 and July 31 each year. It was also agreed that while each awarding country would continue to issue its own prospectus or information sheet describing its awards, applications should be invited on a form printed in each nominating country. The Working Party's report is annexed to the report of the Second Commonwealth Education Conference, published last March (see p. 752 of this issue of *Nature*).

A major problem confronting the Commonwealth Education Liaison Committee was the extension of the tenure of scholarships into a third year. The 1,000 awards current at any one time contemplated in the original scheme were mainly intended for two-years postgraduate study, and it was assumed accordingly that about half the awards would be available each year as new awards. In Britain and Canada it has been found that most successful candidates wish to be admitted to courses of research leading ultimately to the Ph.D. degree, for which more than two years study is often required. Some nominating countries are already concerned at the prospect of a decline in the number of new awards made annually. It was to deal with this difficulty that the Commonwealth Scholarships (Amendment) Bill was introduced.

In moving its second reading on November 19, the Under-Secretary of State for Commonwealth Relations, Mr. J. Tilney, explained that the Bill was intended to remove the restriction limiting the number of Commonwealth scholars in the United Kingdom at any one time to 500 under Section 2 (*a*) of the 1959 Act. More than half the Scholars wished to read for their Ph.D., and so long as the total number of awards was limited to 500 (although a substantial number of scholars did not require a full third year) these extensions block a scholarship unit for the full academic year. In consequence, the quota dropped to 450 between April and October, and the average current for the full year was less than the 500 visualized when the 1959 Act was passed and which would be possible under the new Bill. Between 225 and 230 new awards would then be available at present costs instead of 200. The overall limit of £6 million over the five years imposed by the Commonwealth Teachers Act, 1960, for expenditure under both Acts would still apply. Clause 1 would bring the Act into line with that Act by covering the Channel Islands and the Isle of Man.

Reviewing the working of the Plan in Britain, where the Commonwealth Scholarship Commission continued to act as the scholarship agency, it is noted in the report that during the year 394 Commonwealth scholars held awards at universities and colleges in Britain, of whom 229 took up their awards in October 1961 or afterwards. Of those who took up awards in October 1960, 89 were granted extensions into a third year, beginning in October 1962. In the 1961 competition, 232 scholarships were accepted, but these extensions into a third year meant that new awards in 1962 would be fewer than in 1961. Commonwealth visiting fellowships, tenable for up to one year, have also been instituted, and three were held in Britain during the period; it is hoped that up to five fellowships can be awarded.

---

[*] Second Annual Report of the Commonwealth Scholarship Plan for the period ending 31 March, 1962. Prepared by the Association of Universities of the British Commonwealth for the Commonwealth Education Liaison Committee. Pp. 59. (London: Commonwealth Education Liaison Committee, Marlborough House, Pall Mall, 1962.) 5s. (See also p. 749 of this issue of *Nature*.)

Canada comes next to Britain in the number of scholarships awarded and held (with 199 during the year), with Australia next (75), followed by India (22) and New Zealand (18).

This report was freely quoted in the debate when the Bill received an unopposed second reading and was generally welcomed as providing the cross-fertilization of contacts which gave the Commonwealth more reality as a world-wide community. Mr. G. M. Thompson, however, thought that the Government might have used the opportunity for something more imaginative and generous than an increase of some £20,000 a year on the Commonwealth scholarship side of Commonwealth education, and he urged the need to give particular attention to technical and technological awards under the scheme. He was also critical of the concentration on postgraduate awards, which could limit the value of the scheme to a number of emergent territories, some of which regard undergraduate, professional and technical awards as at least as important as awards for postgraduate study. He wanted a larger proportion of one-year scholars and made an incidental reference to the Peace Corps of the United States.

Mr. R. P. Hornby suggested that both educational aid and co-operation should be considered in the wider context of technical co-operation, and that it was important to see that the courses to which students or graduates were nominated were suitable to their needs and that on completion the graduates did, in fact, return to help the countries from which they came. Mr. T. Dalyell stressed the need, as recommended at Delhi, to direct adequate attention to induction courses if overseas students were to obtain the full benefit of their scholarships. He also referred to a number of other ways in which the development of ancillary aids, like audio-visual aids and books, could promote the efficiency of such schemes, particularly for teachers. Constructive suggestions also came from Miss Vickers, who regarded the Bill as one of the most important to come before the House this session, stressing also the value of informal education. Mr. J. Boyden called for more imagination, for greater provision for social education scholarships and stressed the part which voluntary bodies could play, while Mrs. Eirene White touched on the need for more hostel accommodation and on the bearing of developments in Commonwealth scholarships on the expansion of Britain's universities, particularly in respect of staffing.

In replying on the debate, Mr. Tilney said that expenditure on the scheme in the current year was about £1 million and would rise to £1·25 million next year and £1·5 million in 1964–65. He defended the concentration at present on postgraduates; informal education was to some extent a matter for local education authorities in the countries concerned, and in welcoming the appeal for more teachers to work in the Commonwealth, he appealed to local authorities to deal generously on their return with teachers who did so. Two scholarships in adult education were awarded in 1962. In 1961–62 there were 4,017 applicants for about 250 awards available, and the British Council had recently recruited the first ten of the thirty experts in teaching English as a second language under the British scheme announced at Delhi; these would be available for secondment in key posts in Commonwealth countries in the autumn of 1963. There were now 1,225 Commonwealth teacher training students in Britain and about 9,000 Commonwealth students at the technical colleges, and up to 45 bursaries had been offered for a two-year technical teacher training course beginning in September 1963.

The contribution of Britain in training teachers and particularly in technical education is well brought out in two further annexes to the report of the Second Commonwealth Education Conference. The report of the Committee on the training and supply of teachers, which forms Annex 3, stresses the need for more detailed information both about needs and resources, and recommends that special note should be taken of the requirements of developing countries on the training of technical teachers, and priority given to strengthening existing departments or institutions which train technical teachers. Once again stress is laid on the need for assurances that help will be given to those teachers who require it in finding suitable posts on return from overseas. However, the Committee also recommended a strong appeal to the idealism of teachers and to the honour of service abroad in a Commonwealth country.

The report of the Committee on Technical Education and Co-operation in the provision of text-books and other books, which forms Annex 4, reviews the report of the Commonwealth Education Liaison Committee, *Co-operation in Technical Education*, in the light of the recommendation of the Oxford conference in 1959. It warmly welcomes the British offer of special training for six months at a technical college in Britain and six months of planned industrial experience before proceeding to a one-year course of technical teacher training, and of 40–50 bursaries annually to enable teachers from developing countries to attend this special course. It reaffirms the recommendation of the Oxford conference regarding the interchange of scientists and technologists. It suggests that more awards in this field are desirable under the training of teachers scheme, that the share of assistance devoted to technical education should at least be maintained and preferably increased, and that professional bodies should be asked to consider expansion of their advisory services in relation to the recognition of qualifications.

It is thus apparent that there is a considerable and growing volume of organized and official co-operation in education as a background to any voluntary effort. The Commonwealth Education Conference itself fully recognized that the balancing of new needs against available resources is fundamental to the consideration of extensions to the Commonwealth Scholarship and Fellowship Plan. While its outlook on finance is essentially realistic, education is regarded as a productive agency, and expenditure on education as an investment in human resources. The Commonwealth Scholarship and Fellowship Plan, however, could not have been operated without the help and encouragement which the universities of the Commonwealth have so willingly given. The magnitude of co-operation of this kind cannot be expressed in concrete terms.

Such co-operation, however, must be fully considered by the Department of Technical Co-operation or in any appraisal of the total effort of the United Kingdom in service overseas, for example, in the discussion of the problems of staffing universities overseas arranged by the

Overseas Development Institute in December. Important as may be official arrangements to deal with difficulties such as loss of seniority or security, a change in atmosphere or in the climate of opinion could be of decisive importance. While devices such as the dormant contract offer prospects of overcoming such difficulties and a small Working Group was set up by the meeting to look into this and other suggestions, there can be no doubt as to the vital importance of a much deeper public understanding of the whole question of technical co-operation and service overseas. An informed public opinion could do much to remedy the startling neglect which the Government has shown over recent years in such fields as overseas research as well as encourage young men and women to come forward. However, professional associations have also a major part to play, and a responsibility which cannot be ignored to do their utmost to see that those who serve overseas on their return lose neither prospects nor security. Public debate and decision in and out of Parliament are to be warmly welcomed as assisting the formation of an enlightened opinion needed to support effectively the Department of Technical Co-operation. Moreover, such would ensure that neither the Departments of State nor professional associations disregard their opportunities and responsibilities in what is now one of the most vital ways in which Britain can play her part in world affairs. A recent issue of *Impact of Science on Society* (No. 4, 12; 1962) was devoted by Unesco to some problems of interest for developing countries, and directs attention to the dependence of the scientist on a host of skilled technicians and assistants if science is to make its full contribution to the development of natural resources in these countries. The training of such personnel and the provision of scientific and technological staff for teaching and research until a competent indigenous staff is available is one of the key problems in technical assistance. It calls for the particular attention of all scientific and technological associations.

IAN CLUNIES ROSS: A GREAT AUSTRALIAN

Ian Clunies Ross

Memoirs and Papers, with some Fragments of Autobiography. Pp. xxiii + 240. (London and Melbourne: Oxford University Press, 1961.) 40s. net.

The death of Sir Ian Clunies Ross at the age of sixty deprived Australia of one of her best-known public figures as well as a leading scientific administrator. To say that for the last ten years of his life he was chairman of the Commonwealth Scientific and Industrial Research Organization gives only a small indication of his contributions to the intellectual life of Australia. This book is not so much an account of a notable career as an attempt to capture in print a personality that left a deep and lasting impression, not only on friends and associates, but also on the Australian public.

Lady Clunies Ross tells us in the preface that her husband had cherished the hope of writing a personal history of Australia as he had known it over a remarkable half-century of growth and change. Evidently the present volume was conceived and compiled partly as a memorial and partly in an effort to preserve some of the ideas and ideals and the spirit that Ian Clunies Ross might have put into the book that was never written.

There are an introduction followed by two chapters of autobiography, a diary kept during the last two months of his life, eleven memoirs written by public figures and colleagues, a short story by Ross himself and ten of his papers, lectures and broadcasts.

It is the introduction by Frank Eyre that will convey most to those not well acquainted with Ross. It outlines briefly his career and introduces the reader to his personality and character. This is an intimate account told with discernment and understanding. Here we first meet the theme reiterated by several other contributors: Ross's most memorable characteristic was his immense charm, which was completely natural and sprang from a sincere and intelligent interest in all with whom he came in contact, from chauffeur to prime minister. He developed to an extraordinary degree the knack of bringing out the best in people. Little wonder that he was rewarded with their affection. Was it not Lord Chesterfield who said that if a man makes people like themselves a little more they will like him very well? Ross had earned the friendship of so many, even among those who had no opportunity of knowing him personally but only through his talks and broadcasts, that when he died Lord Casey said in a broadcast that a wave of sadness swept over the country.

But Ross's natural liking for people was not without discernment. The one thing he could not tolerate was insincerity—and he took a puckish delight in uncovering it.

Ross graduated in veterinary science at Sydney in 1921. After postgraduate study in Japan and at London and Cambridge he became lecturer in parasitology at the Veterinary School in Sydney. Afterwards, he was officer-in-charge of the McMaster Animal Health Laboratory, Sydney, chairman of the International Wool Secretariat in London, professor of veterinary science at Sydney and finally chairman of the C.S.I.R.O.

Ross made valuable contributions to knowledge on hydatid disease, on toxic paralysis of dogs and man caused by the tick *Ixodes holocyclus* and on helminth diseases of sheep. But his main contributions to science were as an organizer and administrator. One hesitates to measure research in terms of financial expenditure, but it is informative to mention that under Ross's chairmanship the annual budget of the C.S.I.R.O. grew to more than £9 million. The remarkable achievements of the Organization, in fundamental as well as applied science, even considering the large sum at its disposal, testify to the efficiency and wisdom of the administration.

Ross was a truly gifted speaker and hence was called on to talk on all manner of occasions. His facility with the English language, his aptness with analogy and felicity of phrase are evident in the parts of this volume written by himself. The words flow effortlessly and with a clarity and continuity of thought that hold the listener's or reader's interest. But the written speeches convey an incomplete portrait of the speaker, for here again it was his lively personality and obvious sincerity that won his audiences.

Some idea of the wide range of Ian Clunies Ross's interests and activities is given by the list of people who have contributed to this volume. These include the Right Hon. the Lord Casey, the Right Hon. Sir Owen Dixon, chief justice of the High Court of Australia, R. J. F. Boyer, chairman of the Australian Broadcasting Commission, Brian Jones, master of International House, Melbourne, in addition to several colleagues in the scientific field, and his son.

Lord Casey wrote: "Clunies Ross believed passionately in Australia and had a very clear vision of its future greatness". He was in every sense a great Australian: born and educated in Australia but with an enlightened interest of other lands—he learnt to speak Japanese the better to understand that people—his influence in many aspects of the intellectual life of his own young country will be a lasting one.

W. I. B. Beveridge

THE NEPTUNE STORY

The Discovery of Neptune

By Dr. Morton Grosser. Pp. 172. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1962.) 40s. net.

We conduct our lives by means of theories, none more so than those that delude themselves by thinking they never rely on theory, and the difficulties occasioned by misconception as to its nature are perennially with us. The great impact of the discovery of Neptune lies in that perhaps never before or since has it eventually seemed so inescapably demonstrated how wrong the anti-theorists can be: an 'actual object' was found, something that could be 'seen', and therefore a 'real fact'.

Dr. Morton Grosser, the American historian of science, has done us the honour of presenting a beautifully expounded analysis of this classic scandal. A scandal, by the way, is an episode that occurs when the official theory breaks down publicly. From the vantage point of the United States and the passage of a century, he sees the whole affair with crystal clarity and scholarly judgment. The species-Airy, not entirely extinct, is described with fearless accuracy: ". . . he divided people round him into two groups, those that had succeeded and were worthy of cultivation, and those that had not succeeded and were beneath consideration . . . a man strongly opposed to theoretical investigations and sceptical of the abilities of younger scientists . . . expressive of that intellectual emasculation that he encouraged in his corps of drudges".

These few excerpts indicate Dr. Grosser's considered opinion of the leading man of the play-acting farce that was carried through in all seriousness and effectually prevented Adams obtaining there and then the due credit for his brilliant work. A similar atmosphere prevailed in France, where the astute Leverrier soon withdrew reliance on his unenthusiastic compatriots, though the successful outcome of his resorting to Berlin (after even trying Airy) rested heavily on good luck: first, there were two young astronomers, Galle and d'Arrest, prepared to oppose the reluctant Encke, and, secondly, they chanced to have a star-map of the vital zone. The planet was found at once, and the game began: official theory was in perilous danger of being exposed as bogus. In such circumstances, nothing must be admitted, and the order of the day is "the truth and nothing but the truth, but never the whole truth". In retrospect, the devious manœuvres are comically funny, but it was not funny for Adams or for the reputation of British science. A superlative opportunity was culpably thrown away, and followed with a flood of prevarication and recrimination. And nothing has happened since to add to the intellectual credit of British observational astronomy. When the discovery became known, minds were made up with negligible appreciation of what was involved, and excesses of adulation lavished freely in many directions except that of the luckless Adams—a mere theorist.

Without more study than has yet been given to the processes involved, all that can certainly be claimed is that a planet was found near a place that emerged from theoretical procedures. It may be that all the steps can be shown to have complete validity, but this remains to be demonstrated even to this day. Consider just two of many queries: the use of Bode's law meant a period about three times that of Uranus, so the principal perturbations would arise from terms in $v-3v'$, whereas since the true period is about 160 years they actually arise from terms in $v-2v'$, and these have quite different periods and coefficients. Then again, there is difficulty in justifying the curious conversion to 'errors of mean longitude' that was Adams's initial step, and there are other unanswered questions.

The passage over from data to conclusions is sometimes very easily made, especially when strong emotion is involved, indeed so easily that we mainly fail to perceive that an intricate subjective psychological process of a not-necessary character must be concerned, and one that almost defies analysis. But if we are to get to the rights of complex matters, it is no use rushing to agreeable conclusions; instead, every step must be brought to the surface and its validity demonstrated. This has yet to be done even for the present century-old case, and so the true meaning of this sensational piece of scientific history remains very much an open question. Dr. Grosser's erudite work can be thoroughly recommended from every point of view, not least that it may help in directing attention to some of the mysteries that still surround the celebrated discovery of Neptune. R. A. Lyttleton

LINGUISTICS

A Functional View of Language

Being the Waynflete Lectures Delivered in the College of St. Mary Magdalen Oxford, 1961. By Prof. André Martinet. Pp. viii + 163. (Oxford: Clarendon Press, 1962), 21s.

Prof. Martinet is one of the most distinguished of contemporary linguists. He is no doubt most widely known for his phonological work, both theoretical and practical (and more especially for his theory of 'economy' in phonological changes and his application of this theory to the study of the innovations that have taken place in the sound-systems of various Indo-European languages); there are few branches of linguistics, however, to which he has not contributed in the course of the past twenty-five years. In 1961 he was invited to deliver the Wayneflete Lectures in Oxford and in them to develop his views on the nature of language and the principles of linguistic analysis. The present volume represents an expanded version of these Lectures.

Martinet's general theme, as his title suggests and as he explains in his preface, is the role of 'function' in language. He argues that recognition of the communicative function of language and of its constitutive elements will necessarily lead to a 'realist' view of language and show that it is far more varied and far less homogeneous than many 'formalists' or 'structuralists' would admit. Although I have much sympathy with this point of view, I find that Martinet's expression of it is unnecessarily polemical. Moreover, he greatly oversimplifies the issues and seems to use the crucial term 'function', which is constantly invoked and never precisely defined, in a number of different senses in different places in the book. The 'functional' criteria for syntax are far from being as clearly applicable as he suggests.

There are two other points which should be criticized. The first is the definition of minimal grammatical units ('monemes' in Martinet's terminology) as the "smallest segments of speech that have some meaning attached to them". Many linguists would hold that one of the most significant developments of recent years has been the emancipation of grammar from semantics. To say that a form like the Latin word *homini* "conveys three elements of experience: 'man', 'dative' and 'singular' " is to confuse very different kinds of relations and to do so in intolerably vague terms. The second point is the author's tendency to give unverifiable, or at least unverified, causal explanations of linguistic developments. One wonders, for example, whether there is any evidence to support the statement that "an increasing complexity of social relations will be accompanied by an increasing complexity of syntax". The Latin example used by Martinet does not seem very convincing.

Provided that he is not looking for a balanced and comprehensive statement of present-day linguistic theory, the general reader will find much to interest him in the treatment of particular questions. There is a good discussion of dialects in the chapter on "Linguistic

Variety", and of alternative ways of classifying and grouping languages by 'types' in the chapter devoted to this topic. Martinet's account of 'liaison' and part of the verbal system of modern spoken French (what he calls 'unguarded' French—a language which is very different from what we, and the French themselves, learn as 'French' in school and university) is particularly valuable. So too is his outline of the hypothesis that the formally marked nominative case of the Indo-European languages has arisen from an earlier 'ergative' construction such as one finds, for example, in Basque. J. LYONS

ECHINODERMS

Starfishes and their Relations

By Ailsa M. Clark. Pp. v+119 (16 plates). (London: British Museum (Natural History), 1962.) 11*s.* net.

Echinoderms

By Dr. David Nichols. (Hutchinson University Library.) Pp. 200 (26 figures.) (London: Hutchinson and Co. (Publishers) Ltd., 1962.) 12*s.* 6*d.*

MONOGRAPHS by Dr. L. H. Hyman (*The Invertebrates*, 4, *Echinodermata*, New York, 1955) and the late Prof. L. Cuénot ("Echinodermes" in *Traité de Zoologie*, edit. by P–P Grassé, Paris, 1948) have provided, in recent years, admirable comprehensive treatises on the phylum Echinodermata. But to the general reader, the two small volumes that are reviewed here will furnish succinct, clearly written and well-informed guides which are in large measure complementary in their coverage and treatment of the echinoderms, both living and fossil.

Dr. Clark's book, following the tradition of the British Museum (Natural History) hand-books, is amply illustrated with an excellent series of photographs and figures which not only enable the reader to identify the more commonly occurring of the starfishes, brittle-stars, sea-urchins, sea-cucumber and feather-stars that are to be found in British seas, but also give a clear impression of the wide range of form and ecological adaptations of animals that are represented in all the seas of the world and which number within the five classes of the Asteroidea, Ophiuroidea, Echinoidea, Holothuroidea and Crinoidea, some 6,000 species.

Dr. Nichols's volume, though less copiously illustrated, includes a number of good figures in explanation of the internal structure of animals the interior arrangements of which are not always easy to understand; and, drawing in part from the results of his own published researches, he surveys the variations in form of their different organ systems, notably the tube feet, and relates them to their services in locomotion, burrowing, feeding and other organismal activities. Perhaps the most valuable parts of the book are, however, those in which he describes the extinct classes and discusses, in the light of their structure, their probable habits. Echinoderms, after a modest beginning in the Cambrian period with eocrinoid representatives, experimented, in the Ordovician and later periods of the Palæozoic, with a number of designs characterized by the classes of the Heterostelea, Cystoidea, Blastoidea, Edrioasteroidea, Ophiocystioidea, and with other groups such as the Machaeridea, which are less assuredly to be included within the echinoderms. Dr. Nichols discusses their probable methods of feeding, respiration and general mode of life and gives a well-argued account of their supposed phylogenetic radiations. Although there may not be general agreement with some of his views, for example, the origin of post-Palæozoic echinoids from edrioasteroid ancestors, it is refreshing to find the brittle-stars and asteroids once again brought into close relationship through common somasteroid ancestors; and among some novel suggestions, the possibility that the Machaeridea represent the plating systems of the tube feet of ophiocistioids is certainly worthy of further consideration.

Both Dr. Clark's and Dr. Nichols's books are to be commended as authoritative, highly interesting accounts of the structure, classification, development, mode of functioning, natural history and interrelationships of the echinoderms: and in both books there are numerous observations and comments which suggest problems in need of further investigation and research.

J. E. SMITH

ENZYME TESTS IN CLINICAL DIAGNOSIS

Clinical Enzymology

Enzymes in Pathogenesis, Diagnosis and Therapy. By Rudolph Abderhalden. Translated by Prof. Peter Oesper. Pp. xvi+448. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1961.) 9.75 dollars; 76*s.*

An Introduction to Diagnostic Enzymology

By Dr. J. H. Wilkinson. Pp. viii+288. (London: Edward Arnold (Publishers), Ltd., 1962.) 45*s.* net.

ONE of the extraordinary aspects of to-day's boom in enzyme tests for the diagnosis of disease is that there is no reason why it should not have come ten or even twenty years earlier. Most of the reactions have been known for an even longer time, and there is no spectacular 'break through' in technique to account for the present vogue. The concept that tissue enzymes might escape on injury and then be found in the serum or urine at an abnormally high concentration is as old as measuring the pancreatic enzyme amylase in the urine as an aid in the diagnosis of pancreatic disease. This was introduced by Wohlgemuth in 1910 and is still widely used, virtually as it was first described. It has recently been recognized that what was thought to be one serum enzyme, as, for example, serum lactic acid dehydrogenase, is in fact a mixture of isoenzymes. These have the same effect on the substrate, in this case lactic acid, but come from different tissues—heart muscle, liver, etc.—and can be separated by electrophoresis. Yet except for the name 'isoenzyme' this concept has long been accepted for the serum phosphatase. There are at least two serum phosphatases which can be separated according to their *p*H optimum into 'acid' and 'alkaline' phosphatase. Even these have long been known not to be single enzymes—and acid serum phosphatase was separated into that derived from the prostate, those from the liver, the spleen and kidney or from lysed red cells. Special techniques were devised using the unique sensitivity of the red cell enzyme to small amounts of formaldehyde for assessing the true share of the prostatic enzyme in the overall level of serum acid phosphatase.

Perhaps the most important new development, and that which started off the intensive search for new tests, has been the demonstration by Wroblewski *et al.* that after cardiac infarction a rise follows in the level of serum glutamic–oxalacetic acid transaminase. This has turned out to be an invaluable test, almost rivalling the electrocardiogram in the diagnosis of recent cardiac infarct and necrosis. Undoubtedly this discovery has been the stimulus which has triggered off so much new research on serum enzymes in the diagnosis of disease. The time has come to collect the numerous scientific articles in this field into manuals for the non-specialist. The two volumes by Abderhalden and by Wilkinson will both allow the general biochemist to read up much of the past and more recent work. Both are written clearly and tidily subdivided. Thus in Abderhalden's book for each enzyme is neatly presented its physiology, methods of assay, and clinical significance. One-fifth of its pages is given over to a copious index and to more than 1,500 full bibliographical references. This makes it an excellent work of reference. However, though it appeared in 1961, it appears that it was finished several years before then. Wilkinson's book seems to be written more with the view of bench work and is much more up to date. It has excellent brief résumés on subjects such as "enzyme tests in myocardial infarction", "enzyme tests in liver diseases", "diagnostic applications of isoenzyme separation". If the purse will allow it, many laboratory workers will find it well worth their while to acquire both.

H. Lehmann

BIOCHEMISTRY AT THE MOLECULAR LEVEL

Comprehensive Biochemistry

Edited by Prof. Marcel Florkin and Prof. Elmer H. Stotz. Vol. 2: Organic and Physical Chemistry. Pp. xii + 328. (Amsterdam and New York: Elsevier Publishing Company, 1962.) 80s.

There is a wind of change blowing through biochemistry. Those who welcome it as a refreshing breeze will appreciate the appearance of the first volume (actually Volume 2) of this advanced treatise on biochemistry. In the past, biochemists had been concerned with determining what reactions occur in living organisms; but more recently, interest has been focused on the mechanism of biological processes at the molecular level. The present volume reflects this type of approach to biochemistry.

A novel feature is the decision to publish the treatise in five sections, each of which will comprise several small volumes. It is claimed that this will have several advantages. The specialist will be able to purchase only those sections which are of particular interest to him; future revision of volumes will be simpler; individual volumes will not be badly out of date when they appear. It may be noted that, in support of the last point, there are numerous references to papers published in 1960.

The present volume is devoted to organic and physical chemistry and opens with a chapter of some 200 pages by M. L. Bender and R. Breslow on the mechanisms of organic reactions. Both authors are well known for their investigations of the mechanisms of enzyme catalysis and both write in a clear, concise style. They describe the kinetic and mechanistic aspects of all the main types of reactions of organic compounds which are relevant to biochemistry, including nucleophilic substitution in aliphatic systems, elimination and addition reactions involving carbon–carbon double bonds, nucleophilic reactions of carboxylic and phosphoric acid derivatives, addition to carbonyl groups, enols and their relevance to various types of condensation reactions, carboxylation and decarboxylation, aromatic substitution, and various types of oxidation-reduction reactions. Where possible, the authors illustrate the several reactions with examples of biochemical import. In addition, particular attention is paid to the mechanism of action of simple catalysts and their possible relevance as models for the more complex catalysis by enzymes.

The remaining two chapters are written by W. D. Stein. The first of these deals with the equilibria of solutions, while the second treats problems such as diffusion and osmosis, which involve movement of molecules and ions within solutions and across membranes. The author presents his subject logically and attractively by starting with ideal solutions of non-electrolytes and developing the treatment progressively for non-ideal behaviour, solutions of electrolytes, and finally for macromolecules. No attempt is made to give rigorous mathematical proofs of equations, but there are adequate references for the more determined reader. The pattern of the final chapter on diffusion and osmosis is similar. After dealing with Fick's laws of diffusion, the relationships between diffusion coefficients on one hand and molecular weight and viscosity coefficient on the other are discussed. Consideration of more complex systems involving large solutes, electrolytes, concentrated solutions, and the presence of membranes follows naturally.

I myself should have liked to see this book open with a short chapter on classical thermodynamics and the thermodynamics of irreversible processes. The latter topic has been neglected in biochemical text-books, and it would have formed a bridge between the static and dynamic aspects of biochemical processes. It is to be hoped that the editors will find room later in this treatise to rectify this deficiency.

D. T. Elmore

RESIN CHEMISTRY

Alkyd Resin Technology

Formulating Techniques and Allied Calculations. By T. C. Patton. (Interscience Manuals No. 8.) Pp. ix + 197. (London and New York: Interscience Publishers. Division of John Wiley Inc., 1962.) 74s.

This book is specifically designed to cover a quantitative approach to the formulation and design of alkyd resins. It does so in a manner such that some theoretical background is stated and, from this, formulæ are derived and illustrations worked out to make perfectly clear the steps which are taken in the development of a comprehensive scheme to cover the very wide field of alkyd resins. In putting forward his main thesis, namely the application of an alkyd constant based on Carother's classical work, the author has displayed a wide experience and his book has been written with an aptitude to explain in simple language what is, in effect, an exceedingly complex subject. The use of this constant permits the formulator to design a satisfactory alkyd or to effect adjustments where necessary.

Perhaps it is inevitable in a mathematical treatise of this type that simplifications have to be made. In the technological field this may be permitted even if, from a purist point of view, there are a number of postulates which are less acceptable. Examples of these are, the differentiation of acid and monoglyceride alkyds based on attaching the fatty chain at the beta- and alpha-positions respectively (p. 20), or the postulates (p. 74) arising from the reaction of the alpha and beta glycerol groups which assume that the alpha groups react completely before the beta groups, giving linear polymers.

Again, of the four formulæ systems discussed in detail is one concerning M_{AV}, the average molecular weight of the alkyd at gelation. No distinction is made of the big difference between the weight average and the number average molecular weight. When dealing with physical concepts such as gelation, it is the latter which dominates the system. Nevertheless, from a practical point of view, the validity of the foregoing concept is shown to hold for many alkyds of known behaviour. It covers also urethane oils, water-soluble alkyds and modifications with other polymers such as styrene.

No major attempt is made, or has been intended, to describe process work or the influence of temperature on many of these results, but such factors will be familiar to the plant chemist.

A comprehensive bibliography is given at the end of the book drawn largely from American sources. It is gratifying to note several references to British work.

The resin chemist will find stimulus and much to help him in his calculations from this volume. It should find a place in the library and on the bench of many laboratories.

A. I. Escolme

SCIENTIFIC RESEARCH AS A CAREER*

By Dr. I. W. WARK

Commonwealth Scientific and Industrial Research Organization, Australia

THOUGH scientific research is as old as civilization itself, it was not graced with that name until a hundred years ago. Men had to try experiments to survive; they abandoned procedures that led to worse results; they adopted those that gave better. So, by a series of small advances, with many a false start, they evolved methods of tanning and brewing and of constructing shelters; they introduced agriculture, they went from the hazards of the dug-out to the safety—and the incredible beauty—of the Viking ship. False starts had to be eliminated, for they meant hardship, starvation or death.

Nowadays, the scientist strives to keep all but one variable constant, or by statistical methods to make allowance for those he cannot control. Had early man realized the desirability of these things, it would have availed him little, for in general the controlled experiment was impossible. *En masse* he did adopt the statistical approach, though he had no multi-million dollar computers to help him. It was the individual who did the experiments, or had them forced on him—it was he who observed the effects of variations and made the innovations and the inventions. His successes spread because his neighbours looked across the boundary fence; he encouraged their use without payment of royalties.

As time went on, a privileged class was established which had the opportunity to think about matters other than immediate survival. Some members of this group painted or sculptured, some turned to literature and music. Others, the earliest scientists, merely pondered why certain natural phenomena occurred and how the universe worked in all its ramifications. For centuries, however, there was no organized science. The individual was still the unit. He conducted such experiments as could be performed by himself; if he was affluent he may have had hired a single assistant. Old paintings of the alchemists' dens seem to be faithful representations of the laboratories of the day.

Nowadays in many fields the single investigator has given place to the team, with all that this implies. Dependent on the outlook of the leader, the work of the assisting scientists can be made intolerably drab or intensely interesting. There are two sorts of leader, and it is a pity that the first seems to be the more numerous type. He is exemplified by a chemist coming into prominence to-day. One of our C.S.I.R.O. senior studentship holders was working with this man for a Ph.D. degree, and being nearby on a short visit myself, I inquired about his progress. The professor gave me an excellent report; the student was all he could wish for, was a fine experimentalist and had followed up every suggestion with enthusiasm and alacrity. When asked whether the student had shown any originality or initiative, the professor looked very pained and replied: "Look here, Wark, no student of mine is expected to show originality; he does what he is told". Fortunately, our man was so good that even this treatment did not ruin him.

The other type of leader is typified by those whom I, myself, had the good fortune to work with. On my final evening in London, Prof. F. G. Donnan invited me to dinner and, over the brandy, expounded his philosophy: "Half the people trying to do research", he said, "should find something they can do better. They need for ever to be tied to their mentor's apron-strings. A student who requires detailed consultation more than once in two or three months should be encouraged to try some other calling than research". Donnan literally meant a discussion—an exhaustive discussion—once in two or three months, though, of course, one saw him much more frequently. You then presented a short summary. When he had studied it he sent for you, and made suggestions—often brilliant—as to how you might proceed. You decided whether you would take them, for you were master of your own research problem, and by no means all his suggestions were practicable: some, in fact, you had already tried and abandoned. But you certainly got help rather than direction.

In the atomic energy establishments where men work as teams, that director is ablest who encourages every officer to accept the maximum degree of responsibility and independence that he can carry, increasing the load as the officer develops. With all this talk of teamwork, it is well to remember that no team ever made a brilliant discovery. A discovery is made in the mind of a single person. If the time is ripe it may arise independently in the minds of more than one person. But the discoveries for which Nobel prizes are awarded are those that one man alone senses well ahead of his contemporaries, the sort that started rushes into a field of science similar, in a way, to the gold rushes of New Zealand, the Klondike and Kalgoorlie†.

In an extended trip round the world in 1948, and on a shorter one in 1954, I was amazed to find how little true research was in progress. I numbered the really exciting chemical laboratories on the fingers of one hand. On the whole, the celebrated schools were dull, though there were bright patches. The young men were not being given their heads.

I am convinced that far more superior research workers are born than are revealed under present-day conditions. In support of this assertion, perhaps I should reveal my theories as to why many do not do justice to themselves or to the expensive preparations over 8–10 years which were made to launch them.

It is generally agreed that it is the drive to satisfy his own curiosity that characterizes the successful research man. Everybody is born curious. The young child asks question after question, and as often as not gets a reprimand for his inquisitiveness. When he gets to school, let him beware if he seeks knowledge outside the ken of his teacher; as likely as not he will be ridiculed for wanting to know 'more than the text-book'. Not all university lecturers are blameless in this regard. However, the parental attitude may be the most important in encouraging or discouraging an inquiring attitude of mind.

It is in the early postgraduate years that the main good or the main damage is done. At this stage, the student has survived all the other pitfalls and discouragements. As he undertakes his first research assignment he is a precious responsibility to his supervisor. How many professors at this stage are willing to admit that there are some students—albeit few in number—who are inherently better than themselves and who should be encouraged to explore new paths rather than to follow the well-worn tracks of the 'school'? How many professors are willing to send a best graduate to another university—as they do in the United States and elsewhere—to experience the excitement of a new environment and to widen his interests while he is still young? How many are willing to grant a Ph.D. when the man is ready for it, rather than to conform to the present ridiculous trend that nothing short of three years is adequate? Is it not time that the students received more consideration than the 'school'? Professors should arrange suitable exchanges: admittedly there are difficulties, but they can be overcome if the will is there.

---

* Substance of an address delivered on October 10, 1962, at the University of Otago, New Zealand, under the auspices of the University Grants Committee.

† This article was prepared before the Nobel Prizes for 1962 were announced [EDITOR].

There is another very rapidly expanding and insidious influence at work to take the initiative out of the man in his 'twenties just when he should be blossoming into an independent thinker and research worker. Having obtained his Ph.D. degree with an already one-year-too-long course behind him, the young postgraduate often proceeds to some overseas laboratory for further postgraduate studies. He is usually enticed to some laboratory with similar interests, and for two years he now devotes his time to getting what is fittingly described as a 'bar' to his Ph.D. With a paper or two to his credit he is now becoming known in his field and is invited to go from Europe to North America to earn his second bar. Slipping across the border into Canada he acquires the third. By this time he feels he cannot afford to move into any other field. His life has been determined by his first research problem, by his first research supervisor. Along the way three later supervisors have cashed in for their 'schools' on his knowledge and his ingenuousness. He will now have acquired the outlook of what I have heard called 'the professional fellowship holder'. Tied to three or four sets of apron-strings over a period of eight years, he will be fast approaching thirty years of age. He has never made a major scientific decision for himself, never selected his own research project, never tried his own wings. What he now does, in nine cases out of ten, is look for a position which will enable him to go on for the next ten years—and maybe for his whole life—playing minor variations on a theme—not even his own theme, but someone else's.

Yet our young man has done much that is right. To have lived in three or four countries while one is still young is a magnificent cultural start for life, and one which I thoroughly commend. He has made but one mistake, namely, that he has clung too tenaciously to his first scientific love. Had he changed his subject and acquired a new technique—experimental or mental—with each move, he would be in a far better position now. In addition, if instead of a fellowship he had obtained a lectureship or a job with responsibilities attached—in industry or in a research institute—one could not fault his decisions. In particular, the man who is not going to follow the academic life, but is wise enough to do some research work, should make the break with the universities a year or two earlier than is now customary. It is perfectly true that further experience before leaving the university would be valuable. However, the point at issue is whether the experience to be gained in a totally different environment while still young would not be more valuable still.

Prof. W. E. Garner, whose Department of Chemistry in Bristol I so greatly admired in 1948, told me that he encouraged his students and his lecturers to acquire three different techniques before they were thirty-five. This allows four or five years for each technique—long enough for a good grounding. By technique he meant, on the experimental side, such things as X-ray crystallography, vacuum techniques in inorganic chemistry, or distillation methods, and on the theoretical side, subjects like thermodynamics, spectroscopy or quantum mechanics. With any three of these at his command, the research worker can bring to bear on problems at the heart of his subject, big guns that most of his contemporaries lack; he will also be able, from his broader outlook, to recognize what are those very problems.

I should like to register certain reservations with respect to overseas experience and study at the start of a research career. Fifty years ago Australasia was almost a nonentity in the scientific world. To get any appreciation of the excitement of science or even of the method of scientific research it was imperative to travel. Except in a few brave cases of hope and confidence, there was a feeling that it was almost hopeless to try to compete with the world: we were miles behind scratch and would never catch up. Yet we have caught up in some fields, and can lead the world in a few, and there is a justifiable feeling of optimism about the future. I have even found a few kindred spirits from Europe and America who agree with me that one has a far greater chance of being original in the southern hemisphere, for one is not for ever being told there what is impossible by the 'authorities' of the northern hemisphere. (This is a point which might be noted by the student of Europe or North America. There are schools in Australia and New Zealand where a Ph.D. degree could mean more to him than one from his own country.) Too many of them are so surrounded by research students—some try to look after a dozen—that they have no time to think, and thus never escape from the variations of their theme of last year. Beware of any supervisor with more than five research students or you may find yourself in the position of a young man I met in Holland, part of a team of ten. The professor was out of town, and when I asked the student how his research fitted into the main topic of the laboratory, he had no idea. I met him later, when I myself had seen the connexion. Tears of gratitude came to his eyes as I explained it to him: he had been just another pair of hands. Obviously, not all the fault lay with the professor: the student should have had more initiative.

Lest the professional research worker should become too self-satisfied, he should recall that research is not the prerogative of the select few. Every member of the community conducts his private research about a host of matters that interest him. Who, for example, has not done some experimenting with the view of chopping the week's firewood with less effort. Nevertheless, the efforts of the amateur, important though they are, leave much to be desired. Thus, the novice at golf, suspecting his grip is wrong, may change it along right lines. Too anxious, his head follows his club and his shot becomes even worse. So he reverts to the incorrect grip. We all assume the amateur status at times; when fishing for trout, I have a new theory each day but with so many variables it is impossible to confirm or condemn it: that is the charm of something that will for long remain an art.

One might think that having embarked on a career in research the young scientist would have a mind so open that he would welcome new ideas and new generalizations. He must, of course, be critical but not too much so. Thus, Bernard Barber (*Science*, 134, 596; 1961) is convinced that as a class he is resistant to scientific discovery. He quotes Helmholtz as saying that the new ideas need the more time for gaining general assent the more really original they are. Helmholtz, however, resisted Planck's theories: and Lister warned students against blindness to new ideas in science. Others whose ideas met with belated acceptance were Heaviside, and Mendel, whose ideas, expounded in 1865, met with resistance until the turn of the century. Barber says that as late as 1901 the Royal Society asked Karl Pearson in future papers to keep his mathematics apart from biological applications. I myself once ran into trouble because I wished to publish a paper in the *Kolloid Zeitschrift* criticizing the views of the editor, Wolfgang Ostwald. It was published in the *Zeitschrift für Physikalishe Chemie*, but only after a committee had been set up to adjudicate between our rival views. Maybe if one has difficulty in gaining acceptance of one's views, one should be flattered, for one would certainly be in good company.

The term 'research' is used in many different ways. I suppose it is valid to speak of historical and sociological research, but the methods are so different that it is impossible to bracket them with research in physics and chemistry—at least for the present. In the physical sciences the hypotheses can be verified experimentally and should be verified before action is based on them. Verification, while it may be costly, places no human lives in jeopardy. In sociological and economic investigations so many factors are unrecognized or uncontrolled that conclusions are less certain. If the community decides to accept them, the results may be very uncomfortable. Thus, adjustments in the economy in Australia in recent years had more far-reaching results than their architects expected. I would be the last to decry an experimental approach to sociological problems; but the limitations must be recognized. Arising out of these observations, I now refer to a trend that is bound to continue and intensify and which a young man might take into account in deciding on his future career.

The mathematician of to-day is a much more powerful figure in research than his predecessor of fifty years ago. Indeed, it is probably fair to say that the mathematician is gradually taking over much of applied physics. This need not worry the physicist, who is moving into chemistry with growing momentum. Nor the chemist, who, with the physicist, is now a key figure in biological research: and what of the biologist? Does he need to worry? The answer is surely no, for he will become more and more a leader in the sociological fields, ergonomics being a case in point.

There are, of course, fashions in research. Whether one would be well advised to follow one of them is a question each man must decide for himself. Radiophysics and chemical physics are glamorous subjects which, in recent years, have been able to compete for staffing with atomic physics, but classical physics has been neglected. Yet atomic physics may have had its heyday for it is essentially a field for team work, and it is a field, moreover, where the costs are so high that the director must direct rather than inspire. Those physicists whom we have recruited in C.S.I.R.O. for work in classical physics seem to have had a rather more interesting scientific life—at least they have made quite original advances. Fashionable fields might be best for the near first-class, the other branches for the first-class. However, the rewards come later to the most original: the fashionables have a stranglehold on the committees which allot the prizes. In the long run it must be one's own assessment of one's life-work that is most important: public acclaim is nice when it comes, but those who seek it may sacrifice their self-respect.

The universities necessarily set up departments for each of the main branches of science. These often inspire a loyalty towards a particular science. Thus one tends to regard oneself as a chemist or a physicist, or, if one is particularly daring, as a physical chemist. But Nature recognizes no barriers; a natural phenomenon may require a knowledge of many different disciplines for its understanding. Three such phenomena come to my mind: ore genesis, plant growth, and genetics, respectively. So I would propose that, once one has left the university, it would be wise to subordinate one's original loyalty to the wider banner of science. Many of the most exciting fields of research lie in the indistinct regions between the sciences. They give rise to new hybrid disciplines such as biochemistry, biophysics, biological chemistry, geochemistry and geophysics. However, there is no need for a new name every time the fields overlap. The need is for courage to stray into the unexplored border regions. I was a contemporary of, and have had a lifelong association with, Sir Macfarlane Burnet, and so know something of the manner in which he has continued to 'grow' throughout his scientific career. At one stage, with some small amount of help from his friends, he taught himself enough of the calculus to handle the problem then uppermost in his mind. Burnet is far more than a virologist and an immunologist: he is a scientist in the widest sense.

It needs both courage and humility to enter a new field successfully. If one is too humble one does not take the plunge, whereas if one is too adventurous one enters new fields too often and, therefore, too superficially. Coming into an old field with a different background may present some striking advantages. I can illustrate this by referring to a small group of C.S.I.R.O. chemists and petrologists who entered the field of cement manufacture and utilization. They knew nothing of cement at the time, but they brought to its study some techniques hitherto lacking. They revolutionized some of the thinking, and in a short time became one of the leading laboratories of the world.

Perhaps I have dwelt too long on how a man or a woman may fit himself or herself for a career in research. There is the career itself. How satisfying it is, and how does it pay off? It is forty years since I made known my intention to adopt research as a career. I then received much the same sort of reception as a butcher's son of to-day might expect on deciding to become a composer in the style of Bartok. The gloomiest views were taken—not by my parents, I am glad to say—but by the family friends in industry and commerce. Overseas, the career research worker had just been born: he was no longer regarded by statesmen as a luxury, but as a necessity. Different countries have made provision for him in different ways, usually determined on a basis of expediency, sometimes backing a laboratory where good research was being done, sometimes setting up new facilities. Britain set up the Department of Scientific and Industrial Research; the United States established research institutes such as the Batelle, the Mellon, Stanford and Southwest. Continental countries tended to sponsor additional work in the universities, their professors acting as consultants to industry. No country has remained true to any of these ways: all have adopted a mixed approach.

Meanwhile, industry itself, commencing with Europe and rapidly expanding elsewhere, had discovered that the research scientist earns for the company more—far more—than his salary. Large private research laboratories were founded, and particularly in the electrical and chemical industries, help to pile up profits. In the United States, and partly for a very curious reason, the Government, through the Office of Naval Research, found itself placing contracts for quite fundamental research projects with industry. By the adoption of this subterfuge the best scientist became available for governmental work; the maximum salaries fixed by Congress for Government laboratories were too low to attract them.

Thus a person on the threshold of a research career has a wide choice of employing agencies: industry, Government and semi-government laboratories, the universities, and, in certain countries, the private research foundations. I have tried the first three of these types. In the university one gets the maximum freedom, but facilities are often inadequate; in industry the facilities are usually good but there is less freedom; in a Government laboratory both the degree of freedom and the facilities are intermediate. Industry gives one the broadest outlook; the universities, particularly those as isolated as Cambridge and Princeton, are extraordinarily narrow and self-satisfied. Salaries vary; first one group gets ahead and then another. Industry pays the highest top salaries, and the universities the best medium-level salaries. All these are broad statements; there are wide variations with time and with country.

One will find a higher proportion of fundamental research in the universities than elsewhere. By fundamental research I mean that which, if successful, will lead to a change of outlook of major importance to the development of a particular field of science. It is not, as I implied earlier, doing with strontium what somebody has already done with calcium.

Traditions are being forsaken, and fundamental research is no longer the exclusive prerogative of the universities. (I have the feeling that some few university men, not willing to regard teaching as their major function, have resented the spread of research outside university walls. My view—for what it is worth—is that strong support for university research is essential, since the university teaching function would languish without the stimulus from it. Nevertheless, company research, Government research and private institute research will continue to flourish because they pay exceedingly high dividends. There is room for all.) Excellent work of this class is done in industry, in research institutes on the American plan, and in such bodies as the Australian C.S.I.R. and its counterparts elsewhere. However, we have gone further in this respect in Australia than any other similar body and have found it pays handsome dividends. For this the credit must go to the first executive of the C.S.I.R.O., and particularly to the chief executive officer, Sir David Rivett, who was able to convince the Government of the day that the C.S.I.R. must be free to tackle its scientific problems on as fundamental a basis as was necessary for their solution (C.S.I.R.O. was formerly known as C.S.I.R.).

Perhaps you cannot yet decide whether you are more interested in fundamental or applied research ? Whatever you do choose, please try not to be snobbish about it, for there is a tendency for each group to air a superiority (inferiority ?) complex. Since progress in research is quite unpredictable—if one knows the answer it is not research—one can never be certain that a basic discovery will not be exploited, or that the attempt to solve a specific problem will not unearth quite new and profound knowledge. I believe that scientists with these two different outlooks contribute greatly to the successes of one another and do best when sharing a common environment. I myself have tried to 'back it both ways' by working in fields which I hoped would lead to useful applications, but which, at the very worst, would almost certainly provide new scientific knowledge. Thus there is a nice interplay between surface chemistry on one hand and such useful matters as flotation of minerals and hindrance to evaporation on the other.

The Monsanto Chemical Co. of America, believing that it must encourage the most talented recruits to its Research Department to remain there, rather than to chase the dollar elsewhere, has established for its top-flight research workers a classification which enables them to receive salaries to match those in other departments. This is a far-sighted step which one hopes will be copied widely.

Society does not always do the right thing by sections of the community, and in Australia we have some curious survivals in wage-fixing methods. Research workers and university lecturers are not strong pressure groups, but they have one protective characteristic which ensures for them the rudiments of justice. A degree in science is an international passport. So unless a nation pays its scientists reasonably, it may lose all except those who are tied by such strong bonds that even penury cannot weaken their allegiance. Actually, Australia loses more scientists to other countries because of better facilities for research than for higher salaries: most scientists are not mercenary. There is a second protective mechanism at work, for nowadays the community greatly values the scientist, and most members realize that it is his work in the background rather than the very earnest efforts of the trades union secretary or the politician that is responsible for increasing standards of living.

Some of my colleagues chide me for saying that the research man has tangible rewards besides his salary; I refer to his great freedom of action and to his satisfaction in his work. "Have not the business man and the artisan", they say, "similar rewards ?" Be that as it may, I count myself exceptionally fortunate in that I have always found a backer willing to pay me reasonably for what I most wanted to do. I have been permitted, like Tennyson's Ulysses, to travel far, and have enjoyed the company and respect of my fellow men. Perhaps I may be permitted to say that while scientists lack the perquisites of the salesman, they do have some 'fringe' benefits.

I have little patience with the scientist who maintains that because he is a scientist and has shown sufficient talent to get a Ph.D. the community have an obligation to provide him with a job to his liking and a comfortable existence. It is present performance that should count. Research men are justified in claiming some special privileges, but only those that enable them to do their work better. With these privileges they must accept responsibilities, and the vast majority are willing to do so. For example, most work exceptionally hard. Indeed, the scientist who finds he must force himself to work should give serious thought to changing his job—or at least his research project.

From very long experience, the Commissioners of the Exhibition of 1851 state that the only way to find out if one is good at research is to try it. Academic successes as an undergraduate, however spectacular, are nothing more than a good recommendation, and not an infallible guide.

A false start in a scientific life is not all that important, for a year spent in research will provide a good training of mind and hand, which will stand one in good stead later, in any walk of life. A strong group of industrialists in Britain, however, have come out emphatically against a prolonged period of research for those not contemplating a research career.

I would put two criteria above all others for the research man. First, he must have an overpowering curiosity about natural phenomena. When wandering through the bush he must wonder why ants never attain the size of lions, why some trees have darker foliage than others, why some rocks persist while others disintegrate, and where the robins go in winter. Still more, he must have the desire to experiment to find out. Without this he may be a good philosopher, but he is no scientist. He needs patience and diligence, the willingness to work for days and nights on end, at times (but only at times) when the job demands it. He needs a Micawber temperament to see him through the bad periods, and I hope, for his own sake, he is able to exult at successes.

My second major criterion is a strong educational background, leading, among other things, to an easy facility with one's own language. If a man cannot write clearly he cannot think clearly, and there is no place for muddled thinking in research. All whom I have known who have achieved outstanding success in science have written well; almost all have the capacity to describe their most intricate work to the layman. I do not think they all began life with that facility; but they certainly had acquired it before they became recognized as leaders.

I should hate to think that there would be many who would look on research merely as a career. To most of us it is more than that; it is our—perhaps minute but sincere—contribution to the development of science, that man may be better able to control his environment and to live a longer and fuller life. It is more than this; it is our contribution to the culture of the human race. For we must never be fooled by those who talk of the two cultures. Culture is as indivisible as is life itself, and the scientists give as much to it as does any other group.

A career in science opens up far horizons. At the end, one will be able to say with Ulysses:

> "I am a part of all that I have met ;
> Yet all experience is an arch wherethro'
> Gleams that untravell'd world, whose margin fades
> For ever and for ever when I move."

CHEMICAL TRANSMISSION IN THE CENTRAL NERVOUS SYSTEM*

By DR. J. H. GADDUM, F.R.S.

Agricultural Research Council, Institute of Animal Physiology, Babraham, Cambridge

THE evidence that nerves commonly produce their effects by releasing chemical substances at their endings is mostly based on experiments on peripheral tissues. This evidence is summarized in Table 1. The theory of chemical transmission had been discussed for many years before Loewi provided the first experimental evidence of it in 1921. He must have suspected from the first that the substance liberated by the vagus was acetylcholine; but he was careful not to say so and cautiously spoke of "*vagusstoff*". It was not until 1930 that acetylcholine came to be generally accepted as the substance released, and this was mainly due to two factors. Dale and Dudley[1] isolated acetylcholine from horse's spleen, and Chang and Gaddum[2] showed that it was possible to distinguish acetylcholine from other esters, such as propionylcholine, by making parallel assays by different pharmacological methods. At one time it seemed that it would not be easy to distinguish acetylcholine from pyruvylcholine; but Gill and Parsons[3] have now shown that this is not the case. The sample tested in 1933 was probably not pyruvylcholine, but an impure sample of acetylcholine. So far as we know, parallel assays will distinguish between acetylcholine and any other substance. This method was used to show that acetylcholine is liberated in the superior cervical ganglion[4] and elsewhere. Since then other esters, including propionylcholine, have been found in animal tissues, but the only one which has been shown to be liberated after stimulation of nerves is acetylcholine.

The second item in the Tables is that the administration of the transmitter reproduces the effect of stimulating the nerve; the effects of acetylcholine on peripheral tissues are well known[5]. Tissue extracts provide much indirect evidence. An extract of a nerve which liberates acetylcholine (a cholinergic nerve) contains acetylcholine itself, and the enzymes cholineacetylase and cholinesterase, which make it and destroy it. Table 2 shows the drugs which act on the various factors controlling acetylcholine. The release is inhibited by botulinum toxin[6] and morphine[7]. These drugs block transmission, but do not block injected acetylcholine. Drugs such as atropine, which block acetylcholine, do not always block transmission. Some people would say that this shows that acetylcholine is not the transmitter liberated; but Dale and Gaddum[10] came to the conclusion that this phenomenon might be "due to the liberation of a cholinester, but in a relation of so much greater intimacy with the receptor mechanism that atropine cannot prevent its access thereto". This explanation may appear unlikely, but similar explanations are still put forward[11].

The Central Nervous System

It seems likely that some of the mechanisms found in peripheral structures are also present in the central nervous system. Acetylcholine may be excitor or inhibitor, since it causes depolarization and excitation in voluntary muscle and hyperpolarization and inhibition in the heart. The same is true of noradrenaline, which excites the heart and inhibits the intestine. In both these tissues acetylcholine and noradrenaline are opposed; but their roles are reversed. It was therefore not surprising when Bradley and Wolstencroft[12] applied these drugs to single cells in the medulla and found that different cells were stimulated or inhibited, by either drug or both, in almost all possible combinations.

Table 1. EVIDENCE FOR CHEMICAL TRANSMISSION OF NERVOUS IMPULSES

Direct evidence

(1) Stimulation of a nerve releases an identifiable substance (the transmitter).
(2) The administration of the transmitter reproduces the effect of stimulation of the nerve.

Evidence from tissue extracts of

(3) Storage of the transmitter
(4) Synthesis
(5) Destruction

Evidence from the effects of drugs which may block any of these 5 actions.

Tissue extracts have given an indication of the probable distribution of cholinergic fibres in the central nervous system. The distribution of choline acetylase is similar to that of acetylcholine[13], but it can be detected in smaller amounts of tissue[14,15]. The concentration is high in motor roots, which are known to be cholinergic, and high in the caudate nucleus and the thalamus, but negligible in the pyramidal tracts and the optic nerves. It seems probable that these tracts liberate some other substance. The intracellular distribution of acetylcholine or cholineacetylase can be determined by homogenizing brain in sucrose and centrifuging. Acetylcholine and various other interesting substances are found in a fraction which consists largely of pinched-off nerve endings[16].

Until recently there was little direct evidence for the release of acetylcholine in the central nervous system. Bülbring and Burn[17] detected some release in the dog's spinal cord perfused with Ringer, when the whole sciatic nerve was stimulated. MacIntosh and Oborin[18] detected the diffusion of acetylcholine from the surface of the cerebrum into eserinized Ringer, contained in plastic cups. Mitchell and others[19,20] have been using these plastic cups and also push-pull cannulae[21]. In this apparatus Ringer runs down a fine needle into a tissue and is then collected through a plastic tubing surrounding the needle. The acetylcholine released is detected by its action on leech muscle in a microbath[22]. In these ways it has been shown that acetylcholine is constantly released from the cerebral cortex at a rate which is directly related to the local electric activity. The rate is increased by systemic injections of atropine or of the convulsant drug 'Leptazol'. It is increased by local stimulation of the cortex or by transcallosal stimulation, or by stimulation of the contralateral forepaw. When the cannula was in the middle of the caudate nucleus the rate of release was increased by stimulation of a small region of cortex in front of the motor area, but not by stimulation elsewhere. The largest yield of acetylcholine was obtained with stimulation at a rate of 1 per sec; faster rates produced less or none. There is clearly much more to be done with these techniques, which might be used to detect the release of other substances besides acetylcholine. Ramwell and Mitchell[23] have, in fact, detected the release of something else with an action on rat uterus.

Table 2 ACETYLCHOLINE

Direct evidence	Increase	Decrease
(1) Release	Stimulation of nerves	Botulin[6] Morphine[7]
(2) Action	Administration	Atropine Curare Ganglion blockers
Evidence from tissue extracts		
(3) Store[8]	Eserine Anaesthesia	Atropine Convulsions
(4) Formation	Cholinacetylase	Hemicholinium[9]
(5) Destruction	Cholinesterase	Eserine, etc.

---

* Substance of a lecture delivered at University College, London, on December 6.

Another technique for detecting the release of substances in the central nervous system involves the use of the isolated spinal cord of a frog, or toad. Mitchell and Phillis[24] have found that in this preparation acetylcholine is liberated on stimulating motor roots, but not on stimulating sensory roots. This surprising observation suggests that the only cholinergic nerves in the spinal cord are recurrent nerves from motoneurones running to Renshaw cells. This is interesting because of the evidence discussed here that Renshaw cells are the only cells in the spinal cord of a cat which are sensitive to acetylcholine (cholinoceptive).

The effects of acetylcholine itself in the central nervous system are best studied by iontophoretic injection[25,26]. A micro-electrode is filled with a strong solution of the drug and a brief electric current is passed, which carries the drug as ions into the tissue. In one form of the apparatus, five glass tubes are fused together and pulled out simultaneously. The centre tube is filled with saline and used for recording. The other tubes are filled with drugs, which can thus be delivered within a few microns of the recording electrode. The first clear results came from experiments on the spinal cord by workers in Canberra[27], who found that Renshaw cells were excited by acetylcholine and that other cells were not. These Renshaw cells have an inhibitory effect on spinal reflexes; they are supplied with fibres from motoneurones and provide negative feed-back. The action of acetylcholine on these cells resembles its action on voluntary muscle in the fact that it has a short latency and a brief after discharge, and is specifically inhibited by dihydroerythroidine, but not by atropine.

Krnjević and Phillis[28] have applied drugs to the cat's cerebral cortex. The highest concentration of cholinoceptive neurones was between 0·8 and 1·3 mm below the surface. Betz cells, identified by antidromic stimulation of the pyramids, were generally cholinoceptive. This action of acetylcholine developed slowly and had a prolonged after discharge; it was specifically antagonized by atropine, but not by dihydroerythroidine. The response of these Betz cells resembled the peripheral muscarine actions of acetylcholine, while the response of Renshaw cells resembled peripheral nicotine actions.

There is also evidence of cholinoceptive cells in the inferior colliculus, the medulla, the thalamus and elsewhere. Active work in this field is being done in many places.

Amines

The monoamines adrenaline, noradrenaline, 5-hydroxytryptamine (5HT, serotonin) and dopamine have attracted attention because they are drugs with powerful peripheral effects, and are found in extracts of the central nervous system.

Their actions on the central nervous system are complicated. When adrenaline or noradrenaline is injected intravenously it causes emotion; some say that noradrenaline causes anger and that adrenaline causes anxiety. These effects may well be due to reflexes arising from peripheral tissues. When Feldberg[29] injected them into the cerebral ventricles they caused inhibition. The action of noradrenaline on an individual cell may be either excitor or inhibitor[12].

There is no direct evidence that any of these amines is released by nerves in the central nervous system; but there is much indirect evidence from experiments on tissue extracts suggesting that they play an important part in controlling the brain. The first convincing experiments were done by Vogt[30], who showed that noradrenaline was present in the phylogenetically old parts of the brain, that it did not disappear when the cervical sympathetic nerve was cut and that its concentration could be altered by drugs. At about the same time the presence of 5HT in the central nervous system was announced simultaneously by two groups of workers at the International Physiological Congress in Montreal[31,32] and its distribution was shown to be similar to that of noradrenaline[33].

Table 3. MONOAMINES

Noradrenaline, adrenaline, dopamine and 5HT (serotonin)

Direct evidence	Increase	Decrease
(1) Release	Stimulation of nerves	Bretylium[36], etc.
(2) Action	Administration	Ergot derivatives, Phenoxybenzamine, etc.
Evidence from tissue extracts		
(3) Store	Monoamine oxidase inhibitors	Sham rage[30]
	Precursor	Reserpine[36]
(4) Formation	Decarboxylase	α-methyldopa[37,38]
(5) Destruction	Monoamine oxidase	Monoamine oxidase inhibitors
	Methylases	Pyrogallol

Vogt[30] showed that the store of noradrenaline is depleted by drugs which stimulate the centres controlling the sympathetic system, causing sham rage. This may have been due to release by adrenergic nerves, but the evidence is indirect; exhaustion of the store might also be due to decreased synthesis, decreased uptake from the blood, or increased destruction. These drugs do not affect the concentration of 5HT.

The concentration of noradrenaline in peripheral adrenergic nerves is increased by local synthesis and also by uptake from the tissue fluids. It is probable that, after it has been liberated, some of it is taken up by the nerve and used again[34]. Amines do not penetrate the blood brain barrier, but the amino-acids from which they are formed are taken up and the amines are formed inside the cells.

The concentration of monoamines in the brain is lowered by reserpine, which appears to have a direct action in blocking the storage sites. Their concentration is raised by drugs which inhibit the monoamine oxidase, which normally destroys them. Reserpine causes sedation, and monoamineoxidase-inhibitors, such as iproniazid, cause excitement and are used in the treatment of depression. It has been claimed that the accumulation of amines causes excitement, and their loss has the opposite effect. This simple story is inconsistent with Vogt's findings already described. There was controversy about whether the state of the brain depended on noradrenaline or 5HT, and it was decided that excitement was due to the accumulation of noradrenaline and that depression was due to the release of 5HT. It was then found that dopamine was present in large amounts. This amine is formed by the decarboxylation of dopa (dihydroxyphenylalanine) and is the precursor of noradrenaline in the body, but it has functions of its own and some think it is more important than the other amines in the central nervous system.

The fundamental facts about these monoamines were discovered by bioassay, but fluorimetric methods are quicker and more versatile, since they may be used to estimate not only the amines but also their metabolic products[35]. Amino-acids, such as dopa, are taken up by the brain and decarboxylated inside the cells to form amines. The administration of dopa increases the amount of both dopamine and its metabolites found in brain extracts. Drugs, such as α-methyldopa, which block the decarboxylase, have the opposite effect and lower both amines and metabolites. Reserpine blocks storage and so lowers the amine concentration and increases the metabolites. Drugs which block amine–oxidase increase the amines and presumably lower some of the metabolites.

It is thus possible to produce all combinations of change in the amounts of four different amines and their metabolites, inside and outside the cells. It is still true that the accumulation of amines is often associated with excitement and depletion of amines with depression, but the mechanism is not as simple as was once thought. The turnover may be more important than the store.

Histamine is an amine present in the same parts of the brain as the monoamines and in similar concentrations[39]. Little is known about its possible function.

Other Substances

More than half the neurones in the central nervous system do not liberate acetylcholine and it seems likely that they liberate other substances, and that these substances will be found in extracts. γ-Aminobutyric acid (gaba) is formed in the brain from glutamate (as dopamine is formed from dopa) and like dopamine it is liberated by reserpine[40]. Glutamate is a general stimulant of nerve cells and gaba a general depressant. When glutamate is applied by iontophoretic injection it causes depolarization and the initiation of impulses. Gaba prevents this depolarization but does not cause hyperpolarization. The Renshaw cells cause hyperpolarization in motoneurones, so that gaba cannot be the chemical transmitter liberated by Renshaw cells. Glutamic acid and gaba are both present in high concentrations in the central nervous system, and it seems unlikely that they are specifically released from active nerve endings.

Substance *P* is an active polypeptide found only in vertebrates and with a specific distribution in the mammalian brain. There is no good evidence of its function, but it has been suggested that it controls the circulation. Other active substances in extracts include fatty acids, adenosine triphosphate and many more[41]. There is no good evidence that any substance, except acetylcholine, is liberated as a chemical transmitter in the central nervous system. There must be other transmitters, but it is probably unreal to speak of 'the inhibitory transmitter'. Acetylcholine itself is inhibitory at some sites. If the Renshaw cells liberate a substance which inhibits motoneurones, this substance may well be found to excite other neurones in the central nervous system.

CRANIAL CAPACITY OF *ZINJANTHROPUS* AND OTHER AUSTRALOPITHECINES

By Prof. PHILLIP V. TOBIAS
Department of Anatomy, University of the Witwatersrand, Johannesburg

THE cranial capacity of the fossil hominoids, the Australopithecinae, has always been a problem of great interest, especially since several workers such as Keith[1] and Vallois[2] have recognized a 'Rubicon' of brain size between apehood and manhood. Keith's 'Rubicon' was 750 c.c., while Vallois's was 800 c.c. Other workers, including Straus[3] and Dart[4], have emphatically rejected this notion of a cerebral 'Rubicon'. Recent studies (for example, that of Schultz[5]) have shown that there is no clear dividing-line, the largest gorilla cranial capacity (752 c.c.) differing scarcely at all from the smallest capacity of a Javanese *Pithecanthropus* (775 c.c.). Even if we do not recognize a dividing-line, it is of interest to see where the cranial capacities of the australopithecines lie in relation to those of other hominoids. It is the purpose of this article to review the recorded cranial capacities of australopithecines and to place on record the cranial capacity of the Tanganyikan australopithecine, *Zinjanthropus*.

At the outset, it should be stressed that cranial capacity is not the same as actual brain-size, since the cranial cavity accommodates as well as the brain the dura mater and the other coverings of the brain, cerebrospinal fluid and blood. The relationship between endocranial volume and brain volume has been thoroughly reviewed by Zuckerman[6]; there is no consistent ratio between the two values, and it has long been customary to accept the cranial capacity as an approximation to brain-size. For example, instead of comparing brain-weights with body-weights of living primates, as Connolly[7] has done, Schultz[8,9] expresses cranial capacity in cubic centimetres as a percentage of body weight in grammes. In the work recorded here, cranial capacity alone is considered, with no attempt to convert it to brain volume or brain weight.

The Australopithecinae are now known from at least seven, if not eight, sites in Africa: five of them within the Republic of South Africa, one or possibly two in Tanganyika and one in Chad. In addition, Robinson has claimed that the Javanese fossil, *Meganthropus*, belongs to the same sub-family[10,11]. All these fossil ape-men fall into two fairly distinct categories: a more gracile form, sometimes considered a separate genus, *Australopithecus*, and a more robust form, to which has been given the generic name *Paranthropus*[12]. There is a yet more robust form from Olduvai Gorge in Tanganyika, to which Leakey[13] has given the name *Zinjanthropus*, but which some workers regard as closely related to *Paranthropus* (for example, Robinson[14]).

A detailed examination of the cranium of the Olduvai australopithecine has been undertaken by me, at Dr.

Leakey's generous invitation. The resulting report will form the major part of the third volume of a new work which is being prepared by the Leakeys and their collaborators. Meanwhile, however, owing to the considerable interest in the cranial capacity, it was deemed important to place this on record in advance of the larger publication.

Cranial Capacity of the Gracile Australopithecines

Six of the gracile australopithecine crania are sufficiently well preserved to have made good estimates of the cranial capacity possible. Four of these are adult specimens from Sterkfontein, and their capacities are 435, 480, 480–520 and 530 c.c. (refs. 15, 16 and 17). The fifth is the child skull from Taung which, at about 5 years of age, has a capacity of 500–520 c.c. (refs. 15 and 18). The capacity which the Taung individual would have attained to, had it lived to adulthood, has been variously estimated at 570, 600 and 624 c.c. (refs. 1, 4, 19 and 20). The central value of 600 c.c. is accepted here. The sixth specimen is the recently discovered, tolerably complete cranium (*MLD* 37/38) from Makapansgat[21]; according to unpublished information kindly supplied by Prof. R. Dart, this cranium agrees in its dimensions so closely with the very complete cranium (*Sts* 5) from Sterkfontein that the same cranial capacity should be attributed to it, that is, 480 c.c. Thus, six specimens of *Australopithecus* range from 435 to 600 c.c. in cranial capacity, giving an average value of 504 c.c. (Table 1).

Cranial Capacity of the Robust Australopithecines

Until recently, no single specimen of the large-toothed, heavily muscled form of australopithecine had been discovered which was sufficiently complete and undistorted to make possible a reliable estimate of the cranial capacity. True, some guesses had been made: the robust dimensions of the teeth, jaws and crania of *Paranthropus* had led to estimates such as 650 c.c. for the Kromdraai specimen[14], 700 and 750–800 c.c. for two child crania from Swartkrans and "probably over 800" and "probably over 1,000" for two adult specimens[12]. All these estimates agreed in giving the robust ape-man an appreciably bigger cranial capacity than the gracile form; insecurely based as these guesses were, it had virtually become accepted by some workers that the robuster australopithecine was not only bigger-toothed, bigger-jawed and bigger-muscled, but also bigger-brained than the gracile hominid from Taung, Sterkfontein and Makapansgat.

The Leakeys' new fossil cranium from Bed I in the Olduvai Gorge, called by Dr. Leakey *Zinjanthropus boisei*[13], is the first of the robuster forms of australopithecine which is sufficiently complete and well preserved to have enabled an accurate assessment of the cranial capacity to be made.

Endocranial Cast of *Zinjanthropus*

No natural endocast was found with the cranial remains of *Zinjanthropus*. However, so much of the endocranial surface of the calvaria was preserved as to make possible the preparation of a plaster endocast. This was effected by me, with the invaluable expert assistance of Messrs. A. R. Hughes and T. W. Kaufman of the staff of the Department of Anatomy. Approximately the posterior two-thirds of the brain-case was virtually complete; likewise, the frontal poles and rostral regions. The areas between had to be reconstructed. There is little doubt as to the intervening distance, because of a satisfactory approximation between the anterior and posterior calvarial parts. Furthermore, there were available for comparison a large collection of endocranial plaster casts of gorilla, chimpanzee and orang-utan, of cercopithecoids, of *Pithecanthropus* and other fossil hominines, of modern man, and of the australopithecine natural endocasts hitherto discovered, as well as plaster casts in those instances where no natural cast had formed or been found. In the circumstances, it is felt that the plaster endocast of *Zinjanthropus* cannot be far from the mark and cannot deviate volumetrically from the true cranial capacity by more than perhaps 20 c.c. in either direction.

Table 1. CRANIAL CAPACITY OF *Zinjanthropus* AND OTHER AUSTRALOPITHECINES

Zinjanthropus		530	Tobias 1962
Australopithecus (*A*) Sterkfontein	*Sts* 1	435	Schepers (1946)
	Sts 5	480	Broom, Robinson and Schepers (1950)
	Sts 7	480–520	Broom, Robinson and Schepers (1950)
	Sts 8	530	Broom and Robinson (1948)
(*B*) Makapansgat	*MLD* 37/38	480	Dart, (personal communication)
(*C*) Taung	Taung juv.	500–520	Dart, Schepers (1946).
	Taung adult (estimate)	570–600–624	Le Gros Clark (1947) Le Gros Clark (1955) Dart (1956)
Australopithecus	adult mean ($n = 6$)	504	Present work
Australopithecinae	adult mean ($n = 7$)	508	Present work

Cranial Capacity of *Zinjanthropus*

The volume of the endocast was determined by displacement of water, after the cast had been varnished. In seven determinations, the displaced water was measured by volume and in three further determinations by weight. The mean of the first seven estimations was 529·7 c.c., the mean of the next three estimations 528·1 c.c.—and the overall mean for ten estimations is 529·2 c.c. For practical purposes, we may call the cranial capacity of *Zinjanthropus* 530 c.c.

The Tanganyikan creature falls somewhat short of full adulthood, the third molars being not yet in the fully erupted position of occlusion. The age of the youth may be 15–16 years. Very little, if any, further growth of the brain occurs after this age: in man, for example, brain growth is said to end at about 20–21 years of age[4,23,24], although a few workers would extend the period of growth somewhat longer[4]. In the chimpanzee, Zuckerman found that "in the resting stage after the eruption of the first molar", the capacity is already 90 per cent of the adult capacity in males and 95 per cent in females (*op. cit.*, p. 34). Since *Zinjanthropus* is practically dentally mature, the value of 530 c.c. may be accepted as very close to the adult cranial capacity.

In other words, its capacity is exactly the same as that of the largest adult *Australopithecus* from Sterkfontein, but falls short of the value estimated for the adult capacity of the Taung ape-man, that is, 600 c.c. Although the Olduvai creature is by far the biggest-toothed and biggest-muscled of all the robust ape-men thus far discovered, its brain-size proves to have been no larger than that of its smaller-toothed gracile cousins.

If this is true of the most robust of all the australopithecines, it is probably equally true of the somewhat less robust South African forms of *Paranthropus*. In this regard, it is interesting to note that, since the discovery of *Zinjanthropus*, Robinson has revised his earlier estimates of the capacity of *Paranthropus* from the high values quoted above to a modest 450–550 c.c., that is, the same order of size as obtains in the gracile *Australopithecus*[12,14].

Of course, the single valid estimate of 530 c.c. in one robust australopithecine cannot provide us with any estimate of the range of capacities. It may yet prove that the range and the average capacity of the robust forms differ from those for the gracile forms, although the ranges probably overlap to a considerable extent. Only the discovery of more and better specimens can answer this question. Meanwhile, there is no reason why at this stage the six capacities of the gracile *Australopithecus* and the single capacity of the robust *Zinjanthro-*

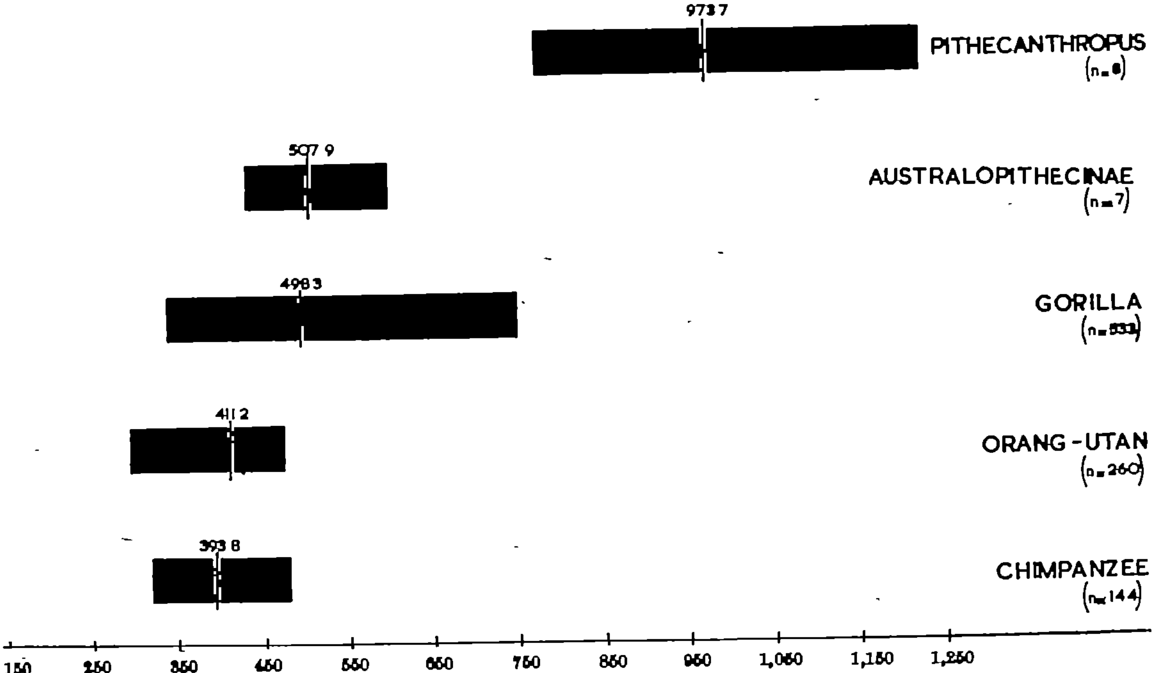

Fig. 1. Cranial capacities of hominoids

pus should not be combined as a single sample of seven australopithecine capacities. The mean of this combined sample is 507·9 c.c. (Fig. 1).

Australopithecine Capacities compared with those of Other Hominoids

The australopithecine mean of 507·9 c.c. is slightly larger than the mean for the biggest-brained of the anthropoid apes, the gorilla, which has a mean capacity of 497·8 c.c. (ref. 2), or 498·3 c.c. if an additional gorilla cranium of very large capacity is included (see following). The mean value for the orang (411·2 c.c.) is 100 c.c. smaller than the australopithecine mean, while the mean for chimpanzee is somewhat smaller again (398·8 c.c.). Nevertheless, the biggest orang and chimpanzee crania (about 480 c.c.) overlap the lower part of the australopithecine range (435 c.c. +).

Ashton's[26] analysis of the endocranial capacities of the Australopithecinae was based on seven crania. He included the Taung child, unfortunately not adjusted for age, and two crania estimated to have capacities of 650 c.c. which are not accepted in the present study. He compared these values with means for male and female chimpanzee and gorilla, as well as for *Pithecanthropus*. (Unfortunately, Ashton has apparently erroneously included the six Ngandong crania under *Pithecanthropus pekinensis*, of which he states Weidenreich[27] gave the cranial capacities of 11 specimens. In fact, Weidenreich tabulated the capacities of only five specimens of *Pithecanthropus pekinensis* (although mentioning another two estimates, 850 and 1,300, in the text). When to these 5 Peking cranial capacities are added Weidenreich's figures for 6 Ngandong crania and 3 Javanese *Pithecanthropus* crania, Ashton's total of 14 crania and his mean of 1,026 c.c. are obtained. Since there is no agreement with Ashton that the Ngandong crania belong to *Pithecanthropus pekinensis* (Campbell[28] places them in *H. sapiens soloensis*), I have excluded them from my *Pithecanthropus* group, including in the latter group only 5 Peking skulls and 3 *Pithecanthropus* skulls from Java.)

Ashton found that all the australopithecine capacities but one were significantly greater than those of the chimpanzee. None differed significantly from those of male gorilla, while only the two estimated capacities of 650 c.c. were significantly greater than those of female gorilla. *Zinjanthropus* thus provides one more australopithecine datum well within the gorilloid range of cranial capacities.

On the other hand, the australopithecine mean falls far short of the smallest hominine mean, which, according to my calculations, is 973·7 c.c. for eight crania of *Pithecanthropus* (=*Homo erectus*). Ashton found that all the australopithecine capacities, even including the estimates of 650 c.c., were significantly smaller than those of *Pithecanthropus*, as computed by him (see footnote). There is a gap of 175 c.c. between the largest australopithecine capacity accepted in the present study (600) and the smallest known pithecanthropine capacity (775). At the same time, the gap between the largest gorilla cranium and the smallest pithecanthropine cranium has been progressively reduced from 152 c.c. (ref. 27) to only 90 c.c. (ref. 2), and now to a mere 23 c.c., by the finding of a single large male zoo specimen with a capacity of 752 c.c. (ref. 5). No australopithecine skull yet discovered is as large as the biggest-brained gorilla cranium.

This raises the point whether the range of presently known australopithecine capacities, in which 165 c.c. separates the largest and the smallest, can be regarded as a reasonable approximation to the population range. In his definitions of the proposed genera, *Paranthropus* and *Australopithecus*, Robinson[13] ascribes to both an endocranial volume "of the order of 450–550 cm^3". This range of only 100 c.c. is clearly too small, as a glance at Table 2 will confirm.

The range between the maxima and minima for a large gorilla sample is 340–685 c.c. (or 340–752 if Schultz's outsize specimen is included); for a large orang-utan sample

Table 2. RANGES AND MEANS OF CRANIAL CAPACITIES OF HOMINOIDS

Species	Size of sample	Range	Difference between minimum and maximum capacities	Mean	Range/mean (%)
Gibbon	86	87–130	43	89 3	48·1
Siamang	40	100–152	52	124·6	41·7
Chimpanzee	144	320–480	160	393 8	40 6
Orang-utan	260	295–475	180	411·2	43·8
Gorilla	533	340–752	412	498·3	82·3
Australopithecinae	7	435–600	165	507·9	32·5
Pithecanthropus (*Homo erectus*)	8	775–1,225	450	973·7	46·2
Modern Man	—	±1,000–2,000	±1,000	±1,300	±77

295–475 c.c.; for a large chimpanzee sample 320–480 c.c.; and for a small sample of *Pithecanthropus* crania 775–1,225 c.c. (refs. 2 and 27). The volumetric differences between these pairs of maxima and minima are: chimpanzee 160, orang 180, gorilla 345 (or 412) and *Pithecanthropus* 450 c.c. (all figures relate to males and females combined). The range of variation seemingly increases as the mean cranial capacity increases: this being so, we might expect the australopithecines, with a mean capacity slightly greater than that of the gorilla, to have a range between those of gorilla and *Pithecanthropus*, though much closer to that of gorilla. Instead, the range for the presently known Australopithecinae is 435–530, a volumetric difference of only 95 c.c. If we accept the central estimate for the Taung adult capacity, the australopithecine range becomes 435–600, a difference of 165 c.c. However, even the range of 165 c.c. is on the small side as compared with those of other higher Primates. This range is about as extensive as the ranges in the smaller-brained chimpanzee and orang, but it is less than half the range in gorilla and *Pithecanthropus*.

Accordingly, estimates have been made of the probable population range for the Australopithecinae. Although the method and detailed results will be presented elsewhere[29], it may be stated here that even the most generous estimate yields a maximum value of 848 c.c. at the australopithecine grade of hominid organization. We may conclude that the estimates of 1,000 c.c. for the upper limits of the australopithecine cranial capacity[4,12] are excessive and highly unlikely.

ROLE OF OPTICAL ISOMERS IN DETERMINING THE ANTIGENICITY OF SYNTHETIC POLYPEPTIDES

By THOMAS J. GILL, III, HANNAH J. GOULD and PROF. PAUL DOTY

Department of Pathology, Harvard Medical School, Boston, Mass., and
Department of Chemistry, Harvard University, Cambridge, Mass.

IT has been recently demonstrated that a variety of synthetic polypeptides are antigenic in rabbits and other mammals[1–5]. Since the synthesis of the polypeptides is under careful control, certain molecular parameters can be systematically varied in order to explore the minimal requirements for eliciting an immunological response and for determining antigenic specificity. It has been shown, for example, that no more than two types of amino-acids are needed in the polypeptide chain[6] and that the antigenic sites probably consist of short amino-acid sequences in the disordered, non-helical regions of the chain[7]. In this investigation we have examined two polypeptides differing only in the residue configuration of the amino-acids in order to determine how this parameter affects the antibody production and the antigenic specificity.

The two polypeptides were synthesized from reaction mixtures of 60 mole per cent glutamic acid and 40 mole per cent lysine. The physical and chemical properties of the polymers are summarized in Table 1. The molecular weights were measured by sedimentation using the approach-to-equilibrium method. The compositions were determined by acid-base titration. The α-helical contents were obtained from measurements of optical rotatory dispersion in the conventional manner[8].

Rabbits were immunized subcutaneously with 10 mg of the antigen in Freund's complete adjuvant, followed three weeks later by another 10 mg in saline–phosphate buffer. Two weeks after the second injection the animals were bled (bleeding I). Some of the animals in both groups then received three further injections of 10 mg of the antigen in saline–phosphate buffer on alternate days after bleeding I, and were bled again one week after the last injection (bleeding II). The antibody concentrations of the individual sera were measured by the precipitin method, which is sensitive to a minimum of 1 μg antibody nitrogen per ml. of serum.

The polypeptide composed of D-amino-acids failed to elicit an immune response detectable by the precipitin method in any of the 24 rabbits tested. Moreover, none of these sera, tested individually, reacted with either the D- or the L-polypeptide. Contrasting with this, the polypeptide composed of L-amino-acids elicited an average of 13 μg antibody nitrogen per ml. of antiserum. (This average value included the 6 rabbits which gave no detectable response out of 12 immunized.) The average antibody concentrations are presented in Table 2.

It was further found that the D-polypeptide did not cross-react with any of the individual sera to the L-poly-

Table 1. PROPERTIES OF THE OPTICALLY ISOMERIC SYNTHETIC POLYPEPTIDES

Formula	Acid-base titration					Molecular weight	Optical rotatory dispersion				
	Mole per cent glutamic acid	Mole per cent lysine	pK_A	pK_B	Iso-electric point		$[\alpha]_D$	a_0	b_0	Per cent helix	Helix sense
$Glu_{58}Lys_{42}$	57·8	42·2	4·45	10·97	5·57	37,000	−101	−606	−122	20	Right
$D\text{-}Glu_{57}D\text{-}Lys_{43}$	57·2	42·8	4·35	11·00	5·65	46,000	+90	600	95	15	Left

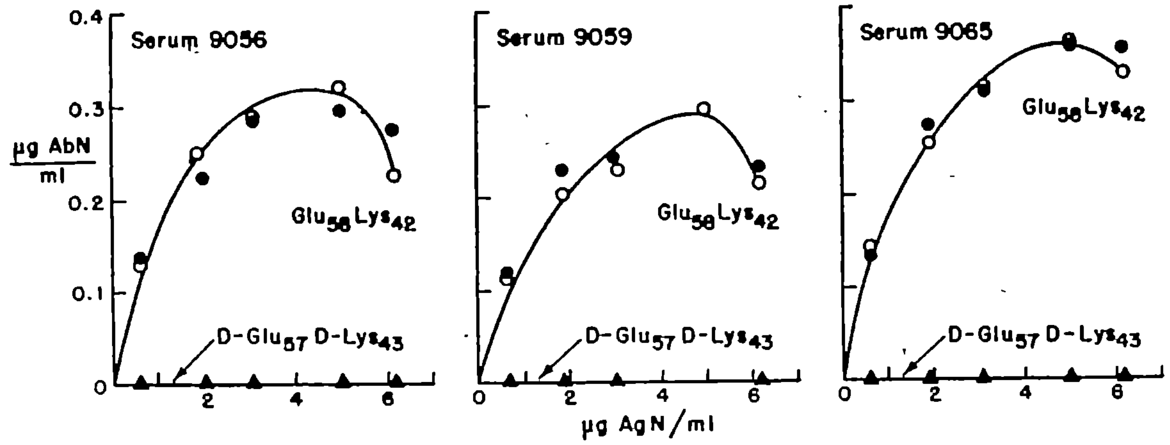

Fig. 1. The reaction of three individual antisera to the L-polypeptide with the L-polypeptide (open circles), the D-polypeptide (solid triangles), and the L-polypeptide in the presence of an equal concentration of the D-polypeptide (solid circles)

Table 2. IMMUNOLOGICAL RESPONSES TO THE OPTICALLY ISOMERIC SYNTHETIC POLYPEPTIDES

Polypeptide	Bleeding I			Bleeding II		
	Animals responding	μg AbN/ml. average	± *S.D.*	Animals responding	μg AbN/ml. average	± *S.D.*
Glu$_{58}$Lys$_{42}$	6/12	13	15	2/8	13	14
D-Glu$_{57}$D-Lys$_{43}$	0/24	0		0/9	0	

peptide, nor did the D-polypeptide inhibit the homologous reaction with the L-polypeptide. Three experiments showing this result are summarized in Fig. 1. In these experiments equal volumes (0·4 ml.) of a solution containing the D-polypeptide at five concentrations and antisera to the L-polypeptide were mixed and allowed to stand at 2° C for five days. At the end of this period the samples were centrifuged and the supernatants decanted. There was no precipitation (solid triangles in Fig. 1). The supernatant (0·6 ml.) and a solution of the L-polypeptide (0·3 ml.), to give a final concentration equal to that of the D-polypeptide, were then mixed and allowed to stand at 2° C for 5 days. The amount of precipitate formed was the same as that obtained when only the L-polypeptide was present (cf. solid and open circles, respectively, in Fig. 1). This result eliminates the possibility that the D-polypeptide reacts with the antisera to the L-polypeptide to form soluble complexes.

The physical and chemical properties of the two polypeptides are very similar. The small compositional differences should not affect the cross-reaction in view of the cross-reactivity between polypeptides with more disparate compositions[4,5]. The molecular weight difference is negligible in view of the cross-reactions between the L-polypeptide (molecular weight = 37,000) and a similar polypeptide of 111,000 molecular weight[10]. The α-helical contents of the two polypeptides are seen to be essentially the same, lying within the accuracy of the determination, although the helical senses are opposite. Finally, the finding that the acid and base dissociation constants and the overall shape of the titration curves are the same indicates that the average distribution of the two amino-acids, that is, the primary sequences, are not grossly different. These considerations demonstrate that the molecules of the two polypeptides are essentially mirror images. Yet one is antigenic and the other is not, and the latter does not cross-react with antisera to the former.

The failure of the cross-reaction leads to the conclusion that the amino-acid side-groups at the spacing characteristic of the peptide chain do not completely determine the antigenic specificity of the polypeptide. Classical studies on the antigenic specificity of proteins have involved modifying the side-groups, and showing that the specificity is changed[11,12]. Indeed, the modification may be the attachment of polypeptides[11,13] or of D- and L-amino-acids[14] to the protein. The present work contrasts with these studies in that the amino-acids in the two polypeptides are the same, but their spacial orientation on the peptide chain is different. Thus, the discrimination displayed by the antibody extends to a section of the peptide chain in combination with its attached groups.

The observation that the D-polypeptide did not elicit antibody production does not at present have a unique explanation. The failure may be either in the sequence of steps leading to antibody production, or in the inability of the γ-globulin chain to fold around the determinant portion of the D-polypeptide. The first explanation includes the possibility that the D-polypeptide cannot be transported to the site of antibody production, or that some prerequisite hydrolysis cannot be performed by the usual enzymes. Some of these possibilities are open to experimental investigation. The second possibility cannot be tested directly, but an exploration with models may offer some test of its validity. Of course, the result is also compatible with the 'selective' hypothesis of antibody formation since the genetic code for antibody directed against the 'unnatural' D-polypeptide would be lacking.

In summary, we have found that the L-amino-acid configuration is essential for a polypeptide to display antigenicity. This suggests that the immune response would not operate against 'proteins' constructed of D-amino-acids, that is, mirror images of those which are normally antigenic. In addition we have demonstrated that the D-polypeptide does not precipitate with antisera to the corresponding L-polypeptide. This failure reveals that the antibody senses the geometrical construction of a region of the peptide chain and not only the amino-acid residues in particular arrangements.

We thank Mr. Heinz Kunz for his assistance. This work was supported by the National Heart Institute (*H*–1771) of the National Institutes of Health and the National Science Foundation (*G*–17556).

DESTRUCTION OF PASTURES BY PARAQUAT AS A SUBSTITUTE FOR PLOUGHING

By A. E. M. HOOD, H. R. JAMESON and R. COTTERELL

Imperial Chemical Industries, Ltd., Billingham Division, Jealott's Hill Research Station,
Bracknell, Berkshire

PARAQUAT (1,1′-dimethyl-4,4′-bipyridylium dichloride) is very active against graminaceous species[1,2]. Because it is rapidly adsorbed by all but the sandiest of soils, and thereby inactivated, it can be used for killing grasses in pastures which may be re-sown immediately without ploughing[3].

To test the use of paraquat for killing swards prior to growing arable crops, two field experiments were carried out at Jealott's Hill. One was permanent pasture followed by winter wheat sown in autumn 1961; the other was three-year ley followed by spring wheat sown in 1962.

Experiment 1. On perennial ryegrass (*Lolium perenne*) dominant permanent pasture, the three main treatments were paraquat (at 3 lb. ion per acre in 24 gallons water containing 0·1 per cent 'Agral' 90) applied on September 19, a similar treatment followed by ploughing on October 7 and a no chemical treatment ploughed on September 12.

On October 12, Hybrid 46 winter wheat was sod-seeded on the first treatment and drilled on the other two treatments.

The three main treatments were duplicated in randomized blocks and each plot was split into four sub-plots, each of 0·016 acre, for nitrogen manuring of the wheat in the spring.

Paraquat completely killed all foliage within seven days. Wild white clover (*Trifolium repens*) and some broad-leaved weeds recovered but were controlled by 'Methoxone' *C* spraying in the spring. Only a few grass plants, mainly meadow foxtail (*Alopecurus pratensis*), rough-stalked meadow grass (*Poa trivialis*), bent (*Agrostis* spp.) and perennial ryegrass, re-appeared on the sprayed/sod-seeded and the no spray/ploughed plots. The plots sprayed before ploughing remained virtually free of weed grasses throughout.

The season was particularly favourable to winter wheat and the rich soil produced outstanding yields with no response to nitrogen fertilizer (Table 1). The sod-seeding treatment was outyielded significantly by both other treatments but still gave a highly satisfactory yield. The seeder used had blunt hoe-type coulters which tore up the turf, made rough furrows and caused patchy establishment.

Table 1. GRAIN YIELDS OF WINTER WHEAT IN CWT./ACRE (ADJUSTED TO 85 PER CENT DRY MATTER)

(1) Sprayed/sod-seeded	55·4
(2) Sprayed/ploughed and drilled	60·7
(3) Not sprayed/ploughed and drilled	58·3
Significant difference (*P* = 0·05)	2·9

Experiment 2. On timothy (*Phleum pratense*)/meadow fescue (*Festuca pratensis*)/white clover ley, the three main treatments were paraquat (as in Exp. 1) on February 19, sod-seeded with 'Jufy I' spring wheat on February 20, paraquat (as in Exp. 1) on February 19, sod-seeded with the same variety on March 13 and no chemical treatment ploughed on February 6 and drilled with the same variety on March 13.

The three main treatments, duplicated in randomized blocks, were each split into three sub-plots of 0·017 acre for nitrogen manuring of wheat in the seed-bed.

All foliage was killed by paraquat within about ten days. White clover and some broad-leaved weeds re-grew, but were controlled by 'Methoxone' Extra spraying.

Germination and brairding of wheat following the February sod-seeding were delayed by cold weather throughout February and March and so any advantage from early sowing in this season was probably less than would be expected in more normal seasons. Final numbers of seedlings on the February or March sod-seeded plots were only about 60 per cent of those on the cultivated plots, possibly due to inadequate tilth in the slit-like furrows made by the disk coulters on the sod-seeder used (which was different from that used in Exp. 1) and to depredations by slugs and other soil pests.

Paraquat killed sown grass species, but had only a temporary effect on couch (*Agropyron repens*), which re-grew over large areas and competed severely with the crop. Ploughing, on the other hand, reduced couch infestation considerably.

Ploughing and drilling in March outyielded sod-seeding at all levels of nitrogen fertilizer application and was also superior to February sod-seeding at 0 and 60 but not at 90 units nitrogen/acre, at which level an inexplicable depression in yield occurred on the ploughed plots (Table 2).

Table 2. GRAIN YIELDS OF 'JUFY I' SPRING WHEAT IN CWT./ACRE (ADJUSTED TO 85 PER CENT DRY MATTER)

	Units fertilizer N/acre		
	0	60	90
(1) Sprayed/sod-seeded February	18·7	28·9	31·4
(2) Sprayed/sod-seeded March	17·2	26·8	26·2
(3) Ploughed/drilled March	27·8	32·0	29·8
Significant difference (*P* = 0·05)		2·0	

Sod-seeding was markedly inferior to conventional practice at the no nitrogen fertilizer-level: this was thought to be due to the effects of competing couch grass particularly in the absence of fertilizer nitrogen rather than to inadequate release of mineralized nitrogen from the uncultivated, dead turf. The advantage from ploughing and drilling over sod-seeding declined with increasing nitrogen rate.

These experiments confirm the suggestion of Arnott and Clement[4] that satisfactory crops may be grown in pastures which, instead of being ploughed and cultivated, have been destroyed by herbicidal sprays; they also point to such practical problems as the design of an efficient coulter for sod-seeding and the control of couch grass and of various soil pests, including slugs, which seem to thrive in unploughed land. Nevertheless, the results of these first experiments are promising for this new technique. As nothing is yet known about the effect of repeated sod-seeding on soil and crops, the present work is being continued. Further experimentation is required to assess the general applicability of this technique in agricultural practice.

NEWS and VIEWS

Association of the British Pharmaceutical Industry :
G. E. Yates

MR. G. E. YATES has been appointed director of the Association of the British Pharmaceutical Industry. Mr. Yates, who is fifty-five, was educated at George Watson's College, Edinburgh, and the University of Edinburgh, taking his M.A. with honours in history. He entered the Home Civil Service in 1931 and served in the Ministry of Health, the Ministry of Home Security, and the Office of the Minister of State in the Middle East. Mr. Yates was a member of the United Kingdom delegations to the United Nations and other international conferences at the end of the War, and, as a delegate to the International Health Conference in New York in 1946, signed the treaty establishing the World Health Organization. He transferred to the Secretariat of the United Nations in 1946; served as secretary of the United Nations Economic and Social Council, and later as senior director in the Department of Economics and Social Affairs. He was executive secretary of many United Nations conferences, including the special commission of the United Nations Economic and Social Council which set up the United Nations expanded programme of technical assistance in 1949 in Geneva, and of the plenipotentiary conference for the Single Convention on Narcotic Drugs, New York, 1961.

Mr. A. Duckworth continues as secretary of the Association of the British Pharmaceutical Industry.

The Public Health Laboratory Service Board :
Prof. J. W. Howie

PROF. JAMES WILLIAM HOWIE has been appointed director of the Public Health Laboratory Service Board in succession to Sir Graham Wilson, who retires from the post in September 1963. Prof. Howie, who is fifty-five years of age, has held the chair of bacteriology in the University of Glasgow since 1951, and is also senior consultant bacteriologist to the Western Infirmary, Glasgow. He is vice-president of the College of Pathologists, and is a member of the Agricultural Research Council. He graduated in medicine at the University of Aberdeen, gaining honours both in his first degree and in his doctorate. He became a lecturer in the Universities of Aberdeen and Glasgow, and then served in the Royal Army Medical Corps during the Second World War as a specialist pathologist in Nigeria and at the War Office. Thereafter he was for five years head of the Department of Pathology and Bacteriology in the Rowett Research Institute, Aberdeen.

The Medical Research Council

IN written answers to questions about the Medical Research Council in the House of Commons on January 29, the Parliamentary Secretary to the Minister for Science, Mr. D. Freeth, stated that in the past five years the Medical Research Council had set up twenty-seven research units and nine research groups, and had also decided to establish a Clinical Research Centre to be linked with the new district hospital to be built at Northwick Park, Harrow. The Council's staff had increased from 2,213 in 1957–58 to 2,772 in 1961–62, its total expenditure on current grants had risen from £201,483 to £481,038, and the number of awards from 138 to 259. This does not take account of support provided for medical research through its research units and groups, training awards and grants for special departmental apparatus. Expenditure on research grants to universities had risen from £201,483 to £561,700.

Psychiatric Research in Britain

IN a written answer in the House of Lords on February 7, the Minister for Science, Viscount Hailsham, stated that the expenditure of the Medical Research Council on psychiatric research had risen successively from £63,000 in 1957–58 to £130,000 (1958–59), £170,000 (1959–60), £228,000 (1960–61) and £247,000 in 1961–62. The money was used during 1961–62 to support the Council's eight psychiatric research units as well as investigations relevant to mental illness being undertaken in other units in social medicine and genetics. It included a special grant to the Institute of Psychiatry, Maudsley Hospital, London; support for five members of the Council's external scientific staff studying problems of mental illness; and nineteen research grants and eleven training awards. More recently the Council had established a research group at King's College, Newcastle upon Tyne, to study the relation between organic and functional mental disorders, and research in psychiatry was also undertaken in university departments and in teaching hospitals with support from the University Grants Committee as well as in the National Health Service.

The Commonwealth Scholarships (Amendment) Bill

AT the Committee stage of the Commonwealth Scholarships (Amendment) Bill in the House of Commons on January 28, the Government was strongly pressed regarding the eligibility for scholarships of those who had not received formal education of university standard, and the Commission was criticized as too strongly representative of the academic outlook. In reply, the Under-Secretary of State for Commonwealth Relations, Mr. J. Tilney, quoted a directive of March 4, 1960, from the Secretary of State for Commonwealth Relations: "Awards tenable at residential colleges of adult education which provide one-year or two-year residential courses may also be considered. These would be especially suitable for students of mature age who have not attended a university". It was therefore open to the overseas countries to nominate non-graduates, but they could not be forced to do so. Other scholarships were available, including those from the British Council. [See also pp. 731 and 752 of this issue of *Nature*.]

The Commonwealth Scholarship Commission

THE third annual report of the Commonwealth Scholarship Commission, covering the year ended September 30, 1962, records a total of 381 scholars in attendance at United Kingdom universities and colleges in the session 1961–62 (Pp. 44. London: H.M.S.O., 1963. 2*s*. 6*d*. net). As expected, more than half the scholars for 1960 applied for extension of tenure of their awards into 1962–63, and accordingly the Commission decided it could not offer more than 209 new awards, for which 396 nominations were submitted. Owing to late withdrawals, only 188 candidates accepted scholarships and the statutory limit of 500 held in 1962–63 was not reached. This limit will be removed under the Bill now before Parliament (see pp. 731, 752 and preceding note). Some 232 applications were received from United Kingdom candidates for awards tenable in eleven different Commonwealth countries, and during the period covered United Kingdom students held Commonwealth Scholarships in nine Commonwealth countries. Four invitations to Commonwealth visiting fellowships for tenure in the session 1961–62 were accepted, but one was afterwards agreed for tenure at a later date. Total expenditure on the Plan in the United Kingdom in the year was £290,000, and the Commission is satisfied that the Plan is making a real and valuable contribution to educational co-operation in the Commonwealth at a high level.

Improving Britain's Overseas Technical Co-operation

In reply to a question in the House of Commons on January 29, the Secretary of Technical Co-operation, Mr. D. Vosper, said that he had reviewed how far Britain's overseas information met the changing needs of the day and had decided to extend the effort in three main ways. First, an increase was proposed in the British Council's English language teaching and training work, including greater use of modern methods. The Council's representation in new and developing Commonwealth and foreign countries would also be strengthened, together with some expansion in Eastern Europe. Secondly, British Information Services in some Commonwealth countries in Asia and Africa would be improved and extended. Thirdly, supplies of television material to the ever-growing number of stations overseas would be increased. This and other changes would involve extra expenditure of about £1 million a year. He also undertook to consider any request from an overseas Government or Governments to send teams of British journalists overseas to conduct short training courses in developing countries if this appeared to be the most suitable way of meeting the need.

Research and Development in Automation

The *B.C.A.C. Record*, 1961–62, published for the British Conference on Automation and Computation through the Institution of Production Engineers, describes the work of the Conference during the past two years. Besides Lord Hailsham's address to the Harrogate Conference on "Automation—Men and Money" in June 1961, it includes the text of the first two Annual Lectures: by Dr. D. C. Christopherson, "Mathematics—Friend or Foe", and by Dr. B. V. Bowden, "Automation—the Next Phase: Can Managers be Automated?". Prof. G. D. S. MacLellan describes the work of a Panel in the field of education and training, and J. E. Coales of a Panel set up to deal with research and development in automation. Copies of the *Record* are available from H. K. Lewis, Ltd., 136 Gower Street, London, W.C.1 (3*s*. 6*d*., postage paid 3*s*. 10*d*.).

The Federal Institute of Industrial Research, Nigeria

The annual report for 1961–62 of the Federal Institute of Industrial Research, Nigeria, covering the initial period of establishment of the Institute, includes a review of the period 1956–62 (Pp. 21 + 6 plates. Lagos: Federal Ministry of Commerce and Industry, 1962. 9*d*. net). The Institute was established to undertake research on all Nigerian raw materials and to develop effective industrial processes by pilot- or large-scale trials if required. About two-thirds of the senior staff posts have now been filled, but less than 60 per cent of the complement of twenty-eight scientists and engineers. The major research project has been the mechanized processing of gavi, a fermented dried meal from cassava, and this has led to the successful development of a pilot-plant producing one ton a day. Other main projects in 1961–62 were on fish drying, leaf proteins, investigations on pulp and paper, solar water heating, plant gums and the utilization of cashew apple. A pilot plant producing one ton of coir fibre a day was set up in a coconut producing area and is now running as a successful commercial venture.

The World Health Organization International Centre for Authentic Chemical Substances

The function of the Centre is to assure the collection, storage and international distribution of chemical reference substances under the authority of the World Health Organization. Recently, the collection of chemical substances available from the Centre has been extended by a set of thirteen substances intended for checking the accuracy of different instruments and methods for determining melting temperatures. The set of World Health Organization melting-point reference substances includes:

	M.p.		M.p.
Azobenzene	69° C	Salophen	192° C
Vanillin	83° C	Sulphapyridine	193° C
Benzil	96° C	Dicyandiamide	210° C
Acetanilide	116° C	Saccharin	229° C
Phenacetin	136° C	Caffeine	237° C
Benzanilide	165° C	Phenolphthalein	263° C
Sulphanilamide	166° C		

The substances are available in a polystyrene plastic package together with a leaflet on "Directions for Use". The following authentic chemical substances are also available:

	Size (g)		Size (g)
Chloramphenicol	0·8	Oestrone	0·03
Digitoxoside	0·05	Progesterone	0·065
Ergometrine maleate	0·02	Tubocurarine chloride	0·03
Melarsen	1	Vitamin A acetate	Five capsules, each containing 0·25 g of a solution in cottonseed oil containing 0·0344 g of vitamin A acetate in each gram of solution. In terms of formerly used International Units, the solution represents 100,000 I.U. per gram.

All the substances are sent free of charge to national administrations or laboratories and institutes working on a non-profit basis. Commercial laboratories are charged 10 dollars (U.S.) or the equivalent amount in other currency per set of melting-point reference substances and 4 dollars (U.S.) per package of the other substances. Orders for the substances should be sent to: WHO International Centre for Authentic Chemical Substances, Apotekens kontrollaboratorium, Box 30019, Stockholm 30. During 1963 the following substances are expected to be issued as authentic chemical substances: cortisone acetate, deoxycorticosterone acetate, dienoestrol, diethylstilboestrol, oestradiol benzoate, ethinyl oestradiol, ethisterone, hydrocortisone, hydrocortisone acetate, liothyronine, methyltestosterone, prednisolone, prednisone and testosterone propionate.

The Zoological Society of London: Awards

The following awards of the Zoological Society of London will be presented by H.R.H. The Duke of Edinburgh, president of the Society, at the annual general meeting on May 16: *Scientific Medal*, to Dr. J. W. L. Beament, of the Department of Zoology, University of Cambridge, for his outstanding work on the detailed physical and chemical study of the insect cuticle and egg shell and the discovery of important general principles concerning water conservation in small terrestrial mammals; and to Dr. N. A. Mitchison, of the National Institute for Medical Research, for his outstanding work on immunology and tissue transplantation; *Stamford Raffles Award*, to Mr. R. E. Moreau, in recognition of his contributions to zoology—as an amateur zoologist, Mr. Moreau has acquired an international reputation as an authority on the birds of Africa; *Thomas Henry Huxley Award*, to Dr. J. Machin, of Queen Mary College, now working at the University of Toronto, for original work submitted as a Ph.D. thesis to the University of London on "The Water Relations of Snail Integument"; *Prince Philip Prize* (open for competition to pupils of zoology, taking the General Certificate of Education Advanced-Level or equivalent examination in any school in Great Britain, Northern Ireland and the Channel Isles and Isle of Man), to Wendy A. Freaker, of St. Swithun's School, Winchester, for her entry, "An Investigation into the Casing Habits of the Caddis-fly Larva, *Limnophilus vittatus*".

The Australian Polarographic Society

The Australian Polarographic Society was founded at the inaugural meeting held at the University of New South Wales on December 3, when the relative merits of an electrochemical and of a polarographic society were discussed. It was agreed that the initial viability of the Society would be enhanced by concentrating the endeavour in such a way that the activities would tend to be of immediate interest to the great majority of members. On this basis, the foundation of a Polarographic Society was preferable at this stage. At a later time, when the Society had proved its viability and value, the prospects for an Electrochemical Society could be reassessed. The objective of the Society is: "To promote the development of polarography in Australia by affording opportunities for contact between those interested in polarography and related fields and by any other means that the Society shall from time to time determine". A Provisional Council has been elected: *President*, Prof. B. Breyer; *Vice-President*, G. S. Buchanan; *Secretary-Treasurer*, J. W. Hayes; *Councillors*, G. H. Aylward, Dr. H. H. Bauer and T. M. Florence. State Representatives are to be co-opted from each State/Territory. Membership is open "to all persons interested in furthering the aims of the Society"; details are available from the secretary-treasurer, Department of Analytical Chemistry, University of New South Wales, Box 1, P.O. Kensington.

The Institute of Mathematical Sciences, Madras

On the occasion of the first anniversary of the Institute of Mathematical Sciences, Madras, announcements were made of two annual visiting professorships entitled: (1) the Niels Bohr visiting professorship; (2) the Ramanujam visiting professorship. The first is a tribute to the memory of one of the creators of modern physics and that of the founder of quantum theory. His interest in the advancement of science in India and in particular the work of the young group of theoretical physicists at Madras was the immediate stimulus for the creation of this Institute. The second professorship is in memory of the Indian mathematician Dr. Srinivasa Ramanujam. Prof. R. E. Marshak, chairman of the Department of Physics and Astronomy, University of Rochester, New York, has accepted the first Niels Bohr professorship in February 1963. The award of the Ramanujam visiting professorship for this year will be announced later.

Sixth International Symposium on Free Radicals

The sixth International Symposium on Free Radicals will be held at the University Chemical Laboratories, Lensfield Road, Cambridge, England, during July 2–5. Papers will be presented by authors from ten countries. The plenary lectures will be given by Dr. R. Livingston (United States), Dr. G. Wilse Robinson (United States) and Prof. J. Weiss (Great Britain). Following the tradition of these meetings, the emphasis will again be on the preparation and properties of trapped radicals, including fluorescence, ultra-violet and electron spin resonance spectra, structural studies and many aspects of reaction kinetics. In addition to the formal sessions, a full programme of social events has been organized, including special entertainment for wives and friends of participants. The symposium will commence with an introductory lecture on the afternoon of July 2, followed by a reception at the Guildhall. Accommodation for men and women will be available in the colleges of the University. Further information can be obtained from Dr. A. B. Callear, Department of Physical Chemistry, Lensfield, Cambridge.

Eleventh International Congress of Applied Mechanics

The eleventh International Congress of Applied Mechanics will be held in the Deutsches Museum at Munich (Germany) during August 30–September 5, 1964. Apart from a number of invited general lectures, the technical sessions of the Congress will be held in two sections: Section 1, mechanics of solids; Section 2, mechanics of fluids and gases. The Congress will, however, not include thermodynamics or numerical methods and computing machines, with the exception of specific applications to pertinent problems of one of the two sections mentioned above. Those persons wishing to present papers to the Congress should submit them to the Programm-Sekretariat des Mechanik-Kongresses, Stuttgart (Germany), Technische Hochschule, Institut für Mechanik, before February 1, 1964 (except that by arrangement with the U.S. National Committee on Theoretical and Applied Mechanics, contributions from the United States will be by invitation, and likewise with the exception of papers submitted by the authors from the U.S.S.R., for which a special arrangement has been made with the U.S.S.R. National Committee on Theoretical and Applied Mechanics). Further information can be obtained from the Organisations-Secretariat des Mechanik-Kongresses, München 2 (Germany), Institut für Mechanik, Arcisstrasse 21.

Naturally Occurring Peptides, Peptide Antibiotics, Proteins and Nucleoproteins

Prof. K. T. Yasunobu and L. K. Ramachandran have written to the Editor stating that they are compiling data on the physical, chemical, functional and structural properties of: (*a*) naturally occurring peptides; (*b*) proteins and nucleoproteins; (*c*) enzymes. They anticipate eventual publication of the data in the form of a book, and ask for any pertinent data to be forwarded for them at the Department of Biochemistry and Biophysics, University of Hawaii, Honolulu, Hawaii.

Announcements

Dr. T. H. Benzinger, director of the Bio-Energetics Laboratories of the Naval Medical Research Institute, National Naval Medical Center, Bethesda, has been awarded the Golden Scheele Medal of the Chemical Society of Stockholm, for his work on "Calorimetric Analysis of Chemical Change".

The sixth International Mineral Processing Congress will be held in Cannes during May 26–June 2. Further information can be obtained from the Sixth International Mineral Processing Congress, 28 rue Arthur-Rozier, Paris XIX^e.

A conference on "Inert Gas Compounds" will be held at Argonne National Laboratory during April 22–23. Further information can be obtained from Herbert H. Hyman, Argonne National Laboratory, 9700 South Cass Avenue, Argonne, Illinois.

The fifth International Conference on Coal Science will be held in Cheltenham, Gloucestershire, during May 28–30. Further information can be obtained from Mr. R. G. J. Kingsmill, National Coal Board Research Establishment, Stoke Orchard, near Cheltenham, Gloucestershire.

The South African National Conference on Nuclear Energy will be held in Pretoria during April 8–11. The main object of the meeting is to make a survey of isotopes and radiation research in South Africa and its future. Further information can be obtained from the Atomic Energy Board, Post Bag 256, Pretoria.

An international symposium on "Humidity and Moisture—Measurement and Control in Science and Industry", sponsored by the National Bureau of Standards, the United States Weather Bureau, the Instrument Society of America, the American Meteorological Society and the American Society of Heating, Refrigerating and Air Conditioning Engineers, is to be held in Washington during May 20–23. Further information can be obtained from Mr. A. Wexler, National Bureau of Standards, Washington 25, D.C.

THE SECOND COMMONWEALTH EDUCATION CONFERENCE

THE brief report of the Second Commonwealth Education Conference*, held at New Delhi during January 11–25, 1962, is accompanied by various annexes. To three of these—the reports of the committees set up by the Conference to study and made recommendations on the Commonwealth Scholarship and Fellowship Plan, the training and supply of teachers, and technical education and the provision of text-books and other books—reference is made elsewhere (see p. 731 of this issue of *Nature*). Others comprise the reports of committees dealing with social education, with education in rural communities, and with financial problems of educational expansion. A further annex details the composition and functions of a Commonwealth Education Liaison Committee and a Commonwealth Liaison Unit.

The Conference was encouraged by the progress already made since the first Conference at Oxford in 1959, particularly under the Commonwealth Scholarship and Fellowship Plan and in the further training of teachers from the newer Commonwealth countries. Notable was the progress under the Bursary Scheme introduced by the British Government. It was agreed that in the years ahead the main emphasis should be placed on the further development of the schemes for the supply and training of teachers and for the further training of those who are to occupy key posts in developing educational systems. However, some of the developing countries were quite clear that scholarships at undergraduate level and awards in professional, technical and other fields would meet their present needs more effectively than awards at post-graduate level. The Conference decided that arrangements established tentatively at Oxford to facilitate Commonwealth co-operation in education should be confirmed as appropriate for constructive use by Governments.

It was recommended that a Commonwealth information centre on the teaching of English as a second language should be established in London, and that the establishment of regional English language centres closely linked with universities and training colleges be given urgent attention. Development of the practice and techniques of social education is at different stages throughout the Commonwealth, and any programme of social education requires the active support of Government, voluntary organizations and voluntary community leaders. Voluntary organizations, above all, must have adequate facilities to play their part effectively. Social education should receive high priority in educational development programmes.

The problems of rural education in different parts of the Commonwealth have much more in common than differences of latitude, climate or history might suggest. Although it is necessary first to establish the generally desirable objects of rural educational policy, even at this early stage recommendations are warranted concerning the systematic exchange of information, arrangements of visits by experts, conferences of experts on matters of common interest, etc. Agricultural education should be considered as a part of technical or vocational education as a whole and not treated in isolation.

Financial problems of educational expansion were not discussed quantitatively, but the Committee considering this aspect recommended that countries requiring assistance in respect of capital or recurrent expenditure for educational expansion should seek it through bilateral arrangements. Close attention should be given to educational planning to secure the most effective use of the available funds and every effort made to assure the interest of the community.

There is thus wide scope for co-operation among Commonwealth countries. This is especially so in meeting the major needs of the various countries in respect of educational and training opportunities, the supply of teachers, particularly in science and mathematics, and of specialists in technical and higher education, and the supply of specialized equipment and text-books.

SCIENTIFIC RESEARCH IN BRITISH COLONIAL TERRITORIES

ALTHOUGH reduced in scale and scope, *The Colonial Territories, 1961–62**, now compiled with the help of the Department of Technical Co-operation, continues on similar lines, but there is a marked absence of information of particular interest to the scientist or technologist. Here, as elsewhere, a close veil is drawn over all research work proceeding overseas, and only in the short notes on technical and higher education and on medical and health services are matters of primary interest mentioned.

Campaigns against malaria and yaws have in some territories reached the stage at which maintenance services can be established and more attention devoted to problems of environmental sanitation in rural areas. Rural water supply and sanitation schemes continued in Kenya with aid from the World Health Organization and United Nations Children's Fund so satisfactorily that it is planned to extend these activities to other areas. Although little progress was made in providing facilities for the mentally ill, problems of mental health were more prominent. Dental health services steadily developed. Malaria and tuberculosis continued to be major preoccupations in many territories, but in some very substantial progress was made towards control and eradication of malaria, and although leprosy continued to be a serious problem in certain territories there was some evidence of reduced incidence. Following active eradication campaigns the importance of yaws has greatly declined in most territories, but trypanosomiasis is a continuing threat necessitating consistent and careful measures, and the report indicates the extent to which preventive medicine in industry and health education offer opportunities for expansion and assistance.

Enrolment at universities continued to increase and reached 1,600 at Hong Kong and 1,257 at the University College of the West Indies. A provisional council has been set up for the proposed University of East Africa, and to meet the urgent need for veterinary practitioners in East Africa, improved facilities for veterinary education are being developed near Nairobi, and responsibility for the new veterinary faculty is being transferred from the Makerere University College to the Royal College, Nairobi.

THE BRITISH SOCIETY FOR THE PHILOSOPHY OF SCIENCE

THE seventh annual conference of the British Society for the Philosophy of Science was held during September 21–23, in Tetley Hall, University of Leeds. It comprised a colloquium of four symposia and was attended by some sixty members and guests. Mr. F. T. C. Harris of Middlesex Hospital Medical School was conference secretary.

The four symposia were entitled: "The Idea of a Physical Quantity", "Fundamental Particles and Identity", "Kant's Regulative Principles and their application to Science", and finally, "The Nature of Law in Social Science". In conformity with the Society's usual practice each symposium heard two papers and then entered into a discussion of them.

With the Society's president, Prof. R. B. Braithwaite, in the chair, Dr. J. R. Ravetz (University of Leeds) introduced the first symposium with a historical paper "Galileo and Physical Quantities", which discussed the belief in the existence of physical quantities and the problem of assigning measures to these quantities. Dr. Ravetz claimed that the first of these was an essential assumption in Galileo's investigations, while the second is necessary for the construction of a fruitful natural philosophy. There followed an inquiry into the relationship between the concepts of 'quality' and 'quantity' in which the speaker, Dr. H. V. Stopes-Roe (University of Birmingham), argued that the former concept included the latter. For example, the quality brightness can be given a measure and so construed as a quantity. Gallileo's idea of fundamental individual quantities was claimed by Dr. Ravetz to be inadequate, leading Galileo away from the formulation of a coherent approach to units and thus away from numerical results. On the other hand, Dr. Stopes-Roe suggested that Fourier's approach to this problem similarly failed to treat the unit satisfactorily. He went on to suggest that the concept of quantity should be taken as basic and combined with a liberal approach to the analysis of the concept 'quantity'.

Dr. C. W. Kilmister (King's College, London) took the chair at the second symposium, the first paper of which was a very thorough survey by Dr. H. R. Post, of the Chelsea College of Advanced Technology. Dr. Post explained that elementary particles of one type had no individuality. It was a fallacy to derive this non-individuality from Heisenberg's Principle. In fact it derived from the nature of the theoretical structure of quantum mechanics. Fundamental particles are without 'secondary qualities', he insisted, and their lack of individuality derives less from their ontological status than from their high level of abstraction.

In the second paper Dr. E. W. Bastin (King's College, Cambridge) took the point of view of ontological realism. He argued that in electron spin one had a property which was uniquely identifiable, but must, of course, be attributed to individual events, particles, which existed as such. In discussion Prof. Braithwaite and Dr. Kilmister took the side of Nature, the latter with currently new empirical data.

Prof. S. Korner was chairman at the third symposium, which was opened by Mr. Jonathan Bennett with an argument directed to disproving Kant's view that a science in which some generalizations have exceptions is intellectually disreputable. Contrary to this, Mr. Bennett held that the scientist must qualify his generalizations if he is to avoid confusion. Mr. Bennett explained a 'regulative principle' as one that had no other justification than its utility. Thus, standing unanalysed, it bears comparison to a logical axiom. The Kantian view that everything has a cause is just such a principle. Mr. Bennett went on to show that Kant's claim that the principle of causation had such a status is in fact at variance with that writer's attempted proof elsewhere, of that very same principle: but under the name 'the second analogy from experience'. Entirely to the contrary, Dr. G. Buchdahl (The Whipple Museum, Cambridge) accepted Kant's distinction between a general principle of causation and a 'regulative' principle of determinism. He held that, of the two versions of the deterministic principle discussed by Mr. Bennett, only the first is truly regulative and it is this version that permits the law-like nature of empirical generalization. The chairman introduced the discussion and directed attention to the philosopher's distinction between logical implication and nomical implication, or implication reflecting things as they are. He pointed out that Kant did not regard Newtonian physics as a regularity which happened to be observed, but did in fact believe it to be true. As Prof. Korner remarked, "The opus of great philosophers is a kind of philosophical Rorschach test".

The discussion of the final symposium was carried out under the guidance of Mr. J. W. N. Watkins (London School of Economics). The symposium opened with a paper by Mr. J. G. H. Newfield (London School of Economics), which criticized the views expressed in Mr. P. G. Winch's *The Idea of a Social Science and its Relation to Philosophy* (London, Routledge and Kegan Paul, 1958). Mr. Newfield argued that to criticize sociology by means of *a priori* philosophical criteria was to make a category mistake. For example, it was not a prerequisite for sociology that sociologists study the language of their science, a test procedure for laws was simply to distinguish between their valid and invalid applications and this did not necessarily involve formulating the law. Mr. P. G. Winch (University of Wales) argued that the Humeian position taken by the previous speaker was fully answered by Kant, and it was this philosopher that Mr. Winch followed. It was not the case that regularities were first observed and then logic entered the field. It was more cogent to argue that the observation of empirical regularities was only possible within a preconceived frame-work of order, which was an argument in accord with the hypothetic-deductive point of view of Prof. K. R. Popper. Mr. Watkins agreed with the second speaker that phenomena arise from language. He also argued that Mr. Winch's approach did not admit of social criticism in that it had not been equipped with a metalanguage. Prof. W. C. Kneale, the president-elect, took up a point concerning the reducibility of sociological concepts to dispositional statements about individuals. He pointed out a fundamental difference between the reduction of a behavioural science, sociology, to psychology, and of a physical science, chemistry, to physics, in that the former reduction would have to embrace two different conceptual schemes. For example, it was not possible to describe the spread of economic consumption in psychological terms.

In his closing address the president of the Society, Prof. R. B. Braithwaite, thanked the conference secretary and Mr. B. C. Brookes, University College, London, for their efforts on behalf of the conference, the warden of Tetley Hall, Miss E. M. McAlpine, for the care taken by her staff and herself for the comfort of the participants and the Department of Biology as Applied to Medicine, Middlesex Hospital Medical School, for secretarial assistance.

D. G. HARRIS
F. T. C. HARRIS

EDUCATION OF SCIENTISTS AND TECHNOLOGISTS FOR THE NEW AGE

IN his presidential address to the Science Masters' Association in Manchester on January 2, Dr. B. V. Bowden, pointing out that Britain is already spending more than £800 million a year on education, or 4 per cent of the gross national product, questioned whether all this money was being spent properly, efficiently and on the right things, and whether enough or too much was being spent. In this context, he challenged strongly the meagre expenditure of about £20,000 in 1962 by the Ministry of Education to investigate the efficiency of educational progress. Even making the most generous allowance for expenditure by university departments of education, he doubted whether Britain's expenditure on educational research reached £250,000 a year, and while he valued the impetus from the United States and the initiative and generosity of the Nuffield Foundation, most of the research into new syllabuses and text-books had still to be done. Education was, he thought, as profitable an investment as was open to any nation to-day, and this was especially true in respect of education in the under-developed countries.

Challenging next the belief of many schoolmasters that the universities provide courses in technology for boys who have no aptitude for science, Dr. Bowden, noting that science began in an attempt to solve practical problems and paying tribute to Sanderson's work at Oundle, insisted that science was much more than a body of knowledge; it was a way of life, a way of thought, and at its best only understood by active practitioners. He was concerned that so many of Britain's ablest schoolboys were interested in science but not in technology and engineering. While a successful engineer or technologist must know his science and be able to work with people, even to lead them, it was vital that schoolmasters should strive to persuade more of their pupils to take up the life of the creative technologist rather than that of the scientist. Few boys, in fact, even understood that technologists could be trained at a university. Finally, he thought there was room for a huge programme of research into methods of teaching and the possible effect of new techniques based on modern technology, including the study of the processes of learning and the use of television and films.

The full text of Dr. Bowden's address will be published in the March issue of *The School Science Review*, published by the Science Masters' Association.

RHEOLOGY OF MOTOR OILS

AT the meeting of the Cambridge Rheology Club held on October 29, Mr. J. F. Hutton ('Shell' Research, Ltd.) spoke on "The Rheology of Motor Oils". He started by describing briefly the manufacture of lubricating oils from crude petroleum, continued with a discussion of lubricating oils as Newtonian liquids, and ended with a description of experimental work which has shown that lubricating oils, which are generally regarded as Newtonian liquids, can exhibit non-Newtonian effects and behave as visco-elastic liquids at very high rates of shear.

The most important property of a lubricating oil is its viscosity and the temperature of the oil is the external factor which has the greatest influence on viscosity. A rise in temperature of 1 deg. C causes a decrease in viscosity of the order of 5 per cent. It is desirable that the dependence of the viscosity of an engine lubricating oil on temperature should be reduced and this is achieved primarily by suitable refining. An additional reduction is obtained by dissolving in the oil about 1–3 per cent of a polymer having a weight-average molecular weight of $1–5 \times 10^5$. The most effective type of polymer is a copolymer made from oil soluble and oil insoluble monomers and so designed that its intrinsic viscosity, or thickening effect, increases as the temperature increases.

Addition of a polymer to an oil introduces non-Newtonian properties which, being of importance in lubrication, have been studied by many workers. However, in the short time available, Mr. Hutton chose to talk about the more interesting problem, from the point of view of liquid structure, of non-Newtonian effects in lubricating oils not containing polymers. The detection and measurement of such effects in capillary or Couette viscometers is a most difficult undertaking. Rates of shear greater than 10^5 sec^{-1} are necessary, and in this range it is difficult to separate true shear rate thinning from a fall in viscosity due to viscous heating. A different approach to the problem has been made, notably by J. Lamb and A. J. Barlow, who, from measurements of the propagation of ultra-sonic shear waves through the oils have calculated their relaxation spectra. The results clearly demonstrate the visco-elastic nature of lubricating oils and indicate that the peaks in the spectra are characteristic of the types of molecule present.

In the discussion the comments and questions ranged widely from technological ones concerning the best oil to use in a motor-car to more fundamental ones concerning heating effects in viscometry and the relation between experiments carried out in continuous shear and experiments carried out in oscillatory shear.

The next meeting of the club will be held on March 4 at the Technological Research Station, Spillers, Ltd., Station Road, Cambridge, when Mr. G. G. Zahler and Mr. G. R. Murfitt (Instron, Ltd.) will speak on "The *Instron* High Shear Capillary Rheometer". H. G. MULLER

THE FISHERIES BIOCHEMICAL RESEARCH UNIT

FOR some years the U.K. Development Commission has sponsored a Unit for Biochemical Research bearing on the problems of fisheries, and at present located within the National Institute for Research in Dairying, Reading. In view of the retirement of the honorary director, Dr. S. K. Kon, within the next few years, the Development Commission has decided that it should be transferred to Aberdeen. The advantages of this new location are that the reconstituted Unit will be in close contact with the fishing industry, the University and the existing marine research institutes in Aberdeen. These are the Scottish Department of Agriculture and Fisheries Marine Laboratory and the Torry Research Station of the Department of Scientific and Industrial Research.

After consultation between the Development Commission and the University of Aberdeen, it was agreed that the Unit should be established within the University under the ægis of the professor of biological chemistry, Prof. W. O. Kermack. It is envisaged that initially the staff would consist of five scientific workers, including a director, who would be a reader in the University, and that members of the staff might take some part in the teaching activities of the University, although their primary obligation would be towards research. By this arrangement, the integration of research and advanced teaching would be assisted, and a mutually stimulating relationship established between the staff of the Unit and their colleagues in the University.

The two existing marine laboratories in Aberdeen deal respectively with the scientific and technological problems concerned with living fish in the sea, and with those involved in the storage and processing of fish in the period between catching and marketing. The object of the Fisheries Biochemical Research Unit will be the investigation of the fundamental biochemistry of both marine and freshwater fish. Although the emphasis will be on the basic scientific aspects, it is envisaged that this work will assist in the solution of problems of practical importance to the fishing industry.

It is proposed to plan and build a new laboratory to house this Unit in close proximity to the existing marine laboratories at Torry in Aberdeen. In order to facilitate this development, the Court of the University of Aberdeen has appointed Dr. P. T. Grant to the post of director of this Unit. Dr. Grant is at present a member of the staff of the Department of Biological Chemistry. It has been arranged that this appointment will become operative at a later date, but meanwhile he will be directly concerned with the planning and equipping of the new laboratory.

Dr. Grant was a member of the staff at the National Institute for Medical Research during 1951–56 and worked with Sir Charles Harington and Dr. H. R. V. Arnstein on the biosynthesis of penicillin, and afterwards with Dr. J. D. Fulton on the comparative biochemistry of pathogenic protozoa. Since he has been in Aberdeen he has worked on the enzymology of the protozoa and in particular has been concerned with the components and mechanism of the unusual respiratory enzyme systems present in the *brucei* group of pathogenic African trypanosomes. He has also been interested in the isolation and biosynthesis of mucopolysaccharides present in connective tissue.

POSITIONS OF THE OXYGEN ATOMS IN $UO_{2 \cdot 13}$

By B. T. M. WILLIS

Metallurgy Division, Atomic Energy Research Establishment, Harwell

URANIUM dioxide, UO_2, can dissolve oxygen at high temperatures to form the single phase UO_{2+x}, where x assumes any value in the range $0 \leqslant x \leqslant 0 \cdot 25$. For $UO_{2 \cdot 10}$ the temperature must exceed 600° C and for $UO_{2 \cdot 25}$ the minimum temperature is about 1,050° C (ref. 1).

Neutron diffraction investigations have been made on a single-crystal of composition $UO_{2 \cdot 13}$ with the aim of determining the positions of the oxygen atoms. The ratio of the slow neutron coherent scattering amplitudes of uranium and oxygen is 1·47, so that, unlike for X-rays, an appreciable proportion of the scattered intensity comes from oxygen. However, we must distinguish between oxygen atoms present in the UO_2 crystal before oxidation and 'extra' oxygen atoms; as the former predominate, the location of the extra atoms is analogous to a light-atom determination with X-rays. In these circumstances very accurate neutron structure-factors are required, and it is necessary to correct the observed intensities for extinction (affecting the strong reflexions) and double-Bragg scattering (mainly affecting the weak reflexions).

All non-equivalent *hkl* planes with an interplanar spacing greater than 0·53 Å were measured at 800° C, inside the single-phase region of the phase diagram. No reflexions were observed other than those with *h*, *k* both odd or both even, and so it was assumed in the analysis by least-squares and Fourier methods that the space-group is *Fm3m*, as for UO_2.

Table 1 summarizes the results of the least-squares analysis, which was carried out using a *Mercury* computer programme specially written for this work by Dr. J. S. Rollett. The oxygen atoms in $UO_{2 \cdot 13}$ occupy three different kinds of crystallographic site, and, as there are more equivalent positions for each site than oxygens to fill them, the oxygens are distributed at random among these positions. The programme allowed as adjustable parameters the probability of occupation of each atomic site, as well as the atomic co-ordinates and temperature factors. Altogether 11 parameters were obtained from 33 independent data, and the final 'discrepancy factor' $(\Sigma||F_{obs}| - |F_{calc}|| \div \Sigma|F_{obs}|)$ was 2·2 per cent, which is close to the estimated accuracy of the individual data.

Table 1. CRYSTAL STRUCTURE OF $UO_{2 \cdot 13}$

Atom	Unit cell co-ordinates	Contribution to formula unit U_mO_n		Temperature factor B (Å²)
Uranium	0 0 0...	$m =$	1·00 (0·01)	1·18 (0·06)
Oxygen O	u u u...		1·82 (0·02)	1·45 (0·08)
Oxygen O′	0·5 v v...	$n =$	0·08 (0·05)	1·8 (1·6)
Oxygen O″	w w w...		0·23 (0·11)	7·5 (2·7)

($u = 0 \cdot 267$ (0·001), $v = 0 \cdot 39$ (0·01), $w = 0 \cdot 38$ (0·01). Space group *Fm3m*. Standard deviations of parameters in brackets.)

The principal conclusions from Table 1 are as follows:

(1) The composition determined from the scattering results is $UO_{2 \cdot 13}$ in agreement with that found chemically. A more complete expression for the formula unit is:

$$U_{1 \cdot 00}O_{1 \cdot 82}O'_{0 \cdot 08}O''_{0 \cdot 23}$$

where O, O′, O″ refer to oxygen atoms in the three kinds of site.

(2) The uranium atoms occupy the face-centred positions 000, $\frac{1}{2}\frac{1}{2}0$, $\frac{1}{2}0\frac{1}{2}$, $0\frac{1}{2}\frac{1}{2}$, and all these sites are filled, as in UO_2.

(3) The O atoms at uuu . . . are close to the fluorite positions $\frac{1}{4}\frac{1}{4}\frac{1}{4}$ . . . , but are shifted slightly along <111> towards the interstitial holes at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ . . . (the $\frac{1}{2}\frac{1}{2}\frac{1}{2}$, $\frac{1}{2}00$, $0\frac{1}{2}0$, $00\frac{1}{2}$ positions are the largest holes in the UO_2 lattice). The O atoms represent approximately nine out of ten of the original oxygens in UO_2 before oxidation to $UO_{2 \cdot 13}$; the remaining one-tenth are transferred during oxidation to O′ or O″ positions.

(4) The interstitial atoms O′ and O″ do not occupy the large interstitial holes at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ . . . , but positions about 1 Å away.

Fourier analysis confirms the least-squares results. Fig. 1 is a Fourier projection, based on a Fourier series with the F_{obs} data as coefficients, showing the uranium and oxygen O atoms. Fig. 2 is a difference Fourier projection, using $F_{obs} - F_{UO}$ as coefficients, where F_{UO} is calculated for the uranium and O atoms only. The contours in Fig. 2, which are on a much finer scale than in Fig. 1, show peaks representing the O′ atoms at 0·5 vv . . . and O″ atoms at www . . . .

The least-squares and Fourier results, based on an analysis of the coherent Bragg reflexions only, give the contents and atomic co-ordinates of the average unit cell of the disordered compound: they do not define the local atomic arrangement. However, a plausible interpretation in terms of the local relaxation around an isolated interstitial atom is as follows. This interstitial atom enters the lattice at the O′ position 0·5 0·4 0·4; to maintain charge balance the two nearest U^{4+} ions at $\frac{1}{2}\frac{1}{2}0$ and $\frac{1}{2}0\frac{1}{2}$ are converted to U^{5+}, and the polarizing influence of these U^{5+} ions prevents the interstitial atom occupying the hole at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$. The two nearest oxygens at $\frac{1}{4}\frac{1}{4}\frac{1}{4}$ and $\frac{3}{4}\frac{1}{4}\frac{1}{4}$ are then displaced along <111> to O″ positions and oxygens further out relax a much shorter distance along <111> to O sites at *uuu* . . . . The large 'temperature factor' of 7·5 Å² for the O″ atoms is to be ascribed to the disorder accompanying the relaxation of the nearest-neighbour oxygens.

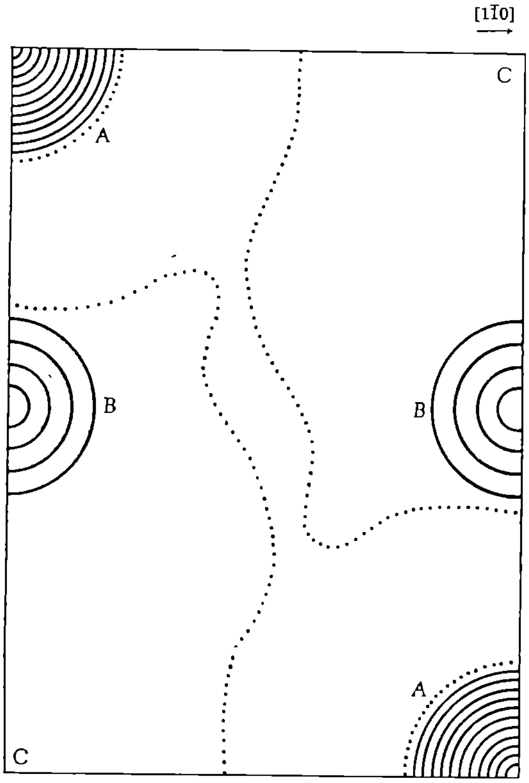

Fig. 1. Fourier projection along [110] of nuclear density of $UO_{2\cdot 13}$ at 800° C. Peaks at *A* represent the uranium atoms at 000 . . . and peaks at *B* the oxygen atoms O at 0 27 0 27 0 27 . . . The interstitial holes are at *C*. Zero contours dotted

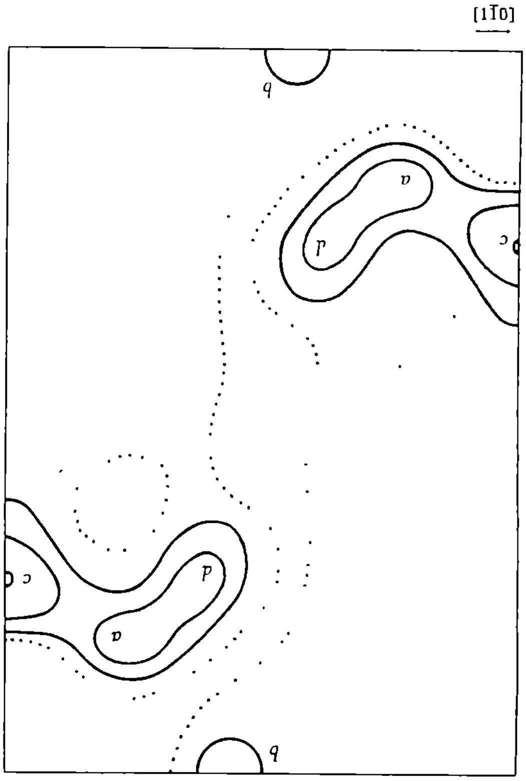

Fig. 2 Fourier projection along [110] with contributions from uranium and oxygen atoms O removed. Interval between contours is one-sixth of that in Fig. 1. Peaks at *a*, *b* represent oxygen atoms O′ at 0 5 0 4 0·4 . . . and peaks at *c*, *d* oxygen atoms O″ at 0,4 0 4 0·4 . . .

ULTRA-VIOLET-ABSORBING COMPOUND(S) REPORTED PRESENT IN THE MURRAY METEORITE

By PROF. J. ORÓ

Lawrence Radiation Laboratory, University of California, Berkeley, California, and Chemistry Department, University of Houston, Texas

PRELIMINARY investigations[1–9] have shown that when a water extract of the Murray meteorite is applied to a column of 'Dowex 1' resin and eluted with water or with 0·05 N hydrochloric acid, the eluates contain ultra-violet-absorbing compound(s).

Since some ion-exchange resins are known to yield water-soluble ultra-violet-absorbing substances[10] the investigations reported here were undertaken to ascertain whether the compounds detected in meteorite extracts are indigenous to the meteorite or are the result of contamination by the analytical technique used. These show that the ultra-violet spectra obtained from meteorite extracts passed through 'Dowex 1' and the spectra given by blank eluates from 'Dowex 1' are essentially identical. Observations concerning the presence of similar water-soluble ultra-violet-absorbing substances in 'Dowex 2' resin are also described.

The observations made by Vaughn[1–4] on the water extract from the Murray meteorite can be summarized as follows:

(1) The spectrum obtained directly with the water extract of the meteorite showed no maxima in the ultra-violet region. A uniform absorption at the short wave-length end of the spectrum and a very weak shoulder in the 260–280 mμ region were only observed[1,2].

(2) No peak was found in the ultra-violet spectrum of the distillate obtained at 300° C in vacuum from the dry residue of the water extract[1].

(3) When the water extract was applied to a 'Dowex 1' column and the column eluted first with water and then with 0·05 N hydrochloric acid, a small amount of ultra-violet-absorbing material was observed to emerge with the water eluate and a larger amount with the acid eluate.

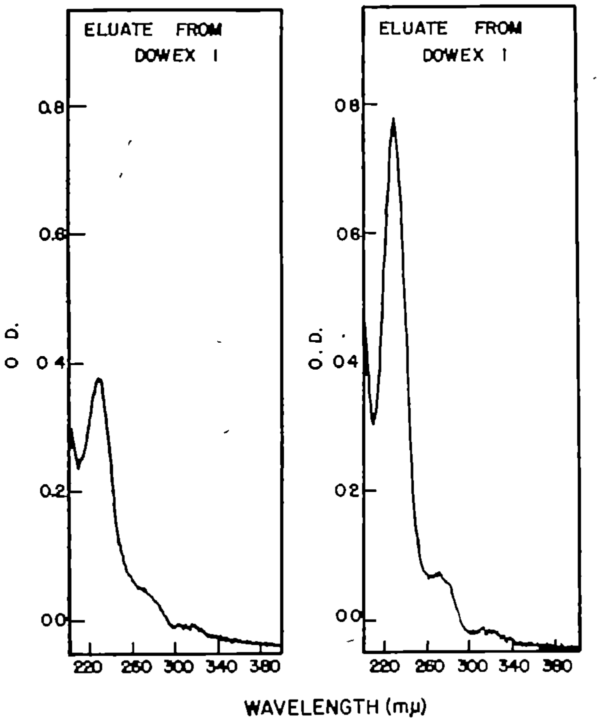

Fig. 1. Ultra-violet absorption spectra of blank eluates from columns of 'Dowex 1' resin (Cl^- form). The eluates were obtained with 0·1 N hydrochloric acid at room temperature (left) and at 90° C. (right)

(4). The ultra-violet-absorbing spectra of the eluates, in particular of the acid eluate rechromatographed a second time through 'Dowex 1', showed at *p*H 2 two absorption peaks, a strong one with a maximum at about 230 mμ and a smaller one with a maximum at about 273 mμ (refs. 2 and 3) (the maxima from the water eluate and from the first acid eluate were less well defined, yet in agreement with the above maxima).

(5) At neutrality and under basic conditions (*p*H 9–10) the 230 mμ maximum shifted towards shorter wave-lengths (about 222 mμ) while the 273 mμ maximum was very much decreased and in some cases disappeared.

(6) The ultra-violet spectrum in the region 290–250 mμ, observed in CCl_4 and benzene extracts of the meteorite, was found to be caused by the presence of elemental sulphur[4].

The 'Dowex 1' ion-exchange resin which I used was obtained from a source identical to that of the resin that had been used previously in the meteorite investigations.

A small column (5 c.c.) of 'Dowex 1' (200–400 mesh, × 8, Cl^- form) was eluted with 10 ml. 0·1 N hydrochloric acid at room temperature. The ultra-violet spectrum of the eluate was recorded in a Cary spectrophotometer (Fig. 1, left). Alternatively, an acid eluate of the same resin was obtained by passing 10 ml. of hot (90° C) 0·1 N hydrochloric acid through a small column (1 c.c.) of 'Dowex 1'. The ultra-violet spectrum of the eluate is shown in Fig. 1 (right). A strong absorption peak at about 230 mμ and a smaller one at about 273 mμ can be observed in the two spectra.

The relatively larger ultra-violet absorption of the eluate obtained at 90° C compared with that obtained at room temperature indicates that the extraction of the ultra-violet-absorbing material from the resin is enhanced by the hot acid.

Elution of the same ultra-violet-absorbing material was also observed from samples of resin which were extracted with ether, regenerated with saturated sodium bicarbonate, washed with distilled water and finally eluted with 0·1 N hydrochloric acid. Fig. 2 shows the spectrum of one such eluate. The fact that this ultra-violet-absorbing material is present after regeneration of the resin indicates that the ultra-violet-absorbing compounds are released from the inside of the resin beads. This observation is also in line with the results obtained in the extraction with hot acid.

Since 'Dowex 2' ion-exchange resin might be used in similar analytical applications, the presence of ultra-violet-absorbing compounds in the acid eluates from this resin was also examined.

A small column (5 c.c.) of 'Dowex 2' (200–400 mesh, × 8, OH^- form) was eluted with 10 ml. of 4 N acetic acid.

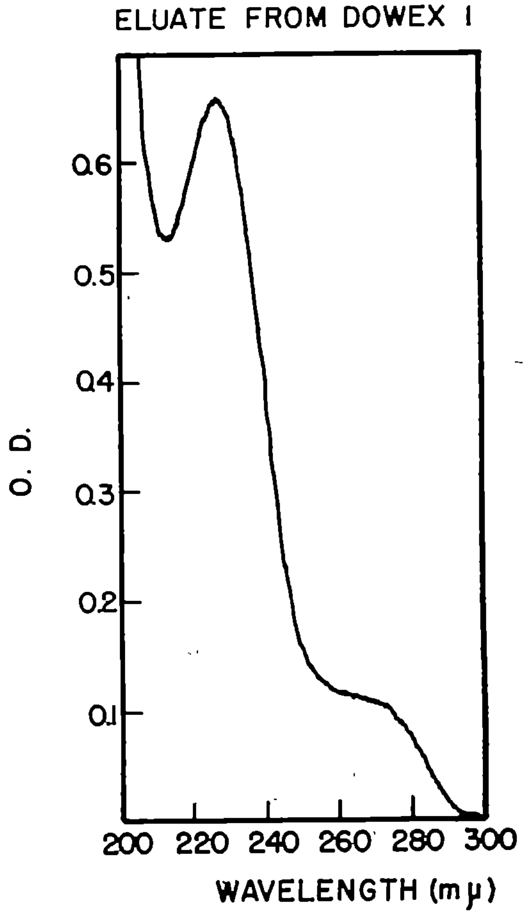

Fig. 2. Ultra-violet spectrum of a 0·1 N hydrochloric acid eluate from a column of 'Dowex 1' resin. The resin has been extracted previously with ether, treated with saturated sodium bicarbonate and washed with distilled water. (Data provided by, Dr. J. Ullrich)

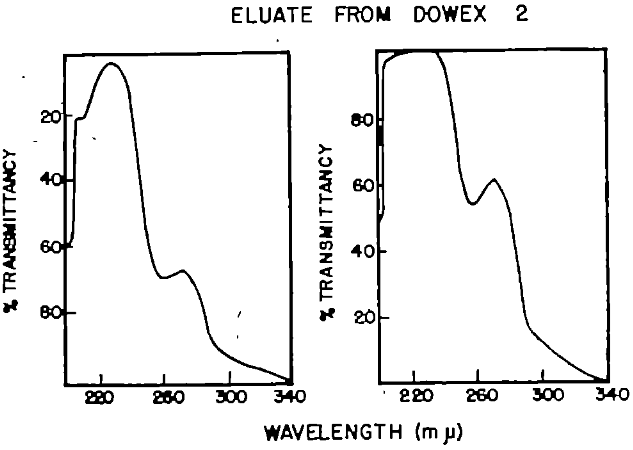

Fig. 3. Ultra-violet absorption spectra of a 4 N acetic acid eluate from a column of 'Dowex 2' resin (OH^- form). The acetic acid was evaporated and the residue dissolved in 0·1 N hydrochloric acid. (Spectra obtained by L. Engberg)

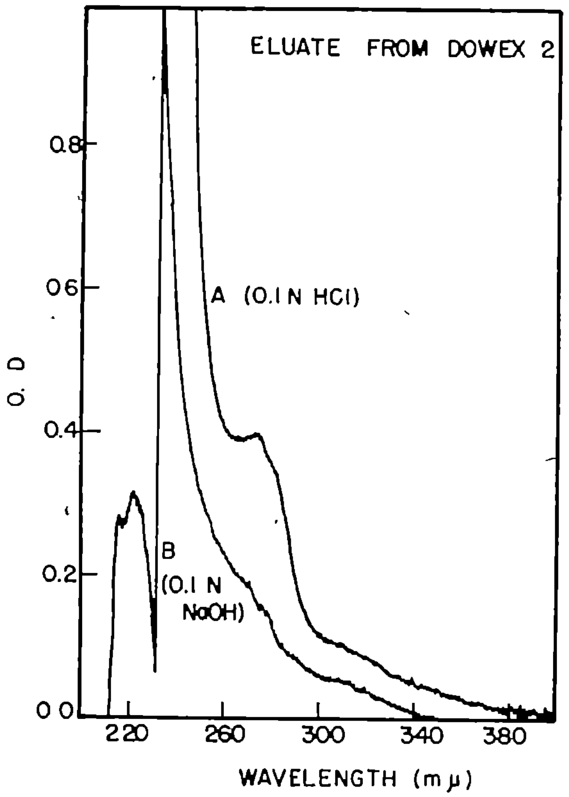

Fig. 4. Spectrum of a 0·1 N hydrochloric acid eluate from a column of 'Dowex 2' resin (curve *A*) and spectrum of the same eluate after it was made 0·1 N basic with sodium hydroxide (curve *B*)

After evaporation of the acetic acid the residue was dissolved in 0·1 N hydrochloric acid. Fig. 3 shows two of the typical spectra obtained from a number of 'Dowex 2' acetic acid eluates by this procedure. The same two absorption peaks at about 230 and 273 mμ can be observed.

The identity of the absorption peaks obtained from resins of type 1 and type 2 is not surprising. In fact, it should be expected since these two types of resins have the same structural polystyrene backbone and are manufactured following essentially the same procedure[11].

The effect of *p*H change on the ultra-violet absorption curve of a hydrochloric acid eluate from 'Dowex 2' is shown in Fig. 4. Curve *A* shows the ultra-violet absorption of the 0·1 N hydrochloric acid eluate, whereas curve *B* shows the ultra-violet absorption of the same eluate after it was made 0·1 N basic with sodium hydroxide. It can be seen that in 0·1 N sodium hydroxide the 273 mμ absorption peak disappeared and the 230 mμ maximum was shifted to about 222 mμ. These changes are identical to those observed by Vaughn with the 'Dowex 1' eluates of a water extract of the Murray meteorite[4].

When 'Dowex 2' (OH⁻ form) columns were eluted with water and then with 4 N acetic acid the ultra-violet-absorbing material was found in the water eluates as well as in the acid eluates, thus paralleling also the elution behaviour described for the meteorite extracts.

On the basis of the identity of the maxima, identity of shifts caused by changes in *p*H and similarity of elution pattern (observations 4, 5 and 3 of Vaughn, respectively) it is concluded that the ultra-violet-absorbing compound(s) detected in water extracts of the Murray meteorite after treatment with 'Dowex 1' came from the resin and not from the meteorite. This conclusion is also in line with the other observations made by Vaughn[1,2].

These results do not exclude the possibility that some ultra-violet-absorbing substances, other than elemental sulphur, are present in the Murray meteorite in amounts below the limit of detectability by the procedure used by Vaughn. The very weak shoulder observed in the 260–280 mμ region in the water extracts may be indigenous to the meteorite or may be due to contamination from organic solvents (benzene, etc.) with which the meteorite samples were extracted prior to the extraction with water. Analysis of the Murray meteorite using more sensitive spectrophotometric methods is in progress.

I thank Prof. M. Calvin for providing the laboratory facilities and the stimulus to carry out this work. The data provided by J. Ullrich and L. Engberg are also gratefully acknowledged.

This work was sponsored in part by the U.S. Atomic Energy Commission and by a grant (*NsG* 257–62) from the National Aeronautics and Space Administration.

ELECTRON DONATION AND ACCEPTANCE BY CARCINOGENIC COMPOUNDS

By Dr. A. C. ALLISON
National Institute for Medical Research, London, N.W.7

AND

T. NASH
Medical Research Council Air Pollution Research Unit, St. Bartholomew's Hospital Medical College, London, E.C.1

In view of the low chemical reactivity of carcinogenic compounds (apart from alkylating agents) under physiological conditions, attention has been focused on their physical properties. Recently, the capacity of carcinogens to donate electrons, and so form charge-transfer complexes, has been discussed. Szent-Györgyi *et al.*[1] have shown that a number of carcinogens can contribute electrons to iodine. Formation of charge-transfer complexes between carcinogenic hydrocarbons and quinones has been described by Laskowski[2] and by Liao and Williams-Ashman[3], and complexes with trinitrofluorenone have been investigated by Takemura *et al.*[4]. Calculations from charge-transfer spectra of ionization potentials of hydrocarbons, including some that are carcinogenic, have been presented[5–7]. The theoretical results of Pullman *et al.*[8] can also be interpreted in terms of the charge density distribution in the molecule of a carcinogen and its capacity to donate electrons. The first part of the investigation reported here was undertaken in order to ascertain how general the property of electron donation is among carcinogens of widely different chemical structure. Particular attention has been given to closely related compounds where some are carcinogenic and others are not.

Electron donation by carcinogens. This property has been measured by formation of charge-transfer complexes with chloranil in acetonitrile and also, in some cases, with 1,3,5-trinitrobenzene in benzene. In the electronic absorption spectrum of a charge-transfer complex, one electron is excited, as a rule, from the highest filled orbital of the donor molecule to the lowest empty orbital of the acceptor. The energy transition of the wave-length of longest absorption is given by:

$$E_{CT} = I_D - E_A + \Delta$$

where I_D is the gaseous ionization potential of the donor, E_A is the electron affinity of the acceptor and additional energy changes Δ are due mainly to solvation and coulombic effects, which are reasonably constant when similar molecules in the same solvent are considered[9,10]. From the equation it will be seen that there should be a simple relationship for a series of complexes when donors of the same general type and the same acceptor and solvent are used (E_A and Δ nearly constant). Since the energy E_{CT} is proportional to the wave number, plots of the wave number of maximum absorption of the charge-transfer band, $\bar{V}$, against I_D should give a straight line. The validity of this interpretation has been demonstrated by many workers (see review of Briegleb[10]), and plots of this type have been obtained with some substances of biological importance by Beukers and Szent-Györgyi[7].

Under conditions similar to those described by Foster[8], we have measured by difference spectrophotometry in a Unicam *SP* 700 or Beckman recording spectrophotometer the maxima of charge-transfer absorption bands of various complexes. The results are presented in Table 1, together with some indication of the relative carcinogenicities of different compounds. For the hydrocarbons this has been taken from Iball[11] and von Haam[12], and for most other compounds from the *Survey of Compounds which have been Tested for Carcinogenic Activity*[13]. Other references are given when necessary. Since compounds have been tested for carcinogenicity under very different conditions, the comparisons between different groups must be at best a rough approximation; but they are most useful when related compounds tested under comparable conditions show marked differences in carcinogenicity. Although the overall picture is important, these provide the most critical tests for any hypothesis of carcinogenesis.

The results summarized in Table 1 confirm and extend the view that there is a broad correlation between electron-donating capacity and carcinogenicity. However, as will be discussed here, at certain points the correlation breaks down in detail, and factors other than electron donor strength clearly have to be taken into consideration.

Electron donation by carcinogens studied by electron spin resonance technique. So far the ability of carcinogens to donate electrons has been deduced from the formation of charge-transfer complexes, and it is important that these results be checked by other techniques which provide quantitative measurements of electron donation and acceptance. Polarographic measurements are presented in the following article, and similar results have been obtained by electron spin resonance measurements of complexes made in collaboration with Drs. W. Slough and D. H. Whiffen of the National Physical Laboratory, Teddington. Following the work of Kainer *et al.*[14], electron spin resonance signals have been reported in a number of charge-transfer complexes, including complexes of indole and iodine[15] and have been measured in a series of complexes of non-carcinogenic aromatic hydrocarbons with iodine[16] and tetracyanoethylene[17].

Table 1. WAVE NUMBERS OF MAXIMUM ABSORPTION OF CHARGE-TRANSFER BANDS, $\bar{\nu}$, OF VARIOUS COMPOUNDS IN COMPLEXES WITH CHLORANIL IN ACETONITRILE AND WITH TRINITROBENZENE (TNB) IN BENZENE

Electron donor strength increases as $\bar{\nu}$ and E_{CT} decrease. In the last column reactions with acridine are listed

Compound	Carcino-genicity	$\bar{\nu} \times 10^{-3}$ chloranil	E_{CT} eV	$\bar{\nu} \times 10^{-3}$ TNB	E_{CT} eV	Acri-dine

c, These compounds were poorly soluble in acetonitrile and charge-transfer spectra were measured in chloroform; with other compounds $\bar{\nu}$ is similar in acetonitrile and chloroform.

Table 2. ELECTRON SPIN RESONANCE MEASUREMENTS OF COMPLEXES OF CARCINOGENIC AND RELATED NON-CARCINOGENIC COMPOUNDS WITH TETRACYANOETHYLENE

Donor molecule	Spin concentration of charge transfer complex	Unpaired spins per mole complex	Line-width (gauss)	Ratio of spin concentration
Azobenzene	7×10^{15} spins/g	$3·7\times10^{-6}$	7·5	1
1,2-Benzpyrene	8×10^{16} spins/g	$5·2\times10^{-5}$	7·1	11
3,4-Benzpyrene	$1·8\times10^{17}$ spins/g	$1·1\times10^{-4}$	7·1	25
1,2-Benzanthracene	$2·0\times10^{17}$ spins/g	$1·2\times10^{-4}$	2·4	27
9,10-Dimethyl-1,2-benzanthracene	$2·4\times10^{18}$ spins/g	$1·3\times10^{-3}$	4·1	340
4-Dimethylamino-azobenzene	$2·5\times10^{18}$ spins/g	$1·4\times10^{-3}$	3·2	350

In our experiments 1 : 1 molecular complexes of highly purified donor molecules and tetracyanoethylene were formed in glass tubes and sealed under nitrogen. The electron spin resonance measurements were made at room temperature at 9,000 Mc/sec using a magnetic-field modulated spectrometer of conventional type. Spin concentrations were measured by comparison with standard samples which in turn were standardized against weighed amounts of diphenyl picryl hydrazyl. Closely similar instrumental conditions were maintained for these measurements.

Preliminary results are given in Table 2. There is clear evidence of increased donor strength of *p*-dimethylaminoazobenzene as compared with azobenzene, 9,10-dimethyl-1 : 2-benzanthracene as compared with 1 : 2-benzanthracene, and 3 : 4- as compared with 1 : 2-benzpyrene. In Table 2 the compounds are placed in order of increasing donor strength.

Electron acceptance by carcinogens. One factor that may help to explain the discrepancies mentioned here is the possibility that electron acceptance by carcinogens is important for activity. This was suggested by Nash[18] and by Mason[19] on different theoretical grounds, and recently some carcinogenic compounds have been shown to have an affinity for electrons while in the gaseous phase. This is true of the hydrocarbons[20] and also aromatic amines (N. L. Gregory and A. C. Allison, unpublished results). The polarographic measurements in solution presented in the following article also show that many carcinogens are both donors and acceptors of electrons.

Szent-Györgyi and McLaughlin[21] observed that a number of carcinogenic compounds give a yellow colour with acridine. They pointed out that the colour could not have been due to charge-transfer as usually understood since it was always the same (yellow) instead of being characteristic of the test compound. However, besides π–π charge-transfer between two molecules, both of which are aromatic, there is another type of charge-transfer illustrated by that between the simple aliphatic amines and trinitrobenzene, with the reversible production of a brown colour. In this case the electron is transferred from the lone-pair on the amino nitrogen, and the interaction is known as n–π charge-transfer. Slifkin[22] has pointed out that with aromatic amines both π–π and n–π charge transfer can occur simultaneously. With regard to the latter, acridine is in a particularly favourable position because the nitrogen atom is negatively charged and has a fractional electron due to pyridine-type mesomerism, besides the usual lone-pair. We can presume that this fractional electron is more readily transferred to another molecule than the corresponding fraction of a 'straight pair' such as is found in the aliphatic amines.

We have previously described the changes produced in the acridine–carcinogen interaction by the addition of a weak organic acid[23]; the 'weak chemical link' formed in the absence of acid can now be more positively identified as n–π charge-transfer localized at the nitrogen atom of the acridine.

We have examined the interaction of carcinogens with acridine by drying down solutions on filter paper[21] and also by analysis of absorption spectra. Concentrated solutions of acridine in chloroform show a yellow colour and shift of absorption to a longer wave-length on addition of carcinogens. Difference spectra between the absorption of the complex and that of the carcinogen and acridine alone show a sharp peak with a maximum at $\bar{\nu} = 24{,}600$ in every case. This peak is in exactly the same position as that seen in the difference spectrum of acridine/acridine-acetic acid, when the acridine in the latter must have been the positively charged partner of the H-bonded complex. This is strong presumptive evidence that the band with carcinogens is due to n–π electron transfer from the acridine, the carcinogen behaving as electron acceptor.

The results summarized in the last column of Table 1 show that the correlation between a positive acridine reaction and carcinogenicity is as good as that between the latter and electron donation. We therefore suggest that carcinogenicity arises as a result of a suitable combination of both electron-donating and electron-accepting properties in a compound. Huggins and Yang, on the other hand, have recently suggested that either property is sufficient[24]. Their suggestion is based on Szent-Györgyi's work and on the observed carcinogenicity of the strong electron acceptor 2,4,7-trinitrofluorenene, but it is possible that this compound is rapidly metabolized to others with very different properties. In any case, evidence is summarized elsewhere[25] that many drugs which are apparently not carcinogenic are either donors or acceptors of electrons, so that either of these properties *per se* is obviously insufficient for carcinogenicity. The combination of both electron-donating and electron-accepting properties in the same molecule is, however, relatively rare, and it is remarkable that it should recur in so many carcinogens with widely differing structures.

Quinonoid character due to lone-pairs. In an earlier communication[18] it was shown that some of the properties of quinones could arise in compounds containing, not opposed carbonyl groups, but opposed lone-pairs, that is, in peroxides, hydrazines, hydroxylamines and their vinylogues, in which the electrical strain set up by neighbouring atomic dipoles could not be relieved by mesomeric charge transfer such as is found in amides or esters. Pseudo-quinonoid character would also be expected, in other compounds containing directly linked oxygen and nitrogen, that is, in nitro compounds and nitrosamines. The quinones themselves have a very high affinity for electrons, but probably little tendency to donate them. In the pseudo-quinones, on the other hand, some degree of electron affinity should be possible without greatly affecting their ability to donate electrons. For example, 2-naphthylamine is a strong electron donor, and *N*-hydroxylation such as occurs *in vivo*[26] will increase its electron affinity by virtue of the hydroxylamine system while leaving the electron-donating capacity of the aromatic amine portion largely unchanged. The compounds should therefore have a much better balance of donor and acceptor properties than the original amine. The following other known carcinogens are pseudo-quinonoid by the aforementioned definition, or have electrical strain of an analogous kind: cholesterol hydroperoxide[27], safrole[28], urethane[18], actinomycin *D* (ref. 29) and dinaphthazine[30].

Hydrocarbons. The ability of condensed ring hydrocarbons to donate electrons from their delocalized π-orbitals has been known for many years. Recent observations on electron affinity in the gaseous phase[20], polarographic measurements (following article) and the interaction with acridine reported here show that the hydrocarbons are also electron acceptors. From the results shown in Tables 1 and 2 and polarographic measurements (following article) it is clear that as a rule the carcinogenic hydrocarbons are stronger electron donors than other hydrocarbons. Thus, there is a progressive increase in donor strength in the series anthracene, 1 : 2-benzanthracene, monomethylbenzanthracene and dimethylbenzanthracene, and in 3 : 4- as compared with 1 : 2-benzpyrene. Methylcholanthrene is a powerful donor.

Nevertheless there are important exceptions. In keeping with previous observations of Takemura *et al.*[4] on complexes with trinitrofluorenone and of Birks and Slifkin[5] on complexes with chloranil, we have found only trivial differences between the electron-donating capacity of various monomethylbenzanthracene derivatives, although some of these are carcinogenic and others are not[12]. Moreover, the carcinogenic dibenzanthracenes are weaker electron donors than some non-carcinogenic hydrocarbons, notably naphthacene and perylene.

At first sight these exceptions seem so impressive as to cast doubt on the importance of electron donation in the carcinogenic process. However, apart from electron acceptance, at least two additional factors must be considered. The first is the steric factor. For charge transfer to occur there must be a very close fit of donor and acceptor molecules, with actual overlap of electron orbitals; bulky substituents are known to decrease charge transfer in carefully studied systems[31]. This might account for such findings as that 20-methyl, -ethyl, -isopropyl and *t*-butyl-derivatives of cholanthrene show progressively decreasing carcinogenicity[32]; that higher alkyl derivatives at position 5 of 1 : 2-benzanthracene are less carcinogenic than the methyl derivative[33]; and that the larger polycyclic hydrocarbons are not carcinogenic[12,33].

That steric factors might be important in carcinogenesis should occasion no surprise, since this is known to be the case with hormones and drugs. It need only be recalled that D-thyroxine fails to alleviate the symptoms of hypothyroidism and that the position of the carbonyl and α, β-unsaturated ketone systems in ketosteroids profoundly affects their biological activities.

In this connexion, the possibility that polycyclic hydrocarbons are steric analogues of steroids has been raised again recently[23]. This suggestion should be treated with reservation, since X-ray analysis shows that steroids are non-planar molecules[34] whereas the carcinogenic hydrocarbons so far studied are essentially planar[35]; 9,10-dimethyl-1 : 2-benzanthracene has one ring at an angle to the others, which are planar (J. Iball, private communication). The structures of carcinogenic hydrocarbons and steroids must therefore be quite different. Nevertheless, many groups of carcinogens (polycyclic hydrocarbons, some aromatic amines and heterocyclic nitrogen-containing compounds, œstrogenic steroids and stilbœstrol) have similar overall dimensions, and it seems possible that these are particularly favourable for carcinogenesis. However, other carcinogens, including naphthylamine and urethan, are much smaller, so there is no universal rule.

The second important additional factor is the stability of hydrocarbons under physiological conditions. It is reasonable to suppose that in order to be carcinogenic the hydrocarbons must persist in active form in the tissues for relatively long periods. Available evidence indicates that metabolites of hydrocarbons are not carcinogenic, and that the amount of hydrocarbon persisting in the tissues is related to carcinogenity[36]. Furthermore, polarographic observations summarized in the following article suggest that carcinogenic and non-carcinogenic hydrocarbon ions are likely to differ in stability, and differences in their metabolism have also been described[37]. Further observations on the stability of various hydrocarbons in tissues under comparable conditions would be of considerable interest.

With regard to electron acceptance in hydrocarbon carcinogenesis, the recent observations of Lacassagne *et al.*[38] on carcinogenicity of aldehyde derivatives of anthracene and of dibenzanthracenes are of interest, since the aldehyde substituents, particularly when hydrogen bonded, would increase electron acceptance. Despite the qualifications that have been necessary, it seems clear that polycyclic hydrocarbons could exert their carcinogenic effects by virtue of their capacity to function both as donors and acceptors of electrons. The calculations of the Pullmans[8] on the necessity of a particular charge-density distribution in the molecule of a carcinogenic hydrocarbon may reflect a capacity for both electron and acceptance, as well as stability. However, it must be recognized that such calculations depend on assumptions that are not at present verifiable; the difficulties in this field are emphasized by the recent controversy with Mason[39]. We also feel that reservations are necessary about the relevance of Birks's[40] suggestion that in carcinogenic hydrocarbons the first singlet π-electron absorption band strongly overlaps the emission spectrum of tryptophan. This is not true of some carcinogenic hydrocarbons[41], and the energies necessary to raise electrons to excited states are rarely available in most organs, so that Birks's suggestion is difficult to translate into biochemical terms.

Steroids. The only steroids that are highly carcinogenic in appropriate test systems are œstrogens[18], and it is of interest that these are the only members of the group to possess aromatic systems and to be relatively strong electron donors (Table 1 and following article). The same is true of the synthetic œstrogen, stilbœstrol, and this compound and most œstrogenic steroids show also easily measurable electron acceptor properties (following article). Cholesterol itself is only weakly carcinogenic (if the unmetabolized compound is carcinogenic at all), but there is good evidence that the products of dehydrogenation of cholesterol (1 : 2-*cyclo*pentadieno-phenanthrenes) are carcinogenic[42], as is also cholesterol hydroperoxide[27]. Though we have had no opportunity to test these compounds, it is virtually certain that both would be stronger donors and acceptors of electrons than cholesterol itself.

Aromatic amines. These are among the classical electron donors known to form charge-transfer complexes[37]. It is therefore of interest that many aromatic amines are carcinogenic, including 2-naphthylamine, 2-aminoanthracene, 2-aminophenanthrene[25], 2-aminofluorene and derivatives, *p*-dimethylaminoazobenzene, aminostilbenes and aminobiphenyls. All these are strong electron donors, as shown in charge-transfer experiments (Table 1) and polarographic measurements (following article).

There is evidence that *N*-hydroxylation (and possibly *o*-hydroxylation in some cases) of aromatic amines increases their carcinogenicity, or may even be essential for it. Thus, *N*-hydroxy-2-acetylaminofluorene is locally carcinogenic when administered to various sites, whereas it seems that 2-acetylaminofluorene itself is metabolized by the liver before it is carcinogenic elsewhere[43]. Possibly deacylation occurs, and the immediate carcinogen is 2-hydroxylaminofluorene; *N*-hydroxylation of 2-naphthylamine also occurs in man and other animals[26], and *N*-hydroxy-4-acetylaminobiphenyl is more carcinogenic than 4-acetylaminobiphenyl[44]. The evidence that aromatic hydroxylamines are more carcinogenic than the parent compounds is of interest in relation to the argument presented here that in hydroxylamines there will be a better balance of electron donor and acceptor properties than in the corresponding amines. That aromatic hydroxylamines retain potent electron-donating properties is readily shown in appropriate experiments, for example, on electron transfer to aromatic diazonium compounds[45].

There is no doubt that carcinogenic aromatic amines and derivatives have both electron donor and acceptor properties, but here again certain qualifications are necessary. No important difference in donor or acceptor strength exists between the carcinogenic *p*-dimethylaminoazobenzene and its inactive diethyl-analogue. It is possible that the bulky ethyl substituent reduces charge transfer with a biologically important compound, or affects the rate of metabolism of the azo carcinogen; and this may also be true of certain substituted dimethylaminoazobenzenes that are not carcinogenic. Again, there are only small differences in donor strength between the carcinogenic 2-naphthylamine and the non-carcinogenic 1-naphthylamine; but in this case it is likely that the hydroxylamine of the latter would be less stable than that of the former. The rates of oxidation or specific hydroxylation of aromatic amines, without loss through coupling to glucuronic or sulphuric acid and solubilization in the aqueous phase, could well be of as much importance in determining whether or not a given amine is carcinogenic as its electron-donating capacity. Here again there is a close analogy with what is known of the duration of action of aromatic amine hormones and drugs.

In all aromatic amines and derivatives, electron-donating capacity is much greater than electron-accepting capacity. On our hypothesis, introduction of appropriate substituents which increase electron acceptance without markedly reducing donor strength would be expected to increase carcinogenicity. This has been achieved by Brown *et al.*[46], who have replaced the unsubstituted ring of *p*-dimethylaminoazobenzene with quinoline and pyridine derivatives which would be acceptors as a result of immobilization of nitrogen lone-pair electrons through hydrogen bonding.

Heterocyclic nitrogen compounds. Nitrogen can enter the aromatic ring in two different ways, first, as in pyridine, where the nitrogen lone-pair of electrons does not take part in the primary aromatic conjugation and, secondly, as in pyrrole, where the nitrogen lone-pair is an essential part of the aromatic system and is therefore too de-localized to be available for hydrogen bonding. In the first case, the nitrogen carries a negative charge and the molecule as a whole is a weak donor or acceptor of an electron. In the second case, the nitrogen carries a positive charge and the molecule as a whole becomes a relatively strong electron donor, for example, indole (Table 1). In larger molecules any π-electron donor or acceptor capacity already present will be modified in the appropriate direction by the entry of nitrogen into the molecule, so that acridine, for example, is a weaker donor than anthracene, whereas carbazole is a stronger.

On the hypothesis advanced here, the introduction of nitrogen into aromatic ring systems would therefore be expected sometimes to increase and sometimes to decrease their carcinogenicity. This is, in fact, the case. Acridine and its derivatives are not carcinogenic[13], and this is also true of pyrenoline, a heterocyclic *N*-derivative of 3,4-benzpyrene[47]. On the other hand, many heterocyclic compounds of nitrogen are carcinogenic, including dinaphthazine, compared with the inactive parent compound pentacene[48], and a series of dibenzocarbazoles[49], angular benzacridines[50], angular benzpyridocarbazoles[51] and tri*cyclo*quinazolines[52]. As already discussed, hydrogen bonding of the nitrogen atom would increase electron acceptor character in all such compounds of the pyridine type. It is suggestive that in the former group only relatively large molecules, which will be π-electron donors as well as hydrogen acceptors, are carcinogenic. Where donor and acceptor properties are very well marked, and the donating and accepting groups are readily identifiable, as in the benzpyridocarbazoles (see polarographic measurements in following article) the compounds are among the most potent carcinogens known[51].

Solubilization of carcinogens by purines. Boyland and Green[53] have recently re-examined the solubilization of polycyclic aromatic hydrocarbons by caffeine and other purines. They concluded that the interaction is due mainly to polarization forces. However, in view of the results with acridine discussed here, the case for *n*–π charge transfer from one or more lone-pairs on the caffeine molecule to the carcinogen is now stronger. The spectral shifts observed by Boyland and Green would agree with Tsubomura and Lang's evidence[54] that *n*–π interaction results in a shift to the red of the main band of the acceptor. If this is so, solubilization of carcinogens by caffeine would be related to electron affinity of the former, although other factors would also affect the solubilities of the complexes in water. Possibly there is a continuous gradation between *n*–π charge transfer and polarization forces.

The complex formation between carcinogenic hydrocarbons and nucleic acid[55] could have a similar basis. The presence of sodium chloride markedly depresses complex formation, which would be expected since the sodium ions would compete for potential purine electron-donating sites. However, this fact implies that the amount of hydrocarbon so solubilized *in vivo* will be very small.

This reaction may be of interest in demonstrating the presence of minor components of potentially carcinogenic hydrocarbons in mixtures, as the results of Eby *et al.*[56] suggest. Only hydrocarbons that are electron acceptors would be solubilized by caffeine in the aqueous phase.

Relevance to biological systems: the 'sandwich' model. The finding that most, if not all, carcinogens (other than alkylating agents) are both donors and acceptors of electrons leads to a model that may help to explain their mode of action *in vivo*. According to this 'sandwich' model the carcinogen lies between two neighbouring active sites in a metabolic system, one an electron donor and the other an acceptor, forming relatively stable charge-transfer complexes with both; in some cases at least, complex formation will be reinforced by hydrogen bonds. For example, electron transfer may normally occur between nitrogen and oxygen on different substrate molecules. The carcinogen would form an *n*–π complex with, say, the nitrogen, and the transferred electron would now be so diffused as no longer to be able to pass over to the oxygen. This may be called the 'rectifier' model, in that π–*n* transfer is not normally observed (so far as we are aware, polycyclic hydrocarbons do not interact with electron-deficient substances such as the Lewis acids). Alternatively, the carcinogen could form a π–π complex on one side of the substrate, and this might prevent electron transfer by reducing the availability of an electron at a lone-pair site elsewhere in the substrate.

The search for biological systems markedly affected by carcinogens has not yet progressed far, but two systems can serve as examples. One is a purified soluble enzyme system from rat kidney, having flavine mononucleotide (FMN) as coenzyme, which oxidizes reduced ribosyl nicotinamide in the presence of 2-methyl-1,4-naphthoquinone (menadione). This is powerfully inhibited by carcinogenic hydrocarbons ($K_i < 10^{-7}$ M)[3]. Both FMN and menadione are electron acceptors, and it seems likely that charge transfer of one or other with carcinogens occurs, the latter perhaps accepting also an electron from some donor (such as a tryptophan residue in the enzyme). This is a highly specific effect, since a similar enzyme from rat mammary tissue is not inhibited by carcinogens[57]. The second example is inhibition of reduced diphosphopyridine nucleotide oxidation in rat liver enzyme systems by carcinogenic hydrocarbons and aromatic amines[58], where similar mechanisms could be involved. These mechanisms are not entirely speculative since complex formation of hydrocarbons with FMN has been reported[59], and charge-transfer of a variety of carcinogens with menadione, coenzyme *Q* and tryptophan can readily be demonstrated spectrophotometrically (unpublished).

From this and other evidence which cannot be reviewed here *in extenso*, there is good reason to believe that carcinogens might affect oxidative phosphorylation, and a plausible case can be made for this being the primary change in carcinogenesis. Prolonged inhibition or uncoupling of oxidative phosphorylation might initiate the neoplastic change through transformation of normal cells into tumour cells, or by providing a metabolic environment favourable for proliferation of tumour cells, or both. The first suggestion, due originally to Warburg[60], has been the subject of much debate, and the fact that the debate continues with undiminished vigour[61] means that the arguments against the hypothesis are not as compelling as its antagonists claim. The hypothesis should in any case be restated to take into account important recent observations on differences between normal and tumour cells, including the utilization of energy for protein synthesis[62] and lipid synthesis[63], and metabolism of reduced diphosphopyridine nucleotide[64]. According to the metabolic selection hypothesis[65], inhibition of oxidative phosphorylation places tumour cells (which efficiently use glycolytic energy for protein synthesis[62] and probably for other important synthetic reactions) at a competitive advantage relative to normal cells; the tumour cells can thus form self-perpetuating clones, in which later modifications leading to malignancy can occur. A variant of this hypothesis is that the normal cells, which are at a competitive disadvantage owing to the presence of carcinogens, are those concerned with the elimination of any tumour cells arising and differing antigenically from cells originally present.

However, the observed effects of carcinogens on oxidative phosphorylation might be epiphenomena, while the fundamental changes occur in other systems. Other possibilities should constantly be borne in mind. The carcinogens might, for example, produce specific changes in permeability of nuclear or other membranes, or interfere with some aspect of nucleic acid or protein metabolism occurring at a lipid–aqueous interface, thereby interfering with normal mechanisms of growth control or differentiation. But our information about these mechanisms in mammalian cells is too scanty to allow analysis of the effects of carcinogens at present.

Some observations which are otherwise puzzling are explained by recognizing that carcinogens act as electron donors and acceptors. One is the marked reduction in carcinogenicity of polycyclic hydrocarbons by pretreatment with halogenated aromatic compounds, benzoquinone and cantharidin[66]; the latter are strong electron acceptors and could prevent the hydrocarbons from reaching their normal sites of action. Charge transfer may also precede the specific binding of carcinogens by proteins of liver[67] and skin[68], irrespective of whether this is directly involved in carcinogenesis.

Considering all the factors that intervene, the correspondence over a wide range of compounds between carcinogenicity and electron donor and acceptor capacity is remarkably good, so that this seems to be the most attractive theory of their mode of action at present available. The theory explains many facts that are otherwise obscure, but not all, and further work is required to ascertain whether the explanations offered for the apparent exceptions are valid.

With regard to screening of potentially carcinogenic compounds, it is clear that simple tests demonstrating charge transfer with trinitrobenzene and acridine would have picked up all the major carcinogens listed in this paper. Although some non-carcinogenic compounds would also have been included, it seems fair to say that any new compound showing these effects should be treated with suspicion until there is good evidence that it is not carcinogenic. We feel that these tests, and others for alkylation of some test compound such as cysteine, should be of value in screening for potential carcinogens.

We thank our colleagues who supplied compounds for testing, in particular Prof. J. A. Miller, Prof. A. Haddow, Prof. M. S. Newman and Prof. N. P. Buu-Hoï. We also thank Drs. D. H. Whiffen and W. Slough for allowing us to quote electron spin resonance measurements made in their laboratory, and Dr. J. W. Cornforth for helpful discussion.

POLAROGRAPHIC MEASUREMENTS OF ELECTRON DONATION AND ACCEPTANCE BY CARCINOGENIC COMPOUNDS

By Dr. A. C. ALLISON, Dr. M. E. PEOVER and T. A. GOUGH

National Institute for Medical Research, London, N.W.7, and National Chemical Laboratory, Teddington, Middlesex

EVIDENCE has been presented in the preceding article that a wide range of carcinogenic compounds are able both to donate and to accept electrons. They are thus potentially capable of forming charge-transfer complexes with electron donors as well as with electron acceptors and this dual property may help to explain how they exert their carcinogenic effects. Electron-donating and -accepting power is determined respectively by the ionization potential and electron affinity of the molecule; direct measurement of ionization potentials can be made in favourable cases but not, at present, of electron affinities. Donating power has also been investigated in relation to charge-transfer spectra using theoretical calculations of energy-levels[1,2]. In this article, the results of experiments with a polarographic technique will be described. Such results have already proved of value in measuring electron-accepting capacity[3-5], as well as electron-donating capacity[6], in connexion with investigations of charge-transfer interaction.

A number of workers have shown that electron-transfer between an organic substance and an electrode surface results initially in the formation of the mono-negative or -positive ion (or the dipositive ion in some cases), which have appreciable lifetimes in a relatively inert solvent[7]. These properties have recently been utilized in the study of organic free-radical anions and cations by electron spin resonance[8]. Thus, at a moving electrode, as used in polarography, the lifetime of the electrode products may be large (some seconds) in comparison with their rate of diffusion from the electrode surface. As a consequence, the current-potential curves will be close to the redox curves for the reactions $A + e \rightleftharpoons A^-$, $D - e \rightleftharpoons D^+$, where A and D are the acceptor and donor molecules. Even when the electrode products A^- and D^+ are highly unstable, the half-wave potentials are not generally shifted from the E_1 values by more than a few hundredths of a volt.

The half-wave potentials can be identified with corresponding redox potentials E_1^{red} and E_1^{ox}. The E_1 potentials are related in a simple manner to the gaseous ionization potential I_D and electron affinity E_A by the equations[9]:

$$E_1^{\text{ox}} = I_D - \Delta E_{\text{sol}}^{\text{ox}} - \text{constant}$$

$$E_1^{\text{red}} = E_A + \Delta E_{\text{sol}}^{\text{red}} - \text{constant}$$

where ΔE_{sol} is the solvation energy contributed by the solvent (the constant is appropriate to the reference electrode). The main contribution to ΔE_{sol} lies in the solvation energy of the ion A^- or D^+, and decreases as the delocalization of the charge increases[4,9]. Recent work shows that with the exception of large condensed aromatic systems the solvation energy term is remarkably constant[4-6]; it varies approximately linearly for large aromatic systems[4,5,9]. Measurement of E_1 values thus provides a convenient method obtaining a parameter linearly related to I_D and E_A, the electron-donating and -accepting energies of the molecule.

We have used as solvent acetonitrile, which has been shown by a number of workers to be convenient for polarography of this type[7,9]. Briefly, measurements were made with 0·1 N tetraethyl ammonium perchlorate as supporting electrolyte, with a Cambridge Instrument pen-recording polarograph, using either a dropping mercury or rotating platinum electrode (600 r.p.m.). Initial polarization of the platinum electrode at $-2·4$ V for 5 min gave a reproducible electrode surface. Potentials are referred to an aqueous saturated calomel reference electrode using a three-electrode cell with compensator[4,10]. The limits of measurement are from about $-2·8$ V to 2·4 V. Roughly, this corresponds to the reduction of fluorene at one extreme and oxidation of benzene at the other. Poorer electron acceptors or electron donors cannot therefore be determined.

The results for a variety of carcinogenic and chemically related non-carcinogenic compounds are given in Table 1. The compounds are grouped in such a way that comparable solvation energy terms are involved. Our results for aromatic hydrocarbons are in good agreement with those of Lund[11], who used a vibrating platinum electrode. Plots of donor strength measured polarographically against those calculated from charge-transfer bands (see preceding article) are shown in Fig. 1. These fall reasonably well on a straight line with a slope of 45°, but the curve for hydrocarbons is clearly different from that for amines.

Most carcinogens show both acceptor and donor properties well within the limits of the technique, being

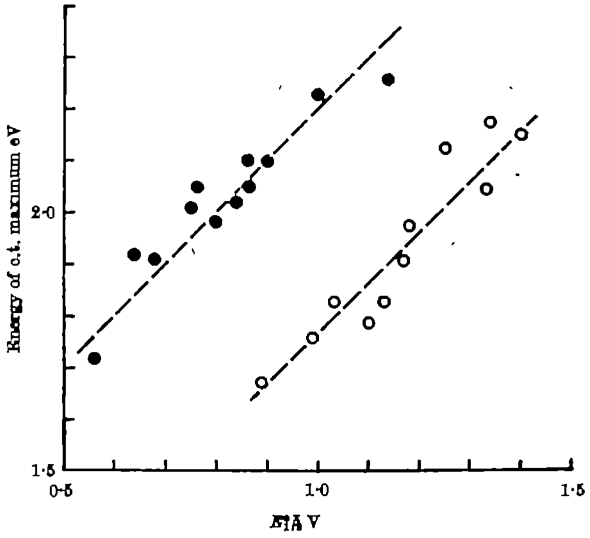

Fig. 1. Plots of energies of charge-transfer (c.t.) maxima of complexes of hydrocarbons (○) and aromatic amines (●) with chloranil against first half-wave potentials for oxidation measured polarographically

Table 1. E_1 VALUES FOR SOME CARCINOGENIC AND RELATED NON-CARCINOGENIC COMPOUNDS

Comparable solvation energy terms are involved in each of the groups. Donor and acceptor strengths increase as E_1^{ox} decreases and E_1^{red} becomes less negative

Compound	V versus S.C.E.		Carcinogenic activity
	E_1^{ox}	E_1^{red}	
3,4-Benzpyrene	1·35	−2·22	−
1,2,5,6-Dibenzanthracene	1·34*	−2·04†	+
1,2-Benzanthracene	1·33*	−2·11†	−
Pyrene	1·22	−2·18	−
Anthracene	1·19	−2·07	−
1,2,5,6-Dibenzpyrene	1·17	−1·90	+
9,10-Dimethyl-1,2-benzanthracene	1·12	−2·16	+
1,2-Benzpyrene	1·10	−1·96	+
5,6-Benzpyrido-(2′3′ : 1,2)-carbazole	1·06	−1·98	+
5,6-Benzpyrido-(3′2′ : 1,2)-carbazole	1·04	−1·95	+
Perylene	1·04	−1·73	−
20-Methylcholanthrene	0·99*	?	+
2-Aminoanthracene	0·56	−2·19	+
Cortisone	>2·2	−2·12	−
Oestrone	1·19	−1·98	+
Stilboestrol	0·90	−2·30	+
Benzene	2·38	N‡	−
Fluorene	1·60	−2·79	−
3-Acetylaminodibenzothiophene sulphone	1·59	−1·79	−
3-Acetylaminodibenzofuran	1·40	−2·21	+
3-Acetylaminodibenzothiophene	1·39	−1·99	+
2-Acetylaminofluorene	1·14	−2·01	+
N-Hydroxy-2-acetylaminofluorene	1·00	−2·12	+
4-Aminobiphenyl	0·93	N‡	+
2-Naphthylamine	0·75	−2·8	+
1-Naphthylamine	0·68	−2·8	−
2-Aminofluorene	0·64	−2·8	+
Azobenzene	1·80	−1·45	−
3′-Fluoro-*p*-dimethylaminoazobenzene	0·90	−1·50	−
p-Dimethylaminoazobenzene	0·86	−1·58	+
p-Diethylaminoazobenzene	0·84	−1·62	−
2-Methyl-*p*-dimethylaminoazobenzene	0·80	−1·60	−

* From Lund, Ref. 11.

† In 96 per cent dioxane, Hoijtink, G. J., *Rec. Trav. Chim.*, **74**, 1525 (1955).

‡ N—not reduced.

relatively good donors[8] and showing measurable acceptor properties, which are nevertheless weaker than those of common acceptors such as quinones[3,4]. It is striking that so diverse a series of functional groupings in the carcinogens produces such a similar pattern of electron donor and acceptor strengths. The only carcinogen listed not showing measurable acceptor property is 4-aminodiphenyl. However, in this case, and that of 2-naphthylamine, it is likely that the active compound is a hydroxyl derivative, which would be an acceptor by virtue of the hydroxylamine system.

In the non-carcinogenic compounds exhibiting both donor and acceptor properties these functions are in general weaker than in carcinogens. However, non-carcinogenic azo-compounds (*p*-diethylaminoazobenzene, 3′-fluoro-*p*-dimethylaminoazobenzene and 2-methyl-*p*-dimethylaminoazobenzene) were exceptional in that their donor and acceptor strengths were of the same order as those of the carcinogenic *p*-dimethylaminoazobenzene. Moreover, the carcinogenic 1,2,5,6-dibenzanthracene is a weaker donor than certain non-carcinogenic hydrocarbons. It should be recalled that the stability of charge-transfer complexes is not always simply related to donor and acceptor strengths[6,12]. Moreover, steric and metabolic effects have to be taken into consideration, as discussed in the preceding article. The polarographic characteristics of the various compounds will be discussed in detail elsewhere. However, it is worth noting here that some differences between carcinogenic and non-carcinogenic compounds were observed. Thus, in the series of pyrene derivatives only those that were carcinogenic were found to undergo one electron oxidation. Pyrene itself was oxidized by a two-electron step, and 3 : 4-benzpyrene by a three-electron step, with the formation of insoluble products. Thus the products of oxidation of the carcinogens are likely to be more stable than those of the non-carcinogens.

Finally, we may point out a further application of the E_1 potentials. From the relevant Nernst equations it is easily shown that:

$$E_1^{red} - E_1^{ox} = \frac{RT}{F} \ln \frac{[D^+][A^-]}{[D][A]} = \frac{RT}{F} \ln K$$

where K is the equilibrium constant of the reaction:

$$D + A \rightleftharpoons D^+ + A^-$$

Thus for any pair of D and A, it is possible to calculate the concentration of free D^+ and A^- ions, in the solvent in which the potentials are measured. This should be of value in the elucidation of electron spin resonance and spectrophotometric studies of such systems[13,14].

EVIDENCE FOR TWO TYPES OF MEDIATION OF NEUTRAL AMINO-ACID TRANSPORT IN EHRLICH CELLS

By DALE L. OXENDER and HALVOR N. CHRISTENSEN

Department of Biological Chemistry, University of Michigan

BECAUSE many of the neutral amino-acids compete with one another for transport[1–3], at least in mammalian systems, a common mediation has generally been taken to serve for them all. A lack of strict quantitative agreement between the affinities indicated by initial rates, and those indicated by competitive action or extent of accumulation has, however, been apparent to us for some time[4,5]. If only one mediating site or carrier serves for transport of all the neutral amino-acids, then they will yield a consistent set of relative affinities whatever amino-acid is used to compare their inhibitory actions. The present results show that at least two sites with overlapping specificities must be operative to account for the relative inhibitory actions observed in the Ehrlich ascites tumour cell.

The techniques of propagating, collecting and separating the Ehrlich ascites tumour cells have been described elsewhere[6]. Uptake of amino-acids was studied at 37° C by incubating 4 per cent suspensions of tumour cells for 1 min in Krebs–Ringer bicarbonate buffer media containing amino-acids labelled with carbon-14. At the end of the incubation time the suspension was diluted with 1 volume of ice-cold buffer and centrifuged for 2 min at 2,500*g*. Radioactivity in a hot acetic acid extract of the cells was counted in a liquid scintillation spectrometer. The results for the packed cells were corrected for 20 per cent extracellular space and expressed as a distribution ratio, that is, c.p.m. per ml. intracellular fluid divided by c.p.m. per ml. extracellular fluid.

Fig. 1 shows the results of an experiment in which the uptake from 1 mM solutions of the amino-acids listed at the top of the figure was measured in the presence of 5-mM levels of the amino-acids listed in the body of the figure. The effectiveness of leucine as an inhibitor may be seen to decrease from left to right, while that of alanine increases. If the competition were for a single site, the trends in the inhibitory action would be parallel and not opposite. Valine appears to follow the same trend as leucine, and glycine the same as alanine. Although a quantitative test has not been completed, two transport-mediating sites promise to be enough to explain the results. One of these we may call the leucine-preferring or *L* site, the other the alanine-preferring or *A* site. Alanine, glycine and α-aminoisobutyric acid have affinities predominantly for the latter site, and leucine and valine for the former. A third type of amino-acid is illustrated in Fig. 1 by methionine, which is strongly inhibitory to all five of the amino-acids selected here for comparison. Accordingly, it must have high affinity for both the postulated sites.

Although these transport mediators are clearly distinguishable, their specificities are nevertheless so broad that all the naturally occurring, neutral amino-acids tested have some affinity for both. Of the poorly metabolized model amino-acids proposed from this laboratory α-aminoisobutyric acid may be recommended for investigating the *A* mediation, and tertiary leucine, for the *L* mediation. Curiously, 1-amino*cyclo*pentanecarboxylic acid is a model for the third type of amino-acid with high affinity for both mediations.

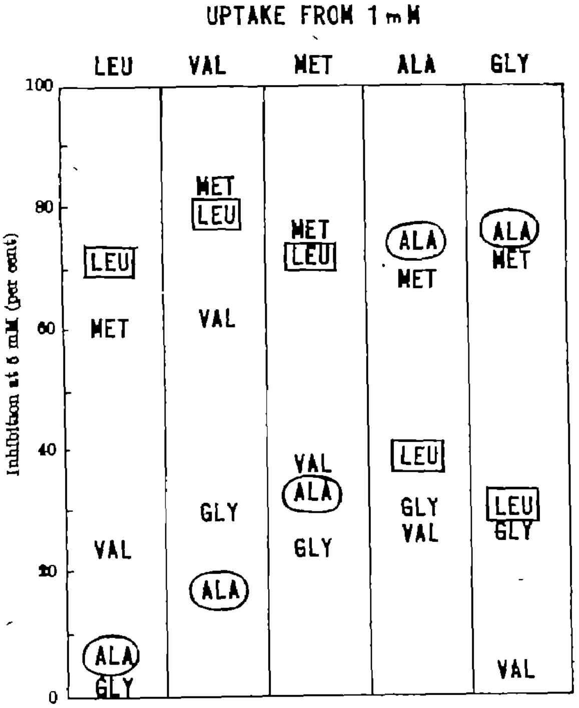

Fig. 1. Relative inhibitory actions for transport among five amino-acids. The position of each amino-acid in the body of the illustration represents quantitatively its percentage inhibition of the uptake of the amino-acid listed at the top of each column

For the same levels, the effluxes of amino-acids using site *A* for entry, such as glycine and alanine, are considerably smaller than their influxes; therefore, they are accumulated to high chemical gradients. The amino-acids preferring the leucine site show effluxes much closer to their influxes; accordingly, they give much lower steady-state distribution ratios, between 1 and 5. Because efflux among all the amino-acids varies independently of influx, their initial rates of uptake bear no fixed relationship to their steady-state distribution ratio. The change of the distribution ratio of representatives of the three groups of amino-acids with time is presented in Fig. 2. Glycine has the slowest initial entry rate but is eventually accumulated to a high degree. In contrast, leucine has one of the fastest initial rates, but it reaches a final distribution ratio of only 3. Methionine and 1-amino*cyclo*pentanecarboxylic acid have high initial rates of entry, and are accumulated to relatively high distribution ratios. Obviously if glycine is finally concentrated so strongly, despite its comparatively slow uptake it must be lost from the cell even more slowly.

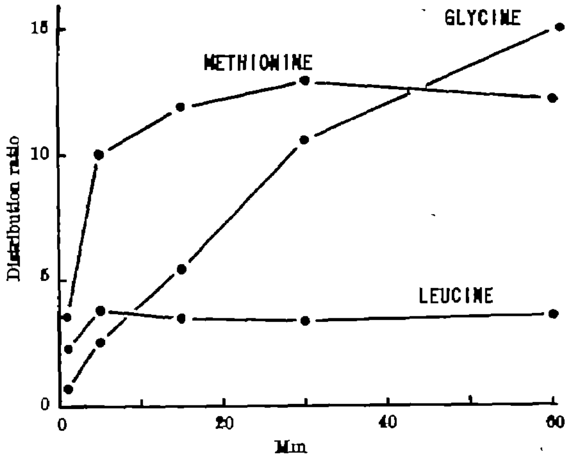

Fig. 2. Time-course of the uptake of three amino-acids by Ehrlich tumour cells at 37°. Initial level of amino-acid labelled with carbon-14 in Krebs–Ringer bicarbonate medium, 1 mM; 25 volumes of suspending medium used

These differences in efflux among the amino-acids indicate that they escape from the cells largely by mediated processes, a conclusion supported by the following findings (to be published): the escape process is subject to saturation and to competition by analogous amino-acids; it is largely stereospecific; in some cases it can be accelerated by the external presence of another amino-acid.

Fig. 3 compares the ability of amino-acids of the three groups discussed here to stimulate amino-acid entry by exchange. In this experiment the amino-acid listed at the top had been permitted to accumulate within the Ehrlich cell from a 10 mM solution. The length of the bars, in relationship to the horizontal line, show whether the subsequent uptake of the amino-acids listed at the bottom during 1 min was faster or slower than it was in the absence of the intracellular accumulation. Valine, 1-amino*cyclo*pentanecarboxylic acid and methionine can be seen to serve for exchange with each other, thereby accelerating uptake. In contrast, α-aminoisobutyric acid and glycine (and alanine, to be published) in our hands give little or no stimulation of exchange unless their internal level is very high (70–100 mM). The results indicate that the *L* site serves far more effectively for exchange; its reversible action may well account for all the exchange-diffusion of neutral amino-acids.

We may tentatively summarize the characteristics of the two sites. First, the steady-state distribution ratios of the group of amino-acids using site *A* (10–20) are much higher than those using site *L* (1–5). Secondly, site *L*

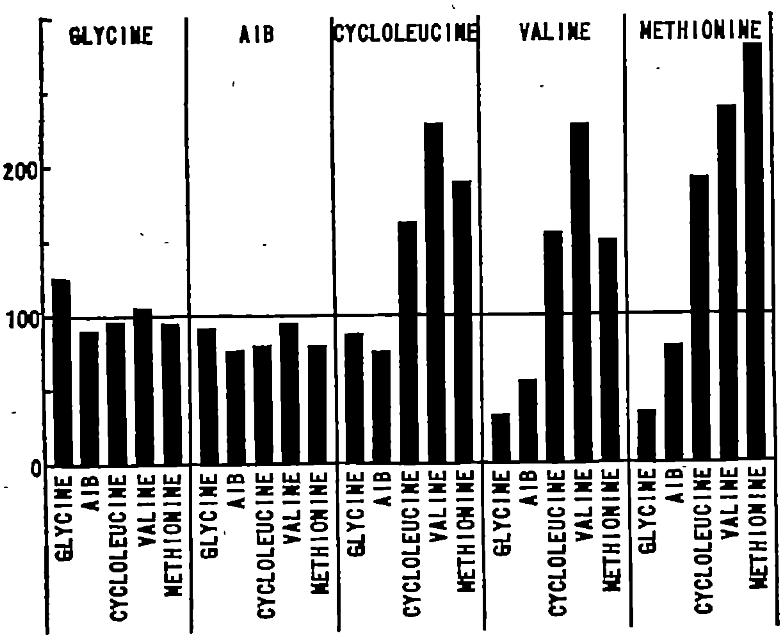

Fig. 3. Effect of five previously accumulated amino-acids on uptake of each other. The amino-acid listed at the top had been allowed to accumulate for 40 min from a 10 mM solution. The cells were then washed and resuspended for 1 min at 37° in fresh medium containing 1 mM levels of the labelled amino-acids listed at the bottom of the figure. The amount of radioactivity taken up is compared with the amount taken up by control cells, setting the latter at 100 per cent

serves for exchange and perhaps for all the mediated exit of the amino-acids from the cells, whereas site *A* appears to operate largely for entry. Thirdly, raising the temperature from 27° C to 37° C accelerates the entry of glycine and α-aminoisobutyric acid by about 3·5 times, whereas under the same conditions the Q_{10} of valine and leucine entry is only about 2·5.

The site serving best for the amino-acids with large hydrocarbon side-chains such as valine and leucine shows increased affinity with both the length and bulk of that side-chain. The drop-off in affinity is very sharp as the number of carbon atoms in the amino-acids falls below 5.

The other site, serving best for glycine and alanine entry, appears to discriminate against amino-acids with 5–6 carbon atoms, especially when their chains are branched. As the number of carbon atoms in a straight chain increases beyond 4, the affinity is again increased. This effect appears to account for the affinity of methionine for this site; the sulphur atom of methionine seems to be approximately equivalent to an additional methylene group in establishing affinity. One possibility being considered is that the *E* site, by the expenditure of energy, can be converted into the *A* site, thus increasing its affinity for certain amino-acids, including methionine, alanine and glycine. The reconversion of *A* to site *L* on passing the osmotic barrier of the membrane would cause the unloading of these amino-acids.

Preliminary results suggest that much the same pair of sites with overlapping affinities participate in amino-acid transport in other cells and tissues[7]. In the mature human red blood cell uptake appears to be largely limited to the *L* mediation[8].

SUPPRESSION OF INFECTIONS RESULTING FROM A DEOXYRIBONUCLEIC ACID VIRUS (VACCINIA) BY SYSTEMIC ADMINISTRATION OF 5-IODO-2′-DEOXYURIDINE

By PAUL CALABRESI, ROBERT W. McCOLLUM and PROF. ARNOLD D. WELCH

Departments of Medicine, Epidemiology and Pharmacology, Yale University School of Medicine,
New Haven, Connecticut

THE ability of 5-iodo-2′-deoxyuridine (IUDR or IDU) to inhibit plaque formation of vaccinia and herpes simplex viruses *in vitro*[1] led to investigations with animal and clinical trials which have demonstrated that IUDR is capable of arresting and curing herpes simplex infections of the cornea in both rabbits and man[2]. These observations have been confirmed and extended to related compounds[3] and other DNA viruses[4]. Since high local concentrations of drug can be achieved by frequent topical application, without systemic toxicity, the eye presents a unique site for therapy with potent anti-viral agents[2]. While this approach has demonstrated impressive clinical value[2,4], it is necessarily limited to ophthalmic and possibly other superficial infections. We have explored the feasibility of inhibiting DNA-viral disorders by the systemic administration of iodinated pyrimidine deoxyribonucleosides. This preliminary communication reports favourable results obtained with parenterally administered IUDR in the treatment of intradermal vaccinia infection.

The rationale for the design and synthesis of IUDR and 5-iodo-2′-deoxycytidine (ICDR) has been described[7–10], as have work on their mechanisms of action[10–12] and the results of initial clinical trials[13,14]. A brief summary of our present knowledge of these agents is important, nevertheless, for understanding of the anti-viral findings to be reported. Each of these compounds, originally synthesized and studied as potential anti-neoplastic agents, is converted enzymatically within cells into the 5′-monophosphate of IUDR (IUDR 5′P) and, presumably, to the di- and tri-phosphate esters. ICDR, a more soluble and thermostable compound than IUDR, must be deaminated, either before or after 5′-phosphorylation, to form either IUDR or its phosphorylated derivatives. These substances not only interfere with the utilization by cells of thymidine and its corresponding derivatives

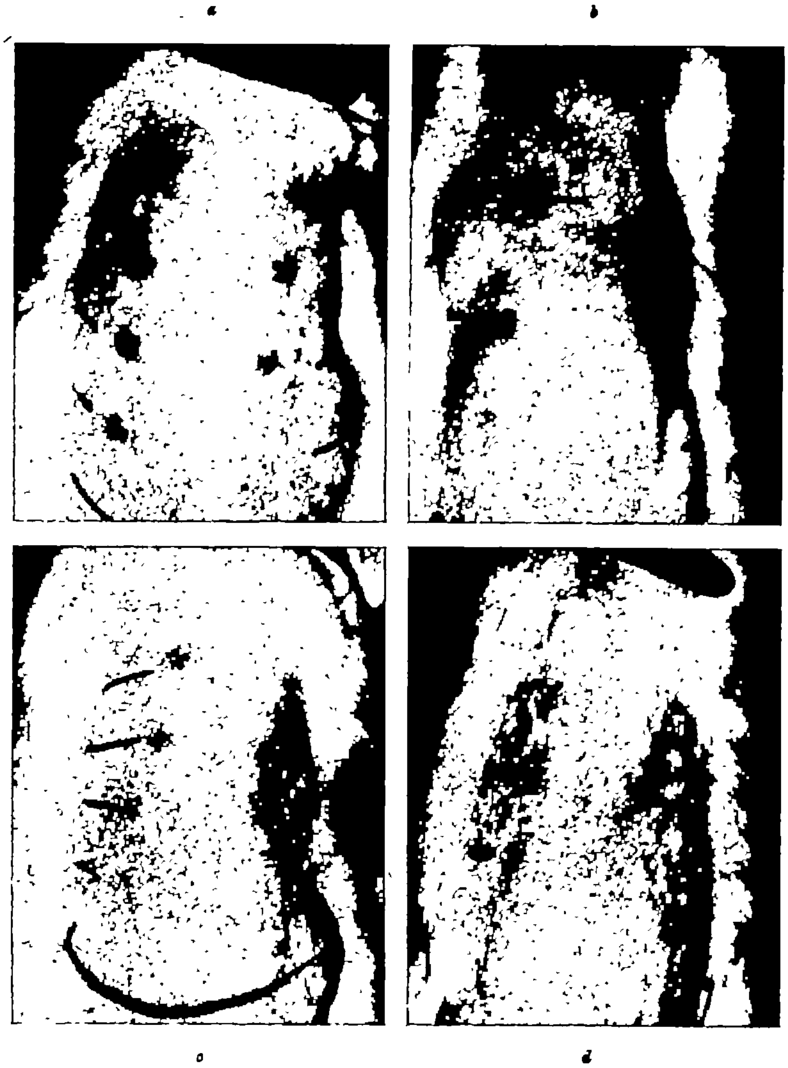

Fig. 1. Dorsal aspect of four rabbits, each representing one of the groups in Exp. 1, on the sixth day after para-spinal intradermal injections of vaccinia virus. Sequential inoculations of the virus preparation in ten-fold dilutions were started at the upper left, progressing downward (caudally), these were continued on the right, again progressing caudally. Although the inoculations were started with dilutions of 10^{-1} in the control animals (*a*), the sequence was begun with undiluted stock virus in the rabbits given IUDR (*b*, *c* and *d*). In each series the last position (lower right in each illustration) was used for vehicle control. The rabbits shown above received IUDR daily for 5 days according to the following dosage schedules (see also Table 1): *a*, control group – no IUDR; *b*, group I – 120 mg IUDR/kg once daily, *c*, group II – 40 mg IUDR/kg every 8 h; *d*, group III – 80 mg IUDR/kg every 8 h

but also lead to the formation of 'fraudulent DNA', in which IUDR replaces thymidine; either mechanism, or both, can inhibit normal replication of DNA and reproduction of cells. In addition, and perhaps with greater selectivity, the replication of DNA in certain viruses, or their cytopathogenicity, may be affected by the drug. The susceptibility of certain actively reproducing human tissues to these agents can lead to alopecia, stomatitis and hæmatopoietic suppression; these effects can be prevented by concomitant regional administration of small amounts of thymidine. Thus, in patients receiving IUDR parenterally in doses of 120 mg/kg daily for 5 days, regional protection has been achieved by daily administration of 4–8 mg of thymidine per kg[15,16]. Because of such toxic manifestations and the possible danger that incorporation of IUDR into DNA could lead to increased mutation rates, and conceivably, neoplastic change, we have administered these drugs systemically only to patients with advanced neoplastic disease; nevertheless, in potentially lethal diseases of man, caused by DNA viruses, such as vaccinia gangrenosum, smallpox, simian *B* virus and herpes simplex encephalitis, chemotherapeutic trial of IUDR deserves consideration.

The present work was initiated to explore quantitatively the significance of preliminary observations in two patients with advanced neoplastic disease, who were undergoing treatment with IUDR or ICDR and who had not been vaccinated against smallpox for at least 20 years. In one patient who was receiving a 2-h intravenous infusion of 80 mg of ICDR/kg daily for 5 days, the standard dose of a commercial calf-lymph smallpox vaccine was applied directly to the skin of both arms 1 h after the first intravenous infusion was begun, and the stratum corneum was penetrated 20–40 times with the sterile scarifying needle. The other patient was vaccinated in a similar manner 1 h after initiation of a total dose of 150 mg of IUDR/kg; the compound was administered as a continuous intravenous infusion for 36 h. In both patients, 'takes' were not obtained; however, revaccination with the same lot of vaccine, after an interval of 3 weeks, caused typical primary reactions in both individuals. In two other patients ICDR failed to prevent 'takes'; but in these subjects studies of the pattern of metabolic alteration of ICDR–^{131}I have indicated that an adequate conversion of ICDR to IUDR did not occur and significant antineoplastic effects were not seen[17]. On the other hand, in the patient given ICDR for 5 days in whom a primary 'take' was prevented by the drug, sustained blood-levels of IUDR were found, the typical toxic effects were seen and a marked regression in a carcinoma of the vulva occurred[17]. In two other patients, who were given IUDR by continuous intravenous infusion (300 mg/kg during a period of 72 h) and vaccinated as above, but with a different commercial vaccine prepared from infected chick embryo tissue, 'takes' were not prevented. Thus, it is clear that because of the complexities posed by possible differences in the potency of commercial preparations of vaccinia virus, the regimens of dosage of these drugs, as well as significant variations in rates of metabolic degradation and utilization of these compounds, more clinical studies are needed to determine the significance of these preliminary findings in man.

In rabbits infected intradermally with vaccinia and treated systemically with IUDR, the results have been much more definitive. The virus used was derived from a pool representing the fourth chick embryo tissue culture passage of a vaccinia strain previously carried through an unknown number of passages on the chorioallantoic membranes of embryonated eggs. Vaccinia hæmagglutinin used in the serological tests was prepared from the egg-passage line; serial two-fold dilutions of serum were challenged with four agglutinating units. In each of two experiments, twelve rabbits were injected intradermally in parallel para-spinal rows of inoculations of the virus preparations in sequential ten-fold dilutions ranging from undiluted stock virus suspension to 10^{-8}. IUDR was administered subcutaneously at sites well removed from the intradermal inoculations of vaccinia virus. The regimens of dosages of IUDR and the results obtained are shown in Table 1.

In both series the treatment increased the amount of virus required to produce dermal lesions; the degree of

	Control	5 per cent dextrose in water, 30 ml. every 8 h	none	(none)	$10^{-6\cdot8}$	$10^{-6\cdot3}$	$10^{-6\cdot6}$	1:320

* In Exp. 1 treatment with IUDR was started 2 h before, and, in Exp. 2, 6 h after virus inoculation (except in Group VI).
† Each group consisted of three rabbits without demonstrable vaccinia antibodies prior to inoculation.
‡ IUDR was administered in a concentration of 5 mg/ml. in solutions of 5 per cent dextrose in water adjusted to a pH of 8·6.
§ Calculated on the basis of an area of induration and erythema not less than 4 mm.
¶ HA-I, hæmagglutination inhibition. Figures represent average maximal serum dilution inhibiting 4 agglutinating units of antigen.
‖ Treated for only 3 days.

suppression of the response to the virus was greater with increasing dosages of IUDR. In addition, central necrosis in dermal lesions was greatly reduced (Fig. 1) and, even when IUDR therapy was not initiated until 48 h after inoculation with the virus (Group VI), a marked increase in amount of virus required to produce infection was observed. There was no evidence of drug toxicity, as indicated by weight loss, hæmatopoietic depression or change in physical appearance.

These preliminary studies suggest that adequate levels of IUDR in the skin can interfere with development of the dermal lesions ordinarily caused by vaccinia virus. Further investigations are in progress to determine the chemotherapeutic value of IUDR in generalized vaccinia infections produced in rabbits previously treated with adrenocorticosteroids. Studies of this nature, as well as comparative trials with isatin β-thiosemicarbazone and related compounds[18,19], will be necessary to determine the advisability of clinical trials of IUDR in generalized and potentially lethal infections with such DNA viruses as smallpox, vaccinia and simian B virus. In addition, studies of the effect of IUDR on the oncogenicity of a variety of DNA viruses (murine, simian and human) in animal species will be carried out.

PENICILLINASES FROM GRAM-POSITIVE AND GRAM-NEGATIVE BACTERIA: A THERMODYNAMIC DIFFERENCE

By DR. J. T. SMITH and J. M. T. HAMILTON-MILLER

Department of Bacteriology, Guy's Hospital Medical School, London

WORK in this laboratory indicates that considerable differences occur in the physical and chemical properties of penicillinases from different bacterial species, for example, in substrate specificity and affinity, inducibility, susceptibility to inhibition, cellular location and pH-activity characteristics. In addition to these, we have found a general difference between penicillinases from Gram-negative and Gram-positive sources, as regards the values of the apparent activation energies for the hydrolysis by them of the β-lactam ring in benzylpenicillin.

Cell-free penicillinase preparations were made from clinically isolated Gram-negative bacteria by disrupting the organisms in a liquid extrusion press[1,2] and sedimenting debris at 20,000g for 50 min. Staphylococcal penicillinase was prepared by growing organisms overnight at 37° C in infusion broth containing 0·5 μg/ml. of methicillin as inducing agent; the organisms were collected and washed by centrifugation and sodium p-chlormercuribenzoate added to 0·001 M to prevent further induction[3]. *B. cereus* was grown overnight at 37° C in infusion broth containing 5 μg/ml. of methicillin as inducing agent, organisms removed by centrifugation and the supernatant fluid used as the penicillinase preparation. *B. licheniformis* penicillinase was obtained from Wellcome Research Laboratories, Beckenham.

Rates of the hydrolytic cleavage of the β-lactam ring of penicillin G (at an initial concentration of 2 mg/ml., a sufficient concentration to saturate all enzymes tested) were determined at various temperatures by the hydroxylamine method[4]. An integrated form of the Arrhenius equation is $\ln\frac{k_2}{k_1} = \frac{A}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$, where k_1 and k_2 are rate constants at temperatures T_1 and T_2, A = apparent activation energy and R = the gas constant. Therefore, when the logarithms of the rate constants are plotted against the reciprocals of the absolute temperature a straight line is obtained, from which the apparent energy of activation can be calculated. The hydrolyses of benzylpenicillin, studied here, were found to be zero order reactions and hence the rate constants are equal to the reaction velocities, so these values were plotted as the rate constants. Activity-temperature data given by Royce *et al.*[5] and Novick[6] for *B. subtilis* and *Staph. aureus* 524 *SC*, respectively, were similarly processed. The value of 7,500 cal/mole for *B. cereus* is that quoted by Henry and Housewright[7], and was determined by the manometric assay. Preliminary experiments showed that induction of *Staph. aureus* and *B. cereus* penicillinases did not alter the value of their apparent activation energies.

The proportion of molecules in a system possessing a given energy can be calculated by evaluating the exponential term in the equation: $N = N_0 e^{-E/RT}$ (derived from the Maxwell–Boltzmann distribution law[8]), where N, number of molecules possessing sufficient energy to react; N_0, total number of molecules present; E, required energy-level; R, gas constant; T, absolute temperature (taken as 310° K). The rate constant for a reaction is proportional to the number of activated molecules. Thus, in this case the rates of reaction are also directly proportional to both the number of activated molecules and the exponential term $e^{-E/RT}$. Now if the energy E is the apparent activation energy, the corresponding exponential term can be used to measure the effect produced in a system by an enzyme which, by lowering the activation energy, increases the proportion of molecules possessing sufficient energy to react.

The exponential terms were calculated for each individual penicillinase, and the results are shown, together with the values for the energies of activation, in Tables 1 and 2. Energies of activation were also found for the non-enzymatic hydrolysis of benzylpenicillin in the presence of different buffers at different pH values[9]: these results, together with the values of the exponential terms, are shown in Table 3; the mean value for the activation energy (13,467 cal/mole) agrees well with that reported by Abraham and Newton[10] (14,500 cal/mole). The mean values of all the apparent activation energies are shown in Fig. 1.

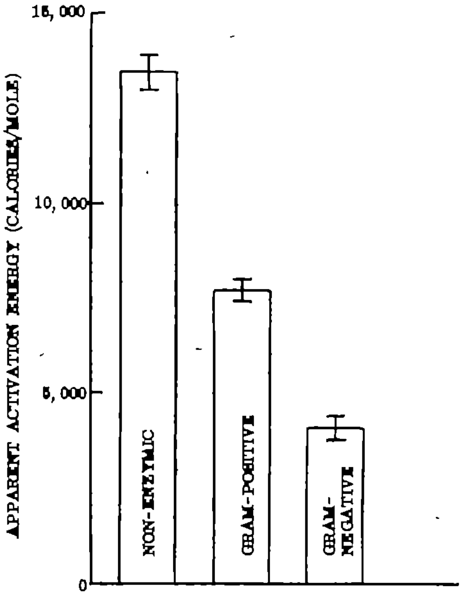

Fig. 1. Showing the relationships between the mean energies of activation ± *S.E.* for the non-enzymatic and penicillinase catalysed hydrolysis of benzylpenicillin

The results obtained were analysed statistically; the difference between the apparent activation energies of penicillinases from Gram-negative and Gram-positive organisms was significant at a probability of < 0·001 (t = 8·89 with 12 *d.f.*), and the difference in magnitude of the corresponding exponential terms was found to be significant at a probability of < 0·01 (t = 3·07 with 12 *d.f.*). As the mean exponential function derived from the apparent activation energies of penicillinases of Gram-negative organisms was 318 times the corresponding exponential function for Gram-positive organisms it follows that penicillinases from the former sources were more efficient catalytic agents than those from the latter sources. However, as only a relatively small number of penicillinases have been studied so far, it is too early to say if this is a general rule.

From the mean values of the exponential functions it was possible to calculate the increase, brought about by the presence of the enzymes, in the proportion of activated penicillin molecules as compared with the fraction present in non-enzymatic hydrolysis mixtures. This increase for each source of penicillinase was found to be: (*a*) using Gram-positive organisms $1·1 \times 10^4$ times; (*b*) using Gram-negative organisms $3·5 \times 10^6$ times; (*c*) using all penicillinases $1·8 \times 10^6$ times.

Further work is at present being carried out on the penicillinases produced by members of the Enterobacteriaceae, and reports have been[11,12] or will be made elsewhere.

We thank Prof. R. Knox and Dr. W. L. G. Gent for advice and criticism.

EFFECT OF HYPOXIA ON BRAIN GANGLIOSIDES

By J. A. LOWDEN* and Dr. L. S. WOLFE

Donner Laboratory of Experimental Neurochemistry, Montreal Neurological Institute, McGill University, Montreal

GANGLIOSIDES are a group of complex, acidic, water-soluble glycosphingolipids occurring predominantly in membrane constituents of a microsomal fraction from grey matter of vertebrate brain[1–3]. The presence of *N*-acetylneuraminic acid (NANA) distinguishes gangliosides from other brain glycolipids. Recent investigations indicate that gangliosides may be involved in the maintenance of the excitable state in cerebral tissues[4–9]. Our present work reports a decrease in the NANA content of isolated and purified gangliosides obtained from human and cat brains which were hypoxic before death.

Gangliosides were extracted from cerebral cortex by a modification of the tetrahydrofuran extraction procedure of Trams and Lauter[10]. Pieces of cerebral cortex were homogenized in 2 vol. of 0·01 M phosphate buffer, *p*H 7, and the mixture blended with 12 vol. of ice-cold tetrahydrofuran. This mixture was filtered on a Büchner funnel and the residue re-extracted with a further 3 vol. of tetrahydrofuran. The volume of the combined clear yellow filtrates was measured and 1/4 of this volume of ether added. The mixture was shaken vigorously and allowed to stand for 2 h at 0°–4° C. The lower phase was removed, the upper phase washed with 100 ml. of water, and the lower phase again removed. The combined lower phases were filtered and passed through an 'Amberlite *MB*-3' ion-exchange column, previously washed with 50 per cent ethanol. To the eluate 0·2 N barium hydroxide was added in the cold until the *p*H was between 10 and 11. 4 vol. of cold absolute ethanol (– 20° C) were added and the barium salts of the gangliosides allowed to precipitate overnight at 0°– 4° C. The precipitate was collected by centrifugation, washed with cold 90 per cent ethanol and suspended in 50 ml. of water. Sulphuric acid (1 N) was added, with continuous stirring in an ice bath, to bring the *p*H to 2·3. The mixture was brought to *p*H 7 with 2 M sodium carbonate and centrifuged at 10,000*g* to obtain a clear supernatant. The supernatant was passed through a fresh, water-washed 'Amberlite *MB*-3' column. To the cooled eluate, 1/10 vol. of 1 N hydrochloric acid was added and the solution placed at 0°– 4° C for 4 h. It was then dialysed in the cold for 48 h against four changes of 5 l. of deionized water. The sac contents were freeze-dried.

Gangliosides were isolated by this method from normal human cerebral cortex obtained at post-mortem within 6 h of death and from fresh specimens obtained at craniotomy. No significant difference was found in the composition of gangliosides from these two sources. Thus gangliosides are not altered in the first few hours after death. The extracted, unfractionated gangliosides are white, water-soluble powders containing 3·2–3·3 per cent nitrogen and less than 0·1 per cent phosphorus. No peptides, amino-acids, sodium or potassium were found. The NANA content of these gangliosides was 1·00 ± 0·05 μM/mg (6 preparations). The NANA content of gangliosides was not altered in brain specimens kept at – 20° C for several weeks before extraction, if they were cut for homogenizing while the brain was still frozen. Thin layer chromatography was carried out, using 100 μg samples of these gangliosides, on silica-gel plates, pre-washed with chloroform, and developed with chloroform/methanol/water (65 : 35 : 7 v/v/v). The plates were sprayed with 0·005 per cent 'Rhodamine-6*G*' in 80 per cent acetone and examined under ultra-violet light or with the aniline–diphenylamine reagent[11]. Five distinct spots were resolved in this system with R_F's of 0·06, 0·11, 0·19, 0·26 and 0·35 respectively.

Table 1. GANGLIOSIDES EXTRACTED FROM HUMAN BRAIN IN DIFFERENT PATHOLOGICAL STATES

Group	Diagnosis	NANA content μM/mg	Age/sex
1	Severe atherosclerotic vascular disease	0·88	73/M
		0·75	76/F
		0·72	83/F
		0·56	60/M
		0·89	67/F
2	Anæmic anoxia	0·71	57/M
		0·85	30/F
		0·88	60/M
3	Severe chronic respiratory disease	0·44	66/M
		0·78	67/M
4	Cardiac arrest and mechanical respiration	0·76	32/F
		0·53	3/F
5	Expanding intracranial lesion	0·75	45/F
		0 65	54/F
			Age-range (yr.)
Altered human gangliosides		0·73 ± 0·12(14)*	3–83
Normal human gangliosides		1·00 ± 0·05(6)*	14–88

* Mean value ± *S.D.* with number of cases in parentheses.

In the course of extraction of a large number of human brains, gangliosides from some specimens were found to contain considerably less NANA than our normal series (Table 1). Repeated extraction and re-purification of these abnormal gangliosides did not increase their NANA content. Furthermore, thin layer chromatography of these gangliosides showed the absence or marked decrease of the slowest moving spot (R_F 0·06). A common feature in the clinical history of the patients, from which the abnormal gangliosides were obtained, was the occurrence before death of some degree of local or generalized hypoxia. Age was not important as the normal series covered an equally broad range. The interval between death and post-mortem did not differ in the two groups and was never more than 6 h. Two samples of brain were obtained at craniotomy from one patient with a large intracerebral hæmatoma. Gangliosides isolated from an area of cortex, compressed locally by the hæmatoma, contained 0·75 μM NANA/mg. Gangliosides from a second sample from an area of the frontal lobe not compressed by the hæmatoma contained 1·02 μM of NANA/mg. In normal brain, gangliosides extracted from these two areas did not differ in NANA content. These findings suggest that hypoxic or anoxic situations in brain, regardless of cause, decrease the neuraminic acid content of gangliosides afterwards isolated and purified.

Further support for the theory that hypoxia or anoxia alters brain gangliosides was obtained from experiments with cats. Adult female cats (approximately 3 kg weight) were anæsthetized with 'Nembutal' administered in a single intraperitoneal injection. A Y-shaped tracheotomy tube was inserted and connected by one of the free arms to a mechanical respirator. The animal's head was fixed in a Horsley–Clark stereotaxic apparatus. A 6–8 cm midline incision was made in the scalp. Electroencephalographic leads were inserted into the skull over the sensory area of the brain, bilaterally. The reference electrode was attached to one ear. An electrocardiographic tracing was made between the left chest and the right fore-limb.

---

* Holder of a fellowship from the Queen Elizabeth II Canadian Research Fund.

After control tracings of the EEG and EKG patterns were taken, the tracheotomy tube was clamped for specified periods and the electrical recordings followed. At the end of the period of asphyxia, the tracheotomy tube was unclamped, the animal examined, and the respirator started, if necessary. The cranium was removed with bone rongeurs and the cerebral hemispheres lifted out immediately on the death of the animal or within 1 h of re-establishment of the airway, if the animal survived the insult. Removal of the cerebrum required about 5 min. Control animals were anaesthetized with 'Nembutal' and the brains then removed. Brain gangliosides were either extracted immediately or after storage at − 20° C.

Normal cat brain gangliosides contained 1·03 ± 0·01 μM of NANA per mg (Table 2). This value is similar to that for other species[3]. In the experimental animals, between 90 and 120 sec after clamping the tracheotomy tube there was complete loss of electrical activity over the brain. 4 min of clamping could be withstood by most animals and was followed by complete recovery of EEG and neurological responses within a few minutes of restoration of a patent airway. After 5 min of clamping, recovery was much slower and abnormal slow wave activity persisted long after the tracheotomy tube was unclamped. Animals subjected to 6 min or more without air did not survive for longer than 20 min following restoration of the airway. The NANA content of the gangliosides extracted from the brains of animals subjected to various periods without air was significantly lowered, as shown in Table 2. Further experiments are planned using nitrogen and nitrogen–carbon dioxide mixtures in a closed ventilating system connected to the tracheotomy tube.

The foregoing findings suggest that gangliosides are irreversibly altered in hypoxic or anoxic conditions. Li and McIlwain[4] recorded depressed resting membrane potentials in cerebral cortex slices in the absence of substrate under hypoxic conditions. Using similar preparations Hillman[7] found that some cells are more sensitive to these conditions than others, and suggested that some cells are permanently depolarized by hypoxia. The addition of the basic protein, clupein, hypopolarized cerebral cells in tissue slices. These cells could be repolarized by the addition of gangliosides. Thomson and McIlwain[8] were also able to restore the metabolic responsiveness of cerebral cortex slices to electrical pulses by a similar treatment. N-acetylneuraminic acid is the only acidic group in the structure of gangliosides. If part of the neuraminic acid occurring in gangliosides in the neuronal membranes is removed an irreversible alteration in the net negative charge of these membranes would be expected to occur. This change could well lead to a loss in excitability. A parallel situation has been demonstrated in erythrocytes where the removal of neuraminic acid by the enzyme neuraminidase leads to a marked decrease in electrophoretic mobility and a loss of surface negative charge[12]. The sensitivity of cerebral tissue to hypoxia and the irreversible nature of hypoxic changes may in part result from the removal of NANA from membrane gangliosides. Of interest here are the *in vitro* studies of Korey and Stein[13], who reported the degradation of gangliosides, only under anaerobic conditions, by a postulated gangliosidase.

Table 2. *N*-Acetylneuraminic Acid Content of Gangliosides Extracted from Normal and Asphyxiated Cats (mean ± *S.D.* with the number of animals in parentheses)

Time tracheotomy tube was clamped (min)	NANA content μM/mg ganglioside
0	1·03 ± 0·01(3)
5–6	0·80 ± 0·03(3)
7–8	0·62 ± 0·04(3)

EFFECTS OF HIGH PARTIAL PRESSURES OF OXYGEN ON FUNGI

By Prof. JOHN CALDWELL
Department of Botany, University of Exeter

In 1931, I postulated that high partial pressures of oxygen had a toxic effect on the enzyme systems in apple tissues[1]. A short paper describing the experiments then carried out was published many years later[2]. I showed[1] that the effect was specifically due to high oxygen pressures and not to actual pressure as such. For example, the output of carbon dioxide in 20 atm. of 5 per cent oxygen was substantially the same as that in 1 atm. of 100 per cent oxygen and no toxic effects of the high actual pressure were observed, though 20 atm. of 100 per cent oxygen was toxic to the tissues.

This view has been confirmed by many subsequent workers and the enzyme systems actually affected have been studied by others[3,4].

I also noted[1] that, whereas plant tissues which have become damaged in respiration chambers are normally attacked by fungi and bacteria giving a greatly increased output of carbon dioxide, in the tissues exposed to high partial pressures of oxygen there was no evidence of invasion by bacteria or fungi, despite the obvious damage. I suggested that high partial pressures of oxygen might have a toxic effect on these organisms also.

It was to examine this problem that the experiments reported here were carried out. If, in fact, fungal tissues and bacteria were destroyed by exposure to reasonably high partial pressures of oxygen this method of sterilization might be of some practical importance.

For the experiments a container of very much the same type as that used in the earlier experiments was made[1].

In the first group of experiments two fungi were used, namely, *Aspergillus niger* and *Penicillium digitatum*. The fungi were grown on 2·5 per cent malt agar on Petri dishes 9·0 cm in diameter. After inoculation the control plates were kept in a box at room temperature and at atmospheric pressure—four plates being usually kept as controls. The others were put into the container and oxygen passed in to expel the air. Thereafter the outlet valve was closed and further oxygen was added until the desired pressure was obtained.

At the end of each experiment the oxygen was allowed to escape slowly (during a period of about 15 min) to reduce the possibility of mechanical damage to the fungal tissues.

Growth of a colony was estimated by measuring its diameter before and after the experiments and, where possible, during them. This, it is realized, is not a very precise measure of growth since the mycelium in some instances, after exposure to pressure, seemed to be rather

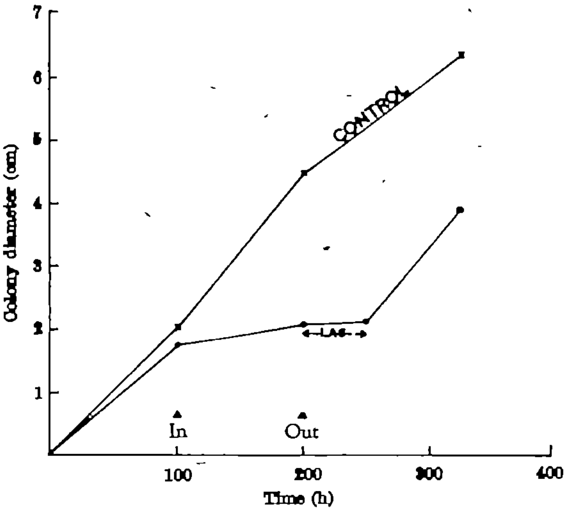

Fig. 1. Colony growth of *Penicillium digitatum* in air at 15 atm. pressure = 300 per cent oxygen

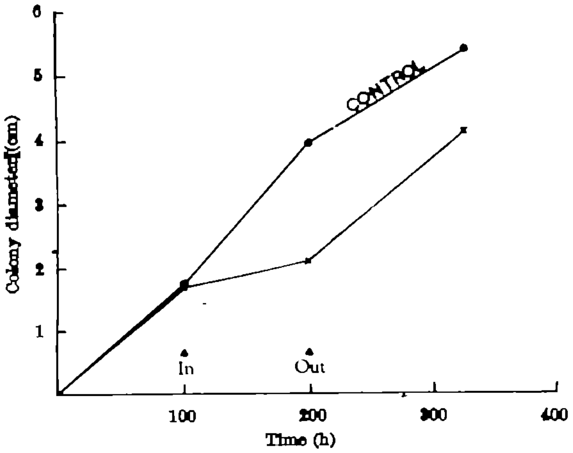

Fig. 2. Colony growth of *Aspergillus niger* in air at 15 atm. pressure = 300 per cent oxygen

below the surface of the agar, though later there was normal surface growth and in any event no allowance is made for the thickness of the mycelial growth. Within the limits of the experiment, however, the diameter of a colony seemed to give a reasonably accurate indication of the effect of the various treatments.

Various preliminary tests were carried out to ascertain whether rapid compression and decompression had any marked effect on the tissues or the agar medium, but in general no obvious effects were observed. Compressed air was used in the first group of experiments, and the growth-rate, both of the cultures exposed to pressure and of the controls, seemed to be normal. Small slits sometimes appeared in the agar at high pressures when decompression was very rapid, but they disappeared after an interval of less than 0·5 h. These were probably caused by gas bubbles.

Various gas mixtures were used at different pressures and with consequently different partial pressures of oxygen. In general, it was found that what controlled the effect on growth was again the partial pressures of oxygen and not the actual pressure of the gas to which the cultures were exposed. This confirms the early conclusions for apple tissue.

In the first set of experiments, using *Aspergillus* and *Penicillium*, the colonies were allowed to grow before the Petri dishes were put into the pressure-chamber, thus ensuring that the mycelium and not merely spores was exposed to the pressure.

After treatment at high pressures it was found that no growth had occurred in the treated colonies, while the controls had grown normally. After the lapse of some period of time, growth of the treated colonies began again. It was clear, therefore, that the effect of high partial pressures of oxygen was, in the case of these two fungi, to suspend the metabolic processes, but not to kill the tissues. In general, it was found that the higher the partial pressure or the longer the exposure to high pressure the greater the time-lag before growth recommenced. *Penicillium* seems more sensitive than *Aspergillus* in this respect.

Brown[3] reported that within wide limits oxygen pressure has little effect on the germination of spores or on fungal growth. This does not hold for partial pressures of oxygen above 100 per cent as growth was always considerably slower or was completely stopped in these circumstances. It is noteworthy that in *Penicillium* especially, some mycelial growth occurred at fairly low partial pressures of oxygen (for example, 3 atm. pure oxygen).

Figs. 1 and 2 show the effect of 15 atm of air (= 3 atm. oxygen) on the two fungi under discussion.

Aspergillus, as has been noted, seemed less sensitive to high partial pressures of oxygen than did *Penicillium*.

Clearly one or two questions still remained unanswered. It was not possible to establish whether growth under pressure stopped instantaneously (or almost so) or whether it continued for a shorter or longer period at a greatly reduced rate before it stopped completely. Nor was it possible in these experiments to determine the partial pressure of oxygen which actually halted the growth of the mycelium. In one experiment 8 atm. of air (1·6 atm. oxygen) seemed to kill the *Penicillium* mycelium after exposure for 500 h.

It was with the view of examining this latter effect that the experiments were continued using a different fungus, namely, a strain of *Phoma violacea* (Bertel) Eveleigh (syn. *P. pigmentivora* Massee), isolated in this Department.

In these experiments pure oxygen was used and the culture plants were put into the container as soon as the colonies had reached a diameter of about 1 cm. These experiments were carried out in a constant-temperature room at 25° C whereas the earlier series were conducted at laboratory temperature of about 18° C.

The results are given in Figs. 3 and 4. It can be seen that the effect of 2 atm. oxygen was very slight indeed. In 4 atm. oxygen, however, the lag is again roughly proportional to the period of exposure and five days exposure seemed to have no permanently deleterious effect. On

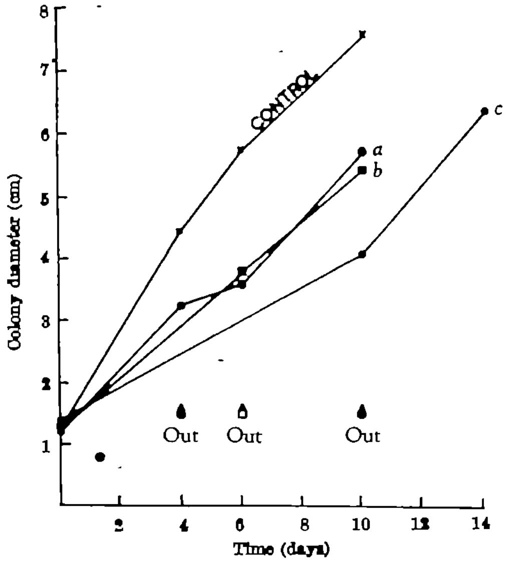

Fig. 3. Colony growth of *Phoma violacea* in 100 per cent oxygen at 2 atm. pressure

a, Four days under pressure; *b*, Six days under pressure; *c*, Ten days under pressure

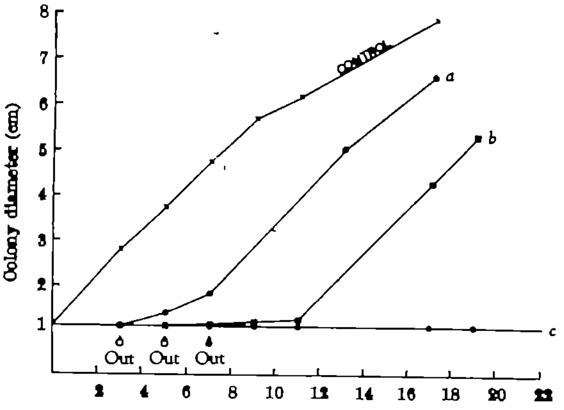

Fig. 4. Colony growth of *Phoma violacea* in 100 per cent oxygen at 4 atm. pressure

a, Three days under pressure; *b*, five days under pressure; *c*, seven days under pressure

the other hand, seven days exposure resulted in no growth of the colony even after a lapse of twenty-five days at normal atmospheric pressure.

In yet another series of experiments, five different fungi were used, namely, *Aspergillus niger*, *Penicillium cyclopium*, *Phoma violaceae*, *Aspergillus wentii* and *Merulius lacrymans*. These were inoculated on to 2·5 per cent malt agar plates on December 26 and kept in an incubator at 25° C until December 30, when the experimental plates were placed in the pressure chamber at 10 atm. 100 per cent oxygen, and the controls were put into a copper box at normal pressure. Both lots of material were kept in a constant temperature room at 25° C. All the colonies had grown during the period in the incubator. On January 9, after ten days exposure to pressure, the pressure was released slowly, and the plates returned to the incubator at 25° C. All the controls had grown normally, but the colonies under pressure had not increased in size at all. After the lapse of 8 days, however, apparently normal growth of the mycelium was observed in the colonies of *Aspergillus niger* but not in any of the others.

In a second experiment, the same five fungi were used in the same medium and with similar treatments. The period under pressure at 10 atm. pure oxygen was, however, reduced to seven days when the cultures were returned to air in the incubator at atmospheric pressure. *Aspergillus niger* and *Penicillium cyclopium* began to grow after the lapse of 6 and 10 days respectively, and did so apparently by the growth of the hyphæ and not of germinating spores. The other fungi did not grow.

In a third experiment with the same five fungi on the same medium and with similar treatment, after 10 days at 10 atm. pure oxygen the cultures were removed to the incubator. Only *Aspergillus niger* and some of *Penicillium cyclopium* cultures grew, the former after an interval of 8 days and the latter after an interval of 12 days. None of the others showed any sign of growth even after four weeks in the incubator.

It appeared, therefore, that 10 days' exposure at 10 atm. pure oxygen was just about critical for *Penicillium cyclopium* but that *Aspergillus niger* was substantially more resistant.

In yet another series of experiments, cultures of *Aspergillus niger* on the same medium were exposed to pressures of 10 atm. pure oxygen for 14 days and while no growth occurred during the period under pressure, growth of the mycelium began again after 10 days at atmospheric pressure in an incubator at 25° C.

Finally, a set of eleven culture plates with well-grown colonies of *Aspergillus niger* were left in 10 atm. of pure oxygen for 28 days before being returned to atmospheric pressure. None of these grew after this treatment, and not even the conidia grew on fresh agar plates, though conidia from control cultures germinated at once on a similar medium under the same conditions.

Preliminary tests by Dr. G. G. Pritchard show that there is a marked accumulation of pyruvic acid in the hyphæ of the fungi exposed to high partial pressures of oxygen, and that this pyruvic acid is removed after recovery and growth in air. It appears, therefore, that the effect of the high oxygen pressure is on similar enzyme systems in fungi to those in other plant tissues[6].

The effect of pressure on the metabolism of the fungi is being studied in detail and will be reported in another paper.

I thank Misses S. M. Robb and E. J. Bowers and Messrs. D. Tilney and M. E. J. Daft for their help in this work or in the preparation of this article.

ANTIPHONAL SINGING IN BIRDS AS EVIDENCE FOR AVIAN AUDITORY REACTION TIME

By Dr. W. H. THORPE, F.R.S.

Department of Zoology, Makerere College, Uganda, and Sub-department of Animal Behaviour, Department of Zoology, High Street, Madingley, Cambridge

IN a small minority of bird species, the females 'sing' as well as the males, and where this happens it is not unusual for there to be vocal elements in the 'courtship' displays, with the result that a rather haphazard and ill-timed duet may occur. However, in many tropical (and some sub-tropical) areas, both of the Old and New Worlds, a much more elaborate form of mutual vocal display is known to occur. In this type the notes of the male and female are different, the sexes alternating so as to sing antiphonally, often with extraordinary precision. This antiphonal singing of tropical birds is most in evidence in species which live in dense scrub jungle or undergrowth and it is a natural assumption that under these conditions mutual recognition and maintenance of contact by visual display is ineffective, and consequently mutual auditory display has tended to accompany it and in some cases take its place.

During a recent period of investigation in Uganda, I was enabled to make a start with the recording and observation of such antiphonal singing in three widely separated groups of birds, one non-passerine and two passerine, namely, the barbets (*Trachyphonus*—family Capitonidae), the fantail warblers, genus *Cisticola* (family Muscicapidae, sub-family Sylviinae) and shrikes of the genus *Laniarius* (family Laniidae, including Laniariidae). It is the singing of this last genus which raises problems of special interest since, in some species, both male and female have a considerable vocabulary which it seems they utilize so as to work out, with practice, a series of duet patterns by which presumably the two can recognize each other individually when out of sight. From preliminary study and recording it seems that each pair of a species such as *Laniarius aethiopicus* tends to develop a particular repertoire of duet patterns by which they can be dis-

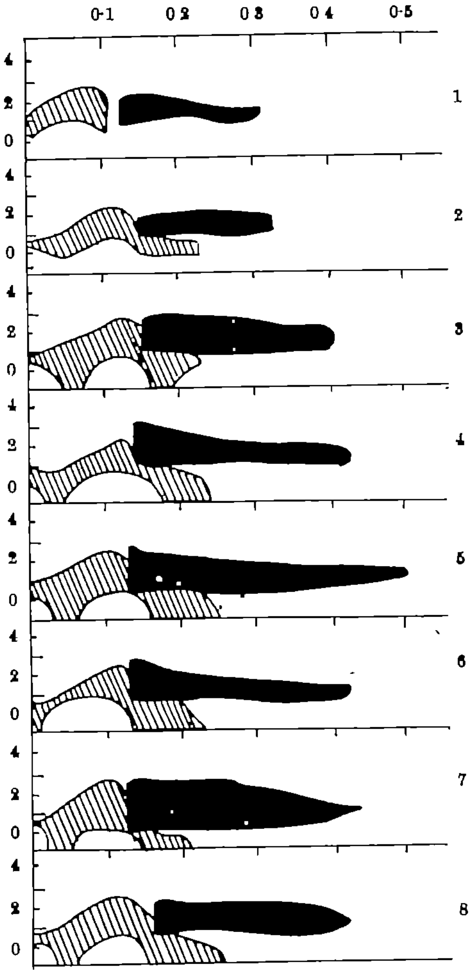

Fig. 1. Diagrammatic sound spectrograms of eight consecutive duet patterns of a pair of *Laniarius erythrogaster*. Old Entebbe, Uganda, March 6, 1962 The note of bird *A* is shown cross hatched; that of bird *B* in black. All higher harmonics and overtones are omitted. Vertical scales· frequency in kc/sec, horizontal scale, time (sec)

tinguished from other pairs in the neighbourhood. The problems which such a performance raises for the student of animal learning and particularly for those interested in vocal imitation and communication are extensive and intriguing. Research on these has only begun and it is hoped that, since I am fortunate to have as a collaborator Mr. Myles E. W. North of Nairobi, a highly expert ornithologist and recorder, it will be possible in due time to carry out a useful field and experimental study of these matters. However, during the first steps of this work some data were obtained which seem to throw new light on an interesting problem in avian physiology and this is accordingly being presented in outline now.

In one of the shrikes studied, *Laniarius erythrogaster*, the black-headed gonolek, the duet is extremely simple. The first bird, presumably the male, makes a 'yoick'-like sound which is followed immediately by a tearing hiss-like sound from the second bird (Fig. 1). In all the birds so far heard (three species of *Laniarius*, one of *Cisticola* and the *Trachyphonus*), the timing of the singing is normally so perfect that in no case would one suppose that two birds were involved unless one sees them or until one happens actually to come between them and hear the sound coming from two different directions. In the particular case of *L. erythrogaster*, a number of observations led me to suppose that the individual peculiarity of the duet was expressed not in peculiarity of pattern, for the bird apparently lacks the ability to vary this, but in a very precise and exactly maintained time-interval between the contributions of the two sexes. The precision of this time-keeping at once raises questions of the auditory reaction time as an expression of the powers of temporal discrimination of the avian ear. There is already circumstantial evidence for supposing[1,2] that the speed of response of the avian ear must be of the order of ten times that of the human ear. The reaction time of human beings, the 'personal equation', has been a concern of psychologists since the famous case, in 1795, when Maskelyn, head of the Greenwich Observatory, discharged an otherwise capable assistant because of a habit of recording all transits about half a second 'too late'. The study of human reaction to an auditory stimulus commenced in the 1860's with the work of a Swiss astronomer Hirsch and was quickly followed by a Dutch physiologist Donders in 1868. Since that time there has been a great deal of work by applied psychologists and physiologists on human reaction times, but I am aware of no information as to the bird's ability in this respect.

In the case of human beings it has been found that in studies in which the subject has to respond by pressing a key, the reaction time to a visual stimulus is of the order of 200 msec, and that to an auditory stimulus of 150 msec. Donders[3] found that if the stimuli used were simple speech sounds and the subject had also to respond by making the same or a similar speech sound, the reaction time was longer, varying according to conditions as follows. In experiment type *A*, the stimulus was always the sound 'ki' and the response also was always to be 'ki'. In experiment type *B*, the stimulus was any one of five syllables and the subject had to respond with the same syllable. In experiment type *C*, the stimulus was again any one of five given syllables but the subject had to respond only to the sound 'ki', using this syllable as his response. Under these conditions the results were found to be as follows: experiment type *A*, 197 msec; experiment *B*, 285 msec; experiment *C*, 243 msec. Modern work on the subject has been summarized by Teichner[4]. Among a number of conclusions he shows that simultaneous stimulation of more than one sense modality produces faster reaction times than stimulation of just one. On the other hand, successive stimulation of different senses produces slower reaction times than stimulation of a single sensory channel. Broadbent and Gregory[5] found that if the verbal response was compatible with the stimulus, in the sense that the subject had to respond by making the same sound as the stimulus, the mean response time was 284 msec, with a *S.D.* of 55·4 msec, whereas if the response was incompatible, that is to say, the subject had to reply with a sound different from that of the stimulus (as does *Laniarius*) the reaction time rose to a mean of 444 msec, with a *S.D.* of 31·1 msec.

Laniarius erythrogaster is of interest in that it is a species which habitually duets in extremely dense foliage and it seems that for a great proportion of the time the birds must be out of sight of each other. The complicating element of a visual stimulus is thus often ruled out. Fig. 1 shows sound spectrographs of a consecutive series of eight duets of a pair of *L. erythrogaster* recorded at Old Entebbe, Uganda, on March 6, 1962. The fundamentals only are shown, the harmonics having been omitted from Fig. 1. The method is accurate to 1·5 msec. Table 1 shows the timing of these eight consecutive duets. Column 1 indicates the duet series, column 2 shows the time in seconds at which the note of bird *A* (the initiator) commences and the figure following, in brackets, shows the time in seconds which has elapsed since the previous note of bird *A*. This figure provides us with what psychologists call the 'fore-period', or amount of warning which the second bird may have in the task of giving its reply. It will be seen at a glance that the calling of bird *A* is not markedly regular, yet in spite of this the reaction time of bird *B* remains extraordinarily constant. It is clear from the study of the sound spectrograms of this and other similar series of duets, of this and other species, that the second bird is taking its time from the start of

Table 1. Timing of Eight Consecutive Duets of a Pair of *Laniarius erythrogaster*

Duet No.	Time (sec) at which note of bird *A* commences	Reaction time of bird *B* (= time in msec between start of the note of *A* and that of *B*
1	0	125
2	2·5 s. (2·5)	145
3	5·7 s. (3·2)	150
4	10·5 s. (4·8)	160
5	15·0 s. (4·5)	150
6	19·3 s. (4·3)	150
7	23·7 s. (4·4)	125
8	29·3 s. (5·6)	150
	S.D. of reaction time	12·6

The figures in brackets show the time in sec since the previous note of bird *A*. This could be regarded as the 'fore-period' for bird *B*. (Old Entebbe, Uganda. March 6, 1962).

the note of the first bird. This is what happens in human beings; for it has been shown[6] that the human subject begins his response as soon as he hears the first phoneme, without waiting for the completion of the letter or number, or whatever the signal may be. As Table 1 shows, the mean reaction time of the bird *B* in this series was a little more than 144 msec, with a *S.D.* of 12·6 msec. This mean reaction time is the fastest yet found for any of these duetting birds, but this speed is not a species-characteristic. As has been indicated here, different pairs of *erythrogaster* may show different reaction times; but once a pair gets under way in a series of duets, the second bird maintains a constant response time, even though this may be very much longer than the minimum possible. Thus in another series recorded by Mr. Myles E. W. North at Entebbe a few months previously, the mean reaction time over a series of seven consecutive duets was 425 msec, but the standard deviation (4·9 msec) was less than that of the birds we have just been discussing. It seems from this that this species must have an extremely precise time sense, the accuracy of which does not decrease even if the response time is extended by a factor of 4. I am not aware of any auditory reaction-time experiments with humans in which the standard deviation is less than about 20 msec.

Although the figures given in Table 1 show a minimum reaction time of 125 msec, it may well be that even shorter times are possible, although they have not been recorded. In fact it is clear that the reaction time of this individual is, if anything, an overestimate since no allowance has been made for the time taken for the sound to travel from one bird to the other. Any estimate of this figure is bound to be somewhat speculative. I think in general it is safe to assume that the birds were about equidistant from the microphone, so no differential need be allowed for in this respect. I have certainly heard these birds duetting and apparently keeping excellent time when they must have been about 20 yards (18 m) apart. Assuming the speed of sound to be 1,130 ft./sec (344 m/sec), we should have to allow 53 msec for the sound to reach bird *B*. In that event, the true mean reaction time in this instance would have been 90 msec and the shortest 72 msec. To be on the safe side in this particular case and to assume that the birds were only 10 ft. (3 m) apart would involve a correction to 135 msec mean and 116 msec minimum.

L. erythrogaster is from this point of view the most interesting of the species so far studied since one can often be virtually certain that the birds are unable to see each other. On the human analogy, this might have been expected to have lengthened the reaction time since Todd (1912; ref. in Teichner[4]) found the reaction time to combined sound and light was not only faster than to light alone but also faster than to sound alone. I have, however, recorded a long series of responses of Chubb's Cisticola (*Cisticola chubbi*) and D'Arnaud's barbet (*Trachyphonus d'arnaudii*), and have not found a response time as fast as that of *L. erythrogaster*. In the case of *Cisticola chubbi* a series of six consecutive duets, recorded when the birds were in sight of one another, gave a mean reaction time of 396 msec but with the remarkably small standard deviation of 2·9 msec—about ⅛ that of which a human would be capable in similar circumstances.

It is to be hoped that it may one day prove possible to keep these birds in captivity under conditions so good that they develop their duets normally. If this can be done it should be feasible to establish a number of points much more accurately than is possible at present. Although it should be possible with a Skinner box type of apparatus to secure in, say, a pigeon, the action of pecking in response to a sound stimulus at the lowest possible reaction time by steadily reinforcing for a quick response, this never seems to have been done and virtually nothing in the way of experimental investigation of the whole animal has been carried out with birds. With any species other than these duetting shrikes it would probably be very difficult indeed to secure a regular vocal reaction in minimum time as a response to sound stimulus. Although we cannot do more than guess at the physiological basis for the rapid and accurate response of this bird, a response about three times faster and much more accurate than that of which a human being is capable in similar circumstances—and with a striking independence of fore-period—it is perhaps plausible to assume that the performance is primarily the expression of superior powers of the avian ear in the matter of time discrimination.

I thank Prof. L. C. Beadle, professor of zoology at Makerere, for the hospitality of his Department and of Makerere University College during the first three months of 1962.

SEASONAL VARIATIONS OF AVIAN AND HUMAN METABOLIC ACTIVITY IN RELATION TO THE DAYLIGHT/DARKNESS RATIO

By D. R. BARBER

Lamacraft, Darnell Close, Sidmouth, Devon

FOR the past three decades it has been known from the work of N. Rollin[1] and others that the dawn song of many different species of passerine birds is subject to wide fluctuation of the time of onset for individual birds within each group.

Nevertheless, by examining the results for each species collectively, a systematic difference in the times of onset of their dawn song is revealed. Thus it is possible to allocate to each species a characteristic 'dawn penetration' (conveniently expressed in terms of the angular position of the Sun below the horizon at the time of onset of dawn song) that is repeated with great regularity from year to year at similar phases of the breeding cycle.

As examples of the wide range of dawn penetration actually observed we may cite two species, *Alauda arvensis* L., and *Fringilla coelebs* L. While the former is consistently an early songster, with a mean dawn penetration of −9°, the latter is far more lethargic with a dawn penetration of only −2°, many birds of this species failing to commence song before sunrise. There is thus a dawn penetration specific for each species lying within the broad interval, −18°–0° solar depression, namely, from the beginning of astronomical twilight to the end of dawn.

On posing the question: How do such differences occur among the different species?, the probability of finding a satisfactory answer would appear highest if the problem is considered from the point of view of metabolic activity. As Rollin[3] has already pointed out, the amount of singing performed by an individual bird is related to season, phase of sexual cycle, development of gonad and endocrine activity, as well as to several meteorological factors. But, overriding these sources of variable behaviour, there is evident in the timing of dawn song an instinctive act linked in some complex manner with the bird's basal metabolism. Such response may be used, under controlled conditions, as a reliable, though indirect, measurement of metabolic activity in the particular avian species under observation.

In the investigation now to be described the most suitable species for the test was *Erithacus rubecula* L., and this for the obvious reason that, of all our resident song-birds, Redbreast alone sings at dawn with great regularity throughout each of the four seasons, save for a brief respite in late summer.

The large collection of observational data used in the analysis which follows constitutes one section of a general study of dawn-song made at Sidmouth, over a long period, for six representative species indigenous to the district. This had for its aim the accumulation of new facts concerning the effects of meteorological and other external factors on the degree of sky brightness at the time of onset of singing.

Analysis of the raw data for *E. rubecula* has revealed a marked influence of the daylight/darkness ratio (in computing this ratio, the times of sunrise and sunset at an altitude of 65 km above the Earth's surface, namely, 8° solar depression, were used; this depression angle corresponds to the observed mean dawn/dusk penetration for *E. rubecula*) on the observed dawn penetration, an effect that persists after applying corrections to the 481 observations for the combined influence of cloud-cover, ambient air temperature, wind force, barometric pressure and atmospheric humidity.

On plotting the observed sky brightness, *B* (on a logarithmic scale) as ordinate, and the log ratio (hours of daylight/hours of darkness) as abscissa, a hysteresis loop is obtained as in Fig. 2*b*. Plotted points refer to group mean values of log *B* for each of the twelve months enumerated, I . . . XII. The mean standard error of a single ordinate value is indicated in the figure by the vertical bar alongside the scale.

The unexpected nature of the relationship between the aforementioned parameters suggested an attempt to ascertain whether or not basal activity in man is also affected in like manner. For this investigation it appeared likely that the simplest and most reliable index of basal metabolism readily available for daily measurement is the pulse. Accordingly, daily records of the radial pulse, with myself as subject, were commenced in March 1959; and these have been continued without intermission.

Since it was realized that significant changes are likely to occur in the pulse-rate records arising from the operation of a variety of conditioning factors—some psychological, and others physical, or physiological, in origin—particular care was taken to ensure so far as was possible a standard pattern of behaviour immediately prior to each daily count. It was at first thought that standardization could best be achieved by making the daily measurement of pulse rate in the first few minutes after waking from the night's rest. However, preliminary tests soon showed that, for this particular subject, a longer post-waking period was more conducive to reproducible counts, especially so if the period was one of moderate indoor exercise.

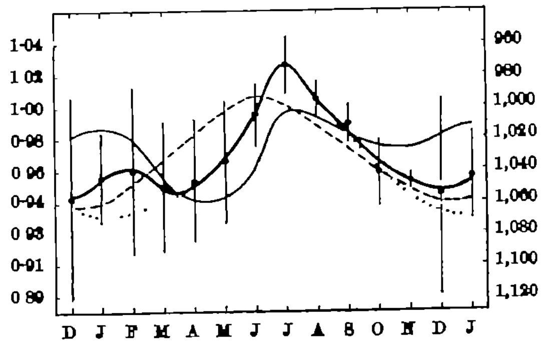

Fig. 1. Observed annual variation of basal metabolism in man (derived from measurements of basal pulse), bold curve. Dotted portions of the curve indicate the expected profile if the secondary maximum is eliminated. Continuous, ——, and broken, - - - lines represent semi-annual and annual components, respectively

Accordingly, the following procedure was adopted. At each daily session, commencing about 1 h after rising at 0640 ± 5 min G.M.T., the subject sits in a chair facing east while a total of one hundred pulse beats is timed with an accurately regulated chronometer to within ± 0·5 sec. From this record, the value of the mean interval, τ, between successive pulse beats is derived, and measured to the nearest millisecond. The *S.E.* of a single measurement of τ is 10 msec, or ~ 1 per cent of the actual value. Ambient room temperature, and prevailing weather conditions, are noted alongside each entry of τ in the log-book. If, for any reason, it is known beforehand that the pulse-rate is likely to be affected on a particular occasion, the record for this date is entered in the normal way together with an explanatory note; but it is rejected in any subsequent analysis of the comprehensive records.

In the discussion which follows, basal metabolic activity is measured by the reciprocal ($1/\tau$) of the mean pulse interval.

Since the data thus obtained now cover more than three complete 12-monthly periods, it has been possible to compute a series of provisional monthly mean values of τ with their standard errors to include the entire period of March 1959–February 1962. These results are presented graphically in Fig. 1, the vertical bar through each monthly mean value denoting the attached standard error. A marked annual variation of basal metabolic activity is shown by the bold curve passing through the experimental points. Characteristic features of this variation are the sharp primary maximum centred on mid-July, and flanked on either side by shallow minima centred on March–April, and mid-December respectively, and a secondary maximum of activity in mid-February that may, or may not, prove to be real.

The reality of the primary maximum and minimum present in the curve of annual variation has been confirmed statistically by a Student's *t*-test. The relevant data for this test are summarized in Table 1.

Table 1

Year	1959	1960	1961	Mean value (msec)
Maximum monthly value	1,052	1,046	1,098	1,065
Variance	−13	−19	+33	
Minimum monthly value	950	986	984	973
Variance	−23	+13	+11	

The mean range is +92, and with four degrees of freedom the estimated standard deviation is equal to 17·46. Thus 't' = + 92/17·46 × $\sqrt{2/3}$ = + 6·46, a value which is significant at the 1 per cent probability-level. The reality of the primary annual variation of τ is thus confirmed.

The secondary maximum of basal activity, prominent in both the 1959 and 1960 data, cannot be traced with certainty in the later 1960–61 records. Should future observations fail to confirm its presence, the annual variation would then be expected to follow those portions of the smoothed curve that are shown dotted in Fig. 1. The two dominant features of the annual variation remaining are the sharp maximum in July and the shallow minimum in December.

If, however, subsequent results confirm the correctness of the provisional curve, a combination of an annual with a semi-annual component is suggested.

The annual component, the curve of fluctuation of which is shown by the broken curve in Fig. 1, may be expected to follow the seasonal change of solar distance and altitude, taking the form represented by the equation $\tau_\gamma = \tau_0(1 - \alpha\gamma)$, where $\gamma = \cos\psi \times (1/\rho^2)$, ψ being the solar zenith distance, and ρ the solar distance modulus. Both τ_0 and α are empirical constants. For the curve of Fig. 1, $\tau_0 = 1047{\cdot}5$, and $\alpha = 0{\cdot}173$.

On subtracting the annual variation from the observed variation, a semi-annual fluctuation of τ is disclosed. This follows a curve denoted by the thin, continuous line in Fig. 1.

Both winter and summer maxima have approximately equal values (τ = 1,008 ± 5 msec); but the intervening minima are quite dissimilar, the corresponding values of τ being 1,063 and 1,027 msec, respectively.

Of particular interest in the present investigation is the possibility of a relationship between human basal metabolism (as measured here by the index, $1/\tau$), and the seasonal changes that occur in the daylight/darkness ratio, R, already defined.

To ascertain whether such a relationship exists, reciprocals of the smoothed monthly values of τ obtained from the bold curve of Fig. 1 were plotted against corresponding values of log R. The result was a looped curve (Fig. 2*a*) which, although inverted, bears some resemblance to the curve obtained from the unpublished dawn-song data for *E. rubecula* previously mentioned. This latter curve is reproduced in Fig. 2*b* to the same log ratio scale so as to facilitate a direct comparison. The average *S.E.* of a single ordinate value is indicated in both diagrams by a vertical barred line alongside the appropriate scale. Monthly sequences are indicated by the Roman numerals I–XII.

It is readily seen that the 'hysteresis loop' for *Homo sapiens* is a much more open one than that for *E. rubecula*. Owing to the far greater asymmetry in the ascending and descending branches of the first-mentioned curve, the observed difference between the respective values of τ, at log R = 0·25, for example, is as much as 43 msec, or about 4 per cent of the mean value.

An inspection of this curve shows a higher level of activity to persist in the period during which the value of log R is falling, namely, from July to October. An asymmetry of this type could result from the incidence of enhanced solar ultra-violet radiation during the months immediately preceding the afore-mentioned interval.

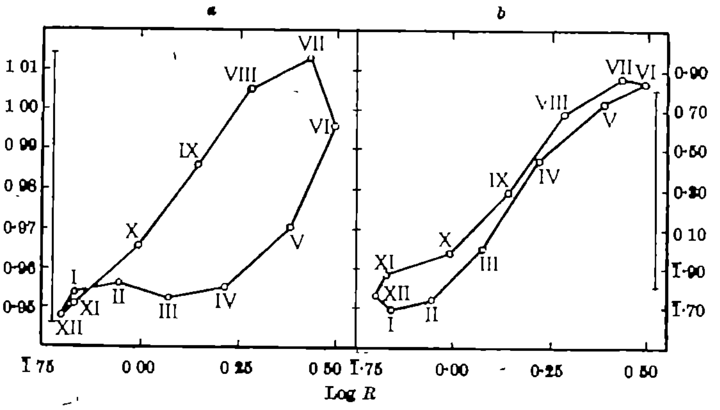

Fig. 2. Hysteresis loops obtained by plotting (*a*), $1/\tau$ for man, and (*b*) log B for *E. rubecula*, versus log ratio (daylight hours/hours of darkness). The relevant *S.E.* is shown by the vertical bar alongside ordinate scale

By contrast, the 'hysteresis loop' for *E. rubecula* suggests a greater song activity in the spring and early summer when the value of log R is rising. This is followed by a spell of lowered activity in late summer and autumn. Partially at least, this sequence may be explained by reference to the avian breeding cycle, since sexual maturity is reached just at that time of year when the rate of increase of the daylight/darkness ratio is most rapid.

When taken together, the results just described—referring as they do to a natural environment in both cases—suggest that the rhythmic seasonal fluctuation of natural illumination exerts a control of basal metabolic activity in both man and birds that is certainly less simple than the type of light control already demonstrated for several different species of birds[3] and mammals under controlled artificial conditions in the laboratory. In experiments with *F. coelebs* L., Thorpe[4] has noted, however, that the time of onset of artificially stimulated song is more nearly related to the rate of change of artificial illumination than to the total period of illumination to which the bird is exposed.

In conclusion, the strictly provisional nature of the results for the human subject must be emphasized. It cannot be too strongly stressed that, before any far-reaching conclusions can be drawn from the results of the investigation described here, much more data are needed to construct a definitive curve of annual variation of the human pulse. Not until then will it be possible to correct the raw experimental data for this particular source of observational scatter; and afterwards to examine the corrected daily values of τ for any residual effects that may then be evident.

Meanwhile, it is thought that the novelty of the experimental approach to this problem alone justifies the publication of a certain amount of information not previously available.

EFFECT OF GIBBERELLIC ACID ON THE PRODUCTION OF PRODIGIOSIN BY *SERRATIA MARCESCENS*

By PRENDIS O. BENNETT and HORACE D. GRAHAM

Carver Foundation, Tuskegee Institute, Alabama

INVESTIGATIONS of the effect of gibberellic acid on micro-organisms are few. Stowe and Yamaki[1] state that "no convincing action of the gibberellins has yet been shown on any organism except higher plants". Some authors have claimed that bacteria and fungi are not affected by gibberellic acid, while others have suggested that these substances are antagonistic to several fungi[2]. Inhibitory effects on the alkaloid content of and spore

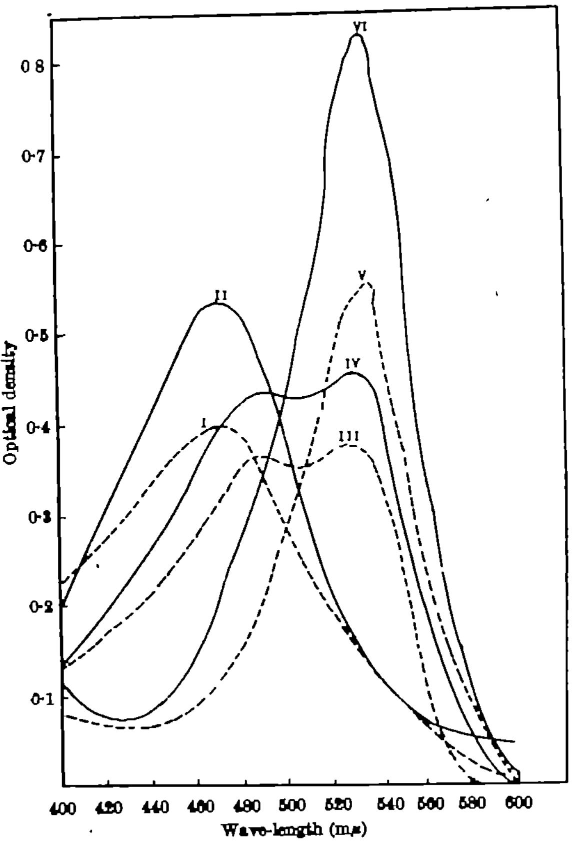

Fig. 1. Absorption spectra of authentic and extracted prodigiosin. ——, Authentic ; – – –, extracted. I and II, in absolute ethanol + sodium hydroxide ; III and IV, in absolute alcohol + water ; V and VI, in absolute alcohol + hydrochloric acid

formation by ergot, a parasitic fungus, have recently been reported by N. I. Ostrovskii *et al.*[3]. Lu *et al.*[4] have reported varying effects of gibberellic acid on soil micro-organisms, particularly the *Azotobacter* types. In their work, terminal respiration, nitrogen fixation and cell numbers were found to be increased under the influence of added gibberellic acid. Decomposition of gibberellic acid in the soil was also reported. The most recent experimentation on micro-organisms dealt with *Azotobacter indicus*, which Greenberg and Tirpak[5] found to be stimulated by gibberellic acid. It was implied that the effect might be a complex physiological one.

This article is concerned with the effect of gibberellic acid on the production of the blood-red pigment, prodigiosin, produced by *Serratia marcescens*. This pigment has attracted much interest recently because it is thought to be the only naturally occurring tripyrrylmethene, and, as such, its biosynthesis may possibly be related to the biosynthesis of the porphyrins[6].

Serratia marcescens, strain Nima, obtained from Dr. Robert P. Williams, Department of Medicine, Baylor University, Houston, Texas, was used. The organism was grown on a modification of the medium of Bunting[7], containing: glycerol, 0·5 per cent; dipotassium phosphate, 1·0 per cent; ferric ammonium citrate, 0·005 per cent; magnesium sulphate, 0·05 per cent; and sodium chloride, 0·05 per cent. The medium was sterilized by autoclaving for 10 min at a pressure of 15 lb. When a solid medium was needed, 1·5 per cent agar was added.

For comparison, a sample of prodigiosin, supplied by Parke, Davis and Co., was used. For convenience, this has been named 'authentic prodigiosin'. In order to compare the spectral characteristics of this so-called authentic prodigiosin and that of the laboratory acetone-extracted pigment, spectral curves of each were prepared. The supposedly pure, authentic prodigiosin was dried for 12 h in a vacuum oven at 40°. A stock solution was then prepared by weighing out 0·25 mg of the substance on an analytical balance, dissolving it in absolute ethanol and making the volume up to 100 ml. in a volumetric flask. Spectra of the acidic, basic and neutral solutions were therefore needed. 10 ml. of stock solution was added to each of three 'Pyrex' glass-stoppered tubes. 1 ml. of 1 N hydrochloric acid was added to the first tube, 1 ml. of 1 N sodium hydroxide to the second tube and 1 ml. of water to the third tube in order to obtain acidic, basic and neutral solutions, respectively. Distinct colours were developed for each of the solutions; acid red, base yellow and neutral, brown. The optical density of each solution was measured over the wave-length range of 400–600 mμ by the use of the Coleman universal spectrophotometer. Readings were begun approximately 1 min after colour development for each solution. A similar procedure was followed for the extracted substance except no actual weighing was done since not enough pigment was extracted. The extractions were taken up in the appropriate solution after evaporation and pooled. Fig. 1 summarizes the results, which compare well with those obtained by Williams *et al.*[8].

Since the acidic solutions of both the authentic and the extracted prodigiosin exhibited sharp spectral peaks (absorption maxima at 535 mμ), it was decided to use an acidic solution in the preparation of the standard curve. 9 ml. of hydrochloric acid–ethanol solution (0·10 N with respect to the acid) was placed in consecutive 'Pyrex' glass-stoppered test-tubes containing 1 ml. of prodigiosin dissolved in absolute ethanol. The final concentrations of prodigiosin ranged from 0 to 2·5 μg/ml. of the hydrochloric acid–ethanol solution. The optical densities of the colours developed were measured with a Coleman universal spectrophotometer, model 14, at 535 mμ. The results are shown in Fig. 2.

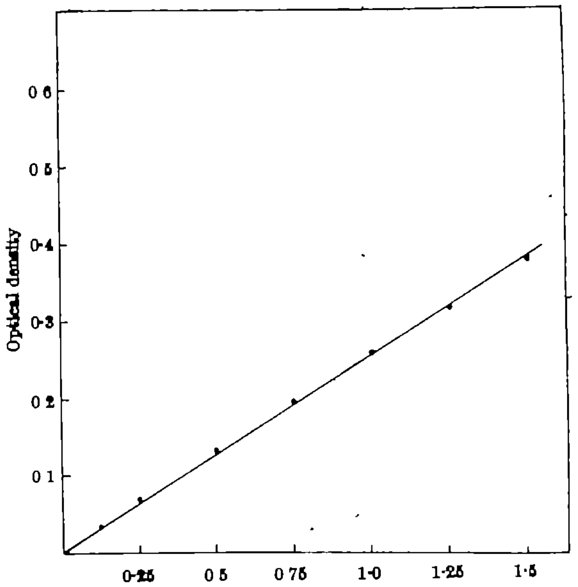

Fig. 2. Standard curve of prodigiosin in 0·09 N ethanol–hydrochloric acid

1 ml. of an 8-h culture of *Serratia marcescens* grown at 30° C, containing 1 × 10^8 cells, was inoculated into 5 ml. of double-strength sterile culture medium. Aqueous solutions of potassium gibberellate (75 per cent potassium salt, Nutritional Biochemicals Corp., Cleveland, Ohio), sterilized by filtration, were added to give final concentrations of 5–1,000 p.p.m. The final volume of all culture tubes was 10 ml., attained by adding distilled

water, where necessary. The cotton-plugged inoculated tubes were incubated at 30° C for varying periods of time.

After incubation, the pigment produced was extracted by a modification of the method of Williams *et al.*[9] and then determined spectrophotometrically. The samples were taken from the incubator and transferred to 300-ml. Erlenmeyer flasks with 35 ml. of acetone. The pigment adhering to the sides of the tubes was dislodged by the use of a bent spatula and rinsed out with a portion of the acetone. After remaining in the acetone solution for 6 h, which was established to be the most advantageous time for optimum pigment extraction, the samples were filtered under vacuum using medium sintered glass filters. To ensure quantitative transfers, the flasks and cell debris were washed with two 5-ml. portions of acetone. After this, 80 ml. of ligroin was added to each sample in a different separation funnel which was stoppered and shaken vigorously to permit extraction of the pigment by the ligroin from the acetone. 350 ml. distilled water was immediately added, which created a separation of the ligroin-pigment layer and the acetone–water layer. After 5 min the acetone–water layers were drawn off and discarded, while the ligroin extracts were drawn off into 300-ml. Erlenmeyer flasks and taken to dryness (one by one) in an oven at 120° C. The samples were taken up in 0·09 N hydrochloric acid–ethanol and, after cooling to room temperature, the optical densities of the solutions measured at 535 $m\mu$. The amount of prodigiosin was calculated from the standard curve.

The results obtained and summarized in Fig. 3 indicate that gibberellic acid inhibited the production of prodigiosin by *Serratia marcescens*. This effect was observed after 72 h of incubation. No effects were observed at 36 h, or at 144 h. At levels of 5–20 p.p.m., the decrease in prodigiosin content was almost linear, but the effect tapered off between levels of 20–50 p.p.m. From 50–200 p.p.m. levels, there was considerable suppression of the prodigiosin content caused by added gibberellic acid. These results are somewhat comparable with the findings of Greenberg and Tirpak[5], who were unable to obtain linearity while examining the effect of gibberellic acid on *Azotobacter indicus*. The period of incubation after which the inhibitory effect was noted is interesting. Possibly, at the shortest period of 36 h, no effect was noted because the pigment was not yet being biosynthesized by the cells at a very great rate. According to Williams *et al.*[9], the time of maximal pigment production coincides with the stationary phase of the growth-cycle, and, in their opinion, the pigment-forming system is not exclusively a property of the viable cells. Therefore, at 72 h, in the senescent phase of the growth-cycle and, concomitantly the period of maximal pigment production, the effect of gibberellic acid was pronounced. Quite likely, the greatest inhibition of prodigiosin production by gibberellic acid occurred at the period of maximum activity of the enzymatic systems concerned with the biosynthesis of prodigiosin by *Serratia marcescens*.

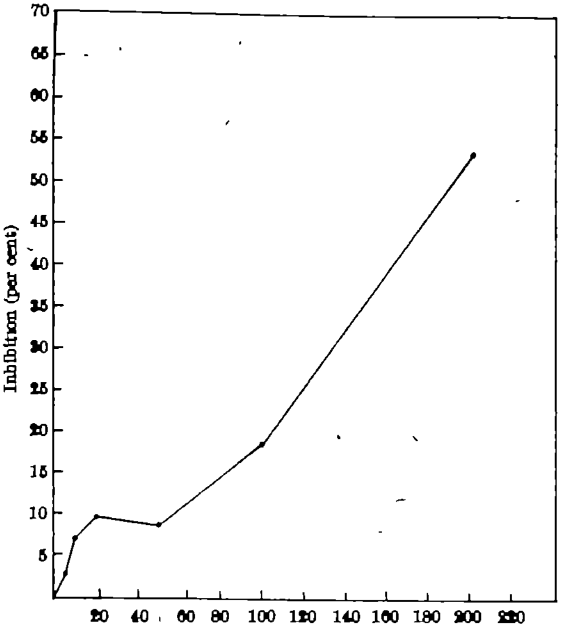

Fig. 3. Inhibition of prodigiosin production in the presence of gibberellic acid

Since gibberellic acid is antagonistic to several fungi[10], this constitutes evidence for a similar effect on the metabolic activity of a bacterium. Stowe and Yamaki[1] referred to reports on the growth-promoting effects of gibberellic acid on liverworts, mosses, algae and ferns, and to brief reports on a mushroom and on yeast. Reference was also made to results indicating that hormonal levels of gibberellin promote the growth and respiration of the *BCG* strain of *Mycobacterium tuberculosis*. Although the major effects of gibberellins on plants have been reported as producing increased rate of growth and increased size and weight, turbidity measurements and plate counts indicated no increase in protoplasmic mass or cell numbers when *Serratia marcescens* was grown in the presence of varying concentrations of potassium gibberellate. However, reports of inhibitory effects of gibberellic acid are not novel. Paleg and Aspinall[11] reported inhibition of the development of the barley spike by gibberellic acid and a decrease in the alkaloid content of plants has been reported[12,13]. Of particular interest is the report on the inhibition of the biosynthesis of rutin and rhamnose[14]. Although total chlorophyll content was increased, the number of leaves per plant also increased. It was not stated whether or not the chlorophyll content per unit weight or area of leaf was affected. The inhibition of rutin biosynthesis by gibberellic acid was thought to be effected through its action on the enzyme or enzymes functioning in the biosynthetic pathway.

In this work it seems likely that the added potassium gibberellate exerted its influence on some enzyme or enzymes concerned with the biosynthesis of prodigiosin without exerting any detectable effects on cell reproduction. Uptake of oxygen examined by using both washed cell suspension and cell-free extracts also indicated an inhibitory action of potassium gibberellate. This further substantiates the view that the added plant growth regulator was probably acting on some enzymatic system(s). The exact mechanism(s) is still unknown, and more fundamental research is contemplated to gain further information.

We thank Miss Gwendolyn Howze, formerly of the Biology Department, Tuskegee Institute, Alabama, for advice. This work was sponsored by a grant from the Brown–Hazen Fund, Research Corporation, New York City.

LETTERS TO THE EDITOR

ASTRONOMY

Impacts on the Earth and Moon

ALTHOUGH nine out of ten of the average meteorites are stoney, the larger objects which collide with the Earth may be predominantly iron. This reversal in characteristics is suggested by the different size law for stone and iron meteorites. The number of impacts on the Earth's surface, N (km^{-2} year^{-1}), with initial mass greater than m_∞ (kg), is at the present time:

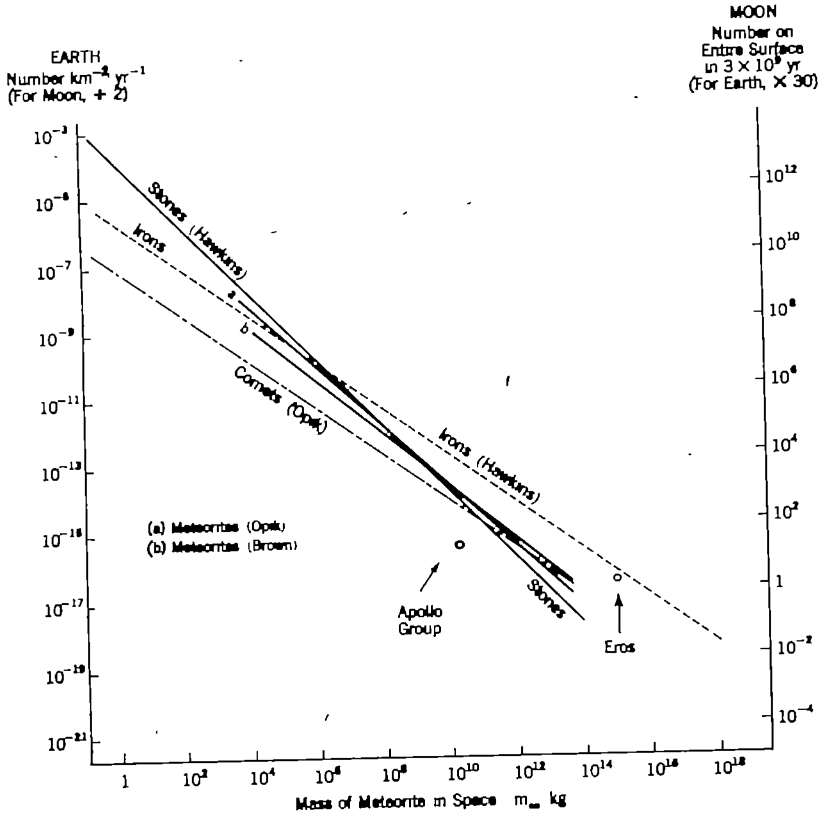

Fig. 1

$$\text{stones: } \log_{10} N = -3{\cdot}73 - \log_{10} m_\infty \quad (1)$$

$$\text{irons: } \log_{10} N = -5{\cdot}61 - 0{\cdot}7 \log_{10} m_\infty \quad (2)$$

These equations can be derived from existing meteorite data[1,2] by assuming that 90 per cent of a stone and 80 per cent of an iron are ablated.

In Fig. 1 the values found from equations (1) and (2) are compared with the data of H. Brown[3] and Opik[4]. The influx rate of stones (1) agrees with other determinations over the range 10^4–10^{14} kg. However, the new value for iron meteorites represents an upward revision of the estimated rate. At $m_\infty = 10^6$ kg the number of irons is equal to the number of stones and at $m_\infty = 10^{16}$ kg the irons outnumber the stones by 10 : 1. It is interesting to note that the rate of collision with cometary nuclei is comparable with that of stony meteorites at the upper end of the size range. We may assume the rates for the surface of the Moon to be 1/2 of the rates for the Earth, thus making allowance for the effect of concentration caused by the Earth's gravitational field.

The extrapolation beyond the range of observation is considerable and it is of interest to attempt to confirm this result by other methods. The largest object passing close to the Earth is the asteroid Eros with a mass of approximately 3×10^{15} kg. The distance of closest approach is $2{\cdot}2 \times 10^7$ km, and, since the search for close approaching asteroids has been confined mainly to the northern hemisphere, the collecting area is $2{\cdot}1 \times 10^{16}$ km^2. The periodicity is 2 years and the rate for $m_\infty \geqslant 3 \times 10^{15}$ kg is $2{\cdot}4 \times 10^{-17}$ (km^{-2} year^{-1}). This is in fair agreement with equation (2). It is probable that very few objects with mass greater than or equal to Eros remain undetected in the vicinity of the Earth's orbit. However, there remains the statistical uncertainty in the small number of events. A similar calculation for the Apollo group gives a value that is some 10^3 times lower than the prediction. Although the number of events is greater this value is probably less reliable than the value derived from Eros. The search for the smaller and faster moving objects is by present estimates far from complete.

We may tentatively conclude that the near-approaching asteroids are iron objects, though, of course, the bulk of the material which remains in the asteroid zone may still be of non-metallic composition. For impacts that occur on the Earth's surface at a rate of 1 every 5×10^6 years, such as the terrestrial events suggested by some authors as the cause of tektite fields, the irons may outnumber the stones by as much as 100 : 1. If we assume that equations (1) and (2) are approximately true for the past then we may estimate the maximum size of object that has collided with the Earth during its geological history. The largest object to collide with the Earth is of mass 10^{17} kg. The Moon has probably suffered one collision with an object comparable in size to Eros, 10^{16} kg.

RADIOPHYSICS

Long Baseline Interferometry of Jovian Decametric Radio Bursts

DURING the 1962 opposition of Jupiter we made some exploratory observations with a long baseline interferometer in an attempt to obtain information on the sizes and distribution of the decametric burst sources. The observations were made at 19·7 Mc/s with a north–south baseline of 32·3 km, equivalent to 1940 λ at the declination of the planet. They have shown that successful interferometry is possible at these large distances in spite of complications due to ionospheric irregularities. The angular diameter of a burst source was found to be

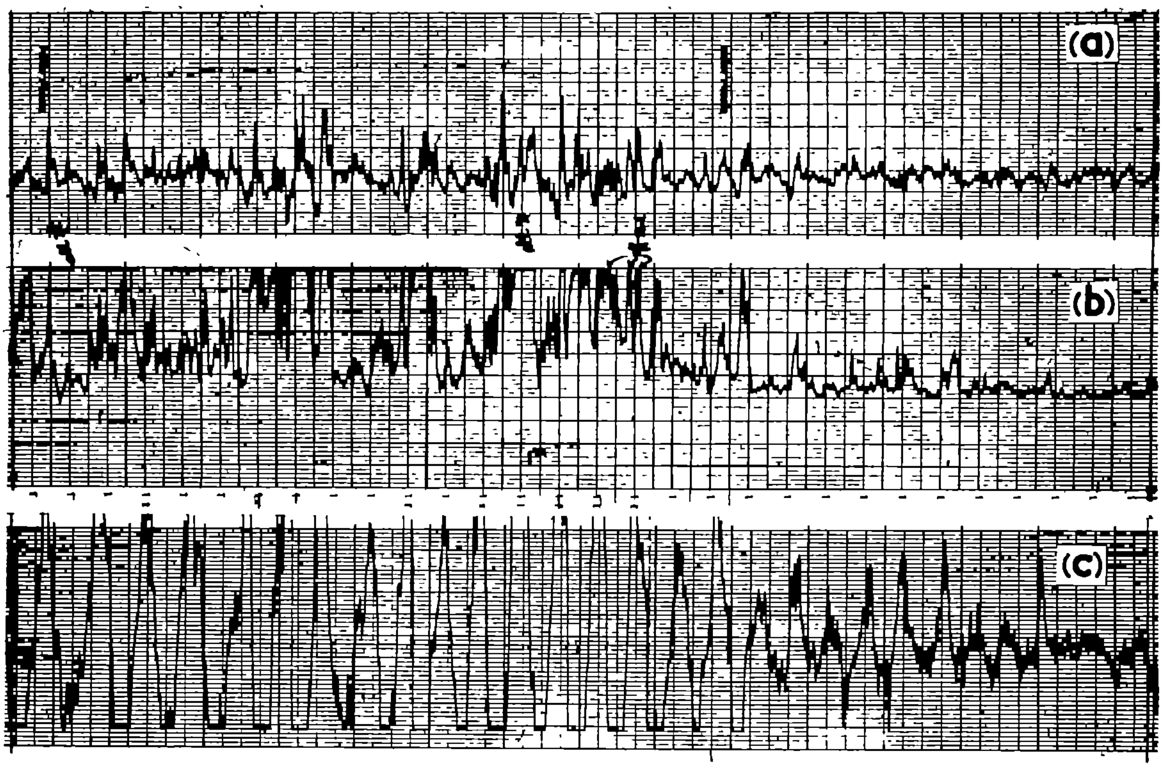

Fig. 1. A 15-min section of the Jovian noise storm recorded on September 24, 1962, at 19·7 Mc/s. Records (*a*) and (*b*) show the total power signals received at the remote and home sites respectively; the local record is a factor of two higher in sensitivity. Record (*c*) is the corresponding phase sensitive interferometer pattern

less than a third of the planet's diameter, and all bursts contributing to a noise storm originated in a single area less than a half of the size of the planet's disk.

Prior observation established that the radiation was predominantly circularly polarized so that differential Faraday rotation was not expected to prejudice interferometry. Consequently, a square array of $\lambda/2$ dipoles was used at each end of the baseline which accepted all components of the radiation. A radio-link, operating at a higher frequency than the signal frequency, was used to transmit the Jovian noise signals from the remote site to the home site at Fleurs, near Sydney. At Fleurs, the noise signal was reconverted to 19·7 Mc/s, using the local oscillator signal, which was also transmitted from the remote site. The remote noise signal and the suitably delayed signal from the home aerial were multiplied by the conventional phase switching method. The total powers received at each end of the baseline and the sine and cosine Fourier components were continuously recorded at the home site. Variations in propagation over the radio-link and in the receiver gains were controlled by means of A.G.C. systems with time constants of 1 min. The time constants of the standard recording systems, determined by the response times of the recorder pens, were 0·5 sec for full-scale deflexion. A special four-channel recorder with a response time of 0·02 sec was used occasionally to examine the few bursts with durations less than 0·5 sec. Two values of receiver band-width, namely, 4 kc/s and 200 kc/s to half-power points, were used at different stages of the observations, which extended from August 16 until October 6, 1962.

The effective interferometer spacing of 1940 λ produced an interference pattern with a fringe separation of 1·7 arc. The low primary directivity of the system permitted observations to be made for a period of 5 h each night near transit. During this period, the rotation axis of the planet changes by 94° with respect to the interferometer baseline, so that over extended periods of time, the high resolving power of the interferometer could be applied to both polar and equatorial directions on the planet.

The degree of correlation between the total power signals from the two ends of the baseline varied considerably from night to night. An example of good correlation is shown in Fig. 1*a* and *b*. These records illustrate one of the difficulties in this type of measurement, namely, the very large dynamic range of the Jovian radiation. With a pre-selected intensity range, only a small percentage of the recorded events are suitable for direct comparison. Where detailed comparison is possible, the high degree of correlation shows beyond any reasonable doubt that the decametric radiation is already in the form of bursts with durations ranging from 0·1 sec to about 60 sec when the waves impinge on the Earth's atmosphere. On these nights, as can be seen from Fig. 1*c*, regular interferometer patterns were produced as the apparent motion of Jupiter carried the burst source through the fringes.

On those occasions when the total power signals were poorly correlated, presumably due to the effects of uncorrelated ionospheric scintillations, the fringe periods were very irregular, reflecting the apparent position changes associated with the scintillations. However, interferometer deflexions were always obtained of amplitude consistent with the instantaneous values of the total power signals even when the latter had no other directly comparable features. The interesting conclusion to be drawn from these results is that the Jovian radiation remains coherent at the ends of a long baseline in the presence of severe uncorrelated scintillations.

Size of burst sources. If p_1 and p_2 are the instantaneous powers delivered to the two receivers during a Jovian noise burst, then the deflexions of the total power recorded are proportional to $\alpha_1 p_1$ and $\alpha_2 p_2$, while their combination results in a deflexion $\beta V(p_1 p_2)^{\frac{1}{2}}$, where the constants α_1, α_2, β may be determined from the receiver calibrations. The factor $V \leqslant 1$ is a measure of the coherence of the radiation over the baseline and the amount by which it departs from unity depends on the type of brightness distribution and its dimensions relative to the fringe spacing.

For the purpose of estimating the angular sizes of the burst sources, six Jovian noise storms were examined. Two of these were recorded with a receiver band-width of 4 kc/s and four with a band-width of 200 kc/s. From the narrow-band records, analysis of 35 bursts led to a value of $\overline{V}_n = 1{\cdot}00$ for the mean fringe visibility, with an *S.E.* of 0·03. From the wide-band interferometer, 35 bursts resulted in a mean fringe visibility of $V_w = 1{\cdot}04$, with an *S.E.* of 0·06. Much of the larger error in the wide-band result may be due to the necessity of applying corrections to the observed fringe visibilities for band-width dispersion. Consideration of the standard errors involved in these mean values leads to estimates of an upper size limit for the burst-emitting sources. From the narrow-band results, for a Gaussian brightness distribution, the angular size of the sources was $< 13'$ arc at the 5 per cent confidence-level. The wide-band result indicates that the source size was $< 19'$ arc. There were no detectable systematic differences in source size between the polar and equatorial directions.

Size of the burst-emitting regions. Restricting consideration to those observations for which the absence of marked ionospheric effects results in a high degree of correlation between the total power records at both sites, it is possible to set an upper limit on the size of the region responsible for the bursts in a storm. In these circumstances and where the bursts are sufficiently frequent, they give rise to a continuous series of fringes. For example, during a storm on September 25, 1962, 27 such fringes were counted over a period of 9 min. The mean fringe period was 19·8 sec with an *S.E.* of 12 per cent for individual measurements. Hence it was most unlikely (at the 5 per cent confidence-level) that independently radiating sources, if indeed there was more than a single source, occupied an area with dimensions greater than ¼ of the fringe separation or 25′ arc. A number of such occurrences showed that there were no differences between equatorial and polar directions.

There seems to be no reason, from the results recorded here, why interferometer observations should not be continued with longer baselines until the Jovian burst sources are resolved. It is our present intention to make similar measurements over baselines of 80 km or more during the 1963 opposition.

We thank Mr. C. F. Fryar for assistance in operating the interferometer during the present experiment.

Sudden Changes in Amplitude and Phase of the Very-Low-Frequency Signal from Station *GBR* at Salisbury, South Australia

A peculiar phenomenon, to our knowledge not reported so far, has been observed on the signals of Station *GBR* on 16 kc/s.

The signals of this Station, monitored for frequency standardization purposes, are mixed with a suitable frequency derived from a 100-kc/s standard oscillator and a record, as the one shown in Fig. 1, is produced. The number of beat cycles over 24-h intervals is counted and the drift of the local source determined.

At about 12.30 h local time (9½ h ahead of U.T.) on May 31, 1962, the number of beat cycles suddenly increased and this faster beat persisted for about half an hour, as shown in the figure.

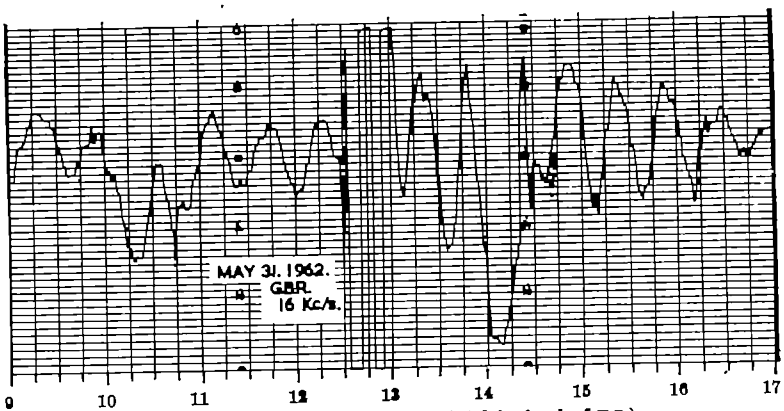

Fig. 1

Similar occurrences were recorded on June 11 at approximately 12.30 h local time, on June 12 at 09·45 h and on June 25 at 09·40 h. These lasted approximately 15, 30 and 8 min respectively.

All possibility of instability of the local source must be ruled out as the same derived signal is mixed also with the signals of the United States transmitter *NBA* on 18 kc/s and no trace of a similar effect has been noticed on the record of this station.

The beat frequency, while the described phenomenon lasted, was of a high stability not likely to be possible to derive from a local source switched on for this period.

We thank the Chief Scientist, Department of Supply, for his permission to publish this communication.

GEOPHYSICS

Lithium Emission in Twilight at Uppsala during November 1962

A patrol spectrophotometer (*SP*3) has been operating at this Observatory for a long period to record lithium emission in twilight at 6708 Å. In spite of the high sensitivity of the instrument no lithium was recorded until a strong emission suddenly occurred on November 7, 1962, in the evening twilight. The last record before this date was made on October 19, 1962, when no emission at all was detected. In the days before and after November 7 the weather conditions were unfavourable, but in spite of this a number of good records have been received.

The spectrophotometer was adjusted on November 7 to sweep over a range of ~ 50 Å each fourth minute, and the spectral line is recorded via photomultiplier and rate-meter on an x–y recorder. The resolution was about 2·5 Å and the instrument was directed 25° elevation north-north-west. Fig. 1 shows the first record of the lithium flash.

After November 7, records were made in zenith both in the morning and evening twilight. Simultaneous records were made with another spectrophotometer of somewhat less light power including the sodium lines for comparison. From these records one can get some idea of the ratio and the time difference of the lithium flash with respect to the sodium flash. Regarding the intensity of the lithium emission a comparison with sodium shows that the lithium emission at the beginning of the period seems to have been at least of the same order as the sodium emission. Regarding the time difference with respect to sodium, the lithium flash follows very near that of sodium, but both are displaced in time with respect to the *OI* 6300 Å flash, which

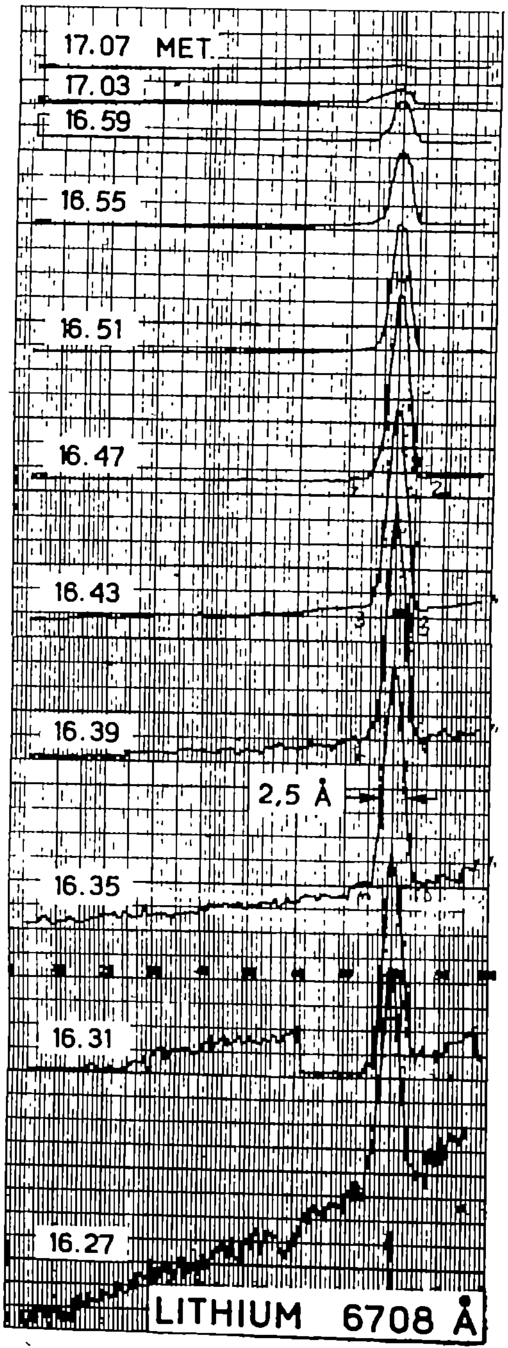

Fig. 1. Sample of lithium twilight record on November 7, 1962, at Uppsala

was recorded separately. The records for November 15 and November 23 are shown in Fig. 2. These records were made with 1-min intervals and are good enough for an analysis. After having normalized the curves for these two days one sees a striking similarity between the lithium and sodium flashes. When discussing the height of the sodium and lithium layers respectively one has to assume a screening height, which for sodium is about 27 km according to Bullock and Hunten[1]. For lithium a screening height was chosen 5 km lower than for sodium, as used by Gadsden and Salmon[2]. Then using the method for determining the height of the maximum density of the sodium-layer proposed by Hunten[3], and Hunten and Shepherd[4], the height (km) for lithium and sodium was found to be approximately:

	Li	Na
November 15	91 km	94 km
November 23	87 km	95 km

Thus it seems that the height of lithium was lower on November 23 than on November 15, corresponding to a decrease ~ 0·5 km a day. A similar decrease of the height of lithium was reported by Gadsden and Salmon[2].

The observations during November 1962 at Uppsala give, in spite of very variable weather conditions, a clear picture of the lithium : sodium ratio with time. At the end of November the lithium had nearly disappeared and the decrease during the actual 4 weeks was very near the same as that reported by Gadsden and Salmon[5], 1961. In Fig. 3 the lithium values are given showing the decrease of the intensity over the whole period. The mean level of sodium-emission relative to lithium is indicated by a

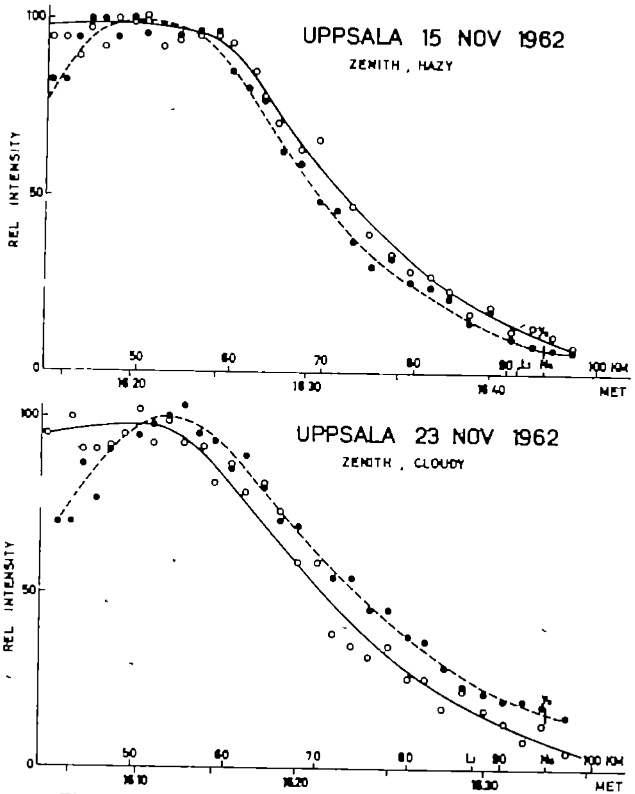

Fig. 2. Comparison of lithium and sodium twilight record. O, Lithium; ●, sodium

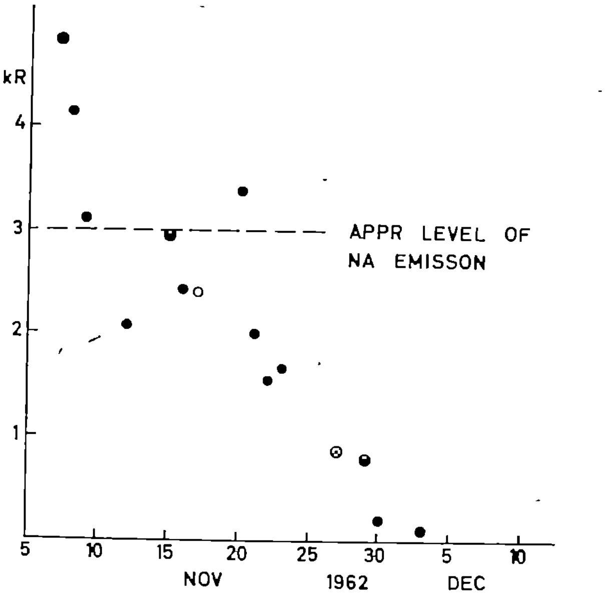

Fig. 3. Diagram showing the decrease of lithium emission during the observing period of about 25 days. O, Clear; O, hazy; ●, cloudy

dashed line. The intensity scale has an uncertainty of about ± 40 per cent.

Earlier enhancement of lithium emission was reported by Barber[6], and related to the nuclear explosion at high altitude over the central Pacific Ocean. From the high intensity and the short life-time of the emission of lithium reported here, it seems with little doubt that the emission is related to some of the U.S.S.R. nuclear explosions.

Earth's Gravitational Potential: Evaluation of Even Zonal Harmonics from the 2nd to the 12th

The Earth's gravitational potential U at an exterior point distant r from the Earth's centre, and having geocentric latitude φ, may be written in a series of spherical harmonics as:

$$U = \frac{GM}{r}\left\{1 - \sum_{n=2}^{\infty} J_n \left(\frac{R}{r}\right)^n P_n(\sin\varphi)\right\} \tag{1}$$

where G is the gravitational constant, M the mass of the Earth, and R the Earth's equatorial radius. $P_n(\sin\varphi)$ is the Legendre polynomial of degree n and argument $\sin\varphi$, and the J_n are constant coefficients. Equation (1) does not take into account the small variation of U with longitude, and represents an average over all longitudes.

In the past five years the first few J_n have been evaluated by various authors from the perturbations of the orbits of artificial satellites. The arithmetic means of the more complete determinations[1–7], with root mean square scatter, are:

$$\begin{aligned} 10^6 J_2 &= 1082{\cdot}7 \pm 0{\cdot}2 & 10^6 J_3 &= -2{\cdot}44 \pm 0{\cdot}08 \\ 10^6 J_4 &= -1{\cdot}6 \pm 0{\cdot}2 & 10^6 J_5 &= 0 \pm 0{\cdot}2 \\ 10^6 J_6 &= 0{\cdot}7 \pm 0{\cdot}2 & 10^6 J_7 &= -0{\cdot}45 \pm 0{\cdot}1 \end{aligned} \tag{2}$$

Some tentative values of J_8 and J_9 have also been obtained. In all these determinations, harmonics of degree higher than those evaluated were necessarily ignored, though they cannot be proved to be negligible, and their neglect contributes towards the scatter among the values derived by the different authors.

We have recently made a new determination of the even harmonics in the Earth's gravitational potential, from the motion of seven satellites, chosen with the view of sampling the gravitational field as thoroughly and evenly as possible: their orbits were inclined to the equator at angles between 28° and 97°. The potential experienced by these satellites is found to be best represented by the following set of coefficients:

$$\begin{aligned} 10^6 J_2 &= 1082{\cdot}78 \pm 0{\cdot}05 \\ 10^6 J_4 &= -0{\cdot}78 \pm 0{\cdot}2 \\ 10^6 J_6 &= 0{\cdot}70 \pm 0{\cdot}1 \\ 10^6 J_8 &= 0{\cdot}24 \pm 0{\cdot}2 \\ 10^6 J_{10} &= -0{\cdot}50 \pm 0{\cdot}2 \\ 10^6 J_{12} &= 0{\cdot}28 \pm 0{\cdot}2 \end{aligned} \tag{3}$$

The quoted errors are tentative estimates of the departures of the quantities from the true physical values, making some attempt to allow for the neglect of J_{14}, J_{16} . . . If the potential is to be represented by fewer even harmonics, the best number is found to be three and the values obtained are:

$$\begin{aligned} 10^6 J_2 &= 1082{\cdot}79 \pm 0{\cdot}05 \\ 10^6 J_4 &= -1{\cdot}09 \pm 0{\cdot}20 \\ 10^6 J_6 &= 0{\cdot}73 \pm 0{\cdot}20 \end{aligned} \tag{4}$$

To complete the potential, values of J_3, J_5, and J_7 must be added to (3) and to (4), from equation (2).

The values of J_2 and J_6 in (3) and (4) are consistent with each other and with those in equation (2). J_2 was found to be almost unaffected by the evaluation of higher harmonics, virtually identical values being obtained when either 3, 4, 5 or 6 harmonics were included. The same cannot be said for J_4, which suffered a sharp change when J_{12} was included: J_4 has in equation (3) a smaller numerical value than any hitherto obtained. Even in (4) the value of J_4 is significantly smaller than in (2), probably because near-polar satellites, which tend to give small values of J_4, were not included in previous determinations. Although the values of J_8–J_{12} in (3) must be regarded as tentative, it appears likely that J_{10} is strongly negative, and may be numerically almost as large as J_4 or J_6.

OCEANOGRAPHY

Definition of the 'Salinity' of Sea-water

For sixty years oceanographers have accepted and used Knudsen's[1] relationship defining salinity in terms of the chlorinity of sea-water. The validity of this relationship has several times been questioned, for example by Carritt and Carpenter[2]. These doubts have been strengthened by the work of Cox, Culkin, Greenhalgh and Riley[3].

To consider the problems involved, a panel has been appointed jointly by the International Council for the Exploration of the Sea, the Special Commission for Oceanographic Research, the International Association of Physical Oceanography and Unesco. The members are: Prof. G. Dietrich (Germany, *chairman*); Prof. D. E. Carritt (United States); Dr. R. A. Cox (United Kingdom); Dr. N. P. Fofonoff (Canada); Mr. F. Hermann (Denmark); Dr. G. N. Ivanoff-Frantzkevich (U.S.S.R.); Dr. Y. Miyake (Japan).

This panel met in Paris in May 1962, when the problems were discussed and a report was drafted which includes certain recommendations. These may be summarized:

(*a*) That salinity should be re-defined in terms of density at 0° (sigma 0); the relationship being chosen to preserve, on average, the present relationship between salinity and chlorinity as closely as possible.

(*b*) That new tables should be computed relating salinity so defined to conductivity and refractive index.

(*c*) That as soon as practicable Copenhagen Standard Sea-Water should be certified in conductivity as well as chlorinity.

The full report has been distributed by Unesco to most oceanographic institutions. Copies of the report can be obtained from the Office of Oceanography, Unesco, Place de Fontenoy, Paris, 7.

It is hoped to debate these recommendations at the International Association of Physical Oceanography meeting in San Francisco in August 1963. In the meantime, the panel would like to receive and consider comments, criticisms and suggestions relating to the report. These should be sent to me.

CHEMISTRY

Influence of Polyvalent Cations on the Rate of Electro-reduction and Aquation of $Co(NH_3)_5X^{n+}$ Complexes

IN previous communications[1,2] the influence of the nature and concentration of anions on the rate of electro-reduction of $Co(NH_3)_5X^{n+}$ complexes has been reported. The influence exerted depends on the nature of the ligand X. This phenomenon has been explained by the assumption that the complex particle does not behave as a conducting sphere with uniform charge distribution (as assumed usually) but that the non-homogeneous charge distribution contributes considerably to the electrostatic free energy of activation and has to be taken into account. The ligand X represents the region of maximum non-homogeneity which induces an opposite non-homogeneity in the ionic atmosphere, the cations of the supporting electrolyte being preferentially attracted into the parts of the ionic atmosphere near the negative pole of the central particle. This increased concentration of cations shields the negative pole of the complex particle or might lead to the formation of an ion-pair between the positively charged complex particle and the cation. Both these effects make the attainment of the favourable orientation (that is, with ligand X removed from the positively charged electrode surface[2]) of the particle in the activated complex depolarizer-electrode[2] much easier and increase the rate of electro-reduction.

Such an acceleration is caused by H^+-ions for complexes with $X = F^-$, formate, acetate, propionate, butyrate. In this case the association of the complex with protons might be governed by the basic properties of the ligand and not by the non-homogeneity of the charge distribution. The later effect can be expected for complexes with ligands X carrying a higher fraction of the negative charge (for example, F^-, SO_4^{2-})[1] and polyvalent cations like Th^{4+}, La^{3+} or Ba^{2+}.

The influence of Th^{4+} on the rate of reduction of various complexes at the dropping-mercury electrode is represented in Fig. 1. A similar but much smaller influence has been observed with La^{3+} ions. Ba^{2+} influences the rate of reduction to a negligible extent. The rate constant of reduction (k_e) in presence of Th^{4+} and La^{3+} ions obeys the equation:

$$k_e = {}_0k_e + {}_Mk'_e\,[M^{n+}] \qquad (1)$$

${}_0k_e$ being identical with the rate constant of the reduction in a solution without polyvalent cations. The experimental value of the constants calculated with the use of the value 7×10^{-6} cm^{2}s^{-1} (ref. 3) for the diffusion coefficient are given in Table 1.

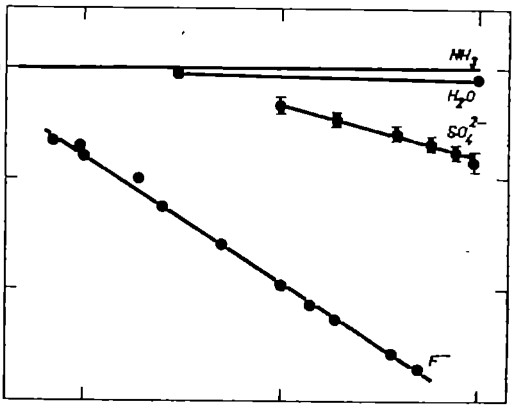

Fig. 1. The change of the half-wave potential of $Co(NH_3)_5X^{n+}$ complexes with Th^{4+} concentration. $\mu = 2$; 1 M H^+; nitrate. Concentration of the complex. 7×10^{-4} M

From the form of the rate law it follows that:

(1) The reduction follows two paths, the first being the reduction of the 'free' complex, the second the reduction of the 'ion-pair' complex-cation.

(2) The ion-pair is reduced much more rapidly than the free complex.

(3) The concentration of the ion-pair is very small and its formation very rapid.

(4) The rate constant ${}_Mk'_e$ equals ${}_Mk_e \cdot K_M$, K_M being the association constant of the ion-pair.

The difference in the influence of La^{3+} and Th^{4+} is greater than would be expected on the basis of shielding effect of the ionic atmosphere only and points to the conclusion that specific affinity ligand-cation contributes considerably to the stability of the ion-pair, especially in the case of $[Co(NH_3)_5F^{2+} \cdot Th^{4+}]$.

The much smaller ratio ${}_{Th}k_e : {}_0k_e$ for $X = SO_4^{2-}$ than for F^- is due to a relatively small affinity of sulphate ions to Th^{4+}. The association of Th^{4+} and $Co(NH_3)_5SO_4^+$ is governed from a great part by the electrostatic effect and the concentration of the ion-pair $[Co(NH_3)_5SO_4^+ \cdot Th^{4+}]$ is much smaller than that of $[Co(NH_3)_5F^{2+} \cdot Th^{4+}]$.

To prove the foregoing conclusions and to show that the effects observed are not due to the change of the electrode double layer caused by polyvalent cations, the rate of aquation of $Co(NH_3)_5F^{2+}$ under the influence of Th^{4+} ions was followed. The aquation follows the rate law:

$$k = k_H + k_{Th} \cdot [Th^{4+}] \qquad (2)$$

k_H is identical with the rate constant observed in a solution of the same acidity without Th^{4+} ions and depends on the concentration of hydrogen ions, increasing with increasing acidity of the solution. The values of k_H and k_{Th} are given in Table 1. The accelerating influence of Th^{4+} ions on the aquation of $Co(NH_3)_5F^{2+}$ is analogous to the influence exerted by Hg^{2+} ions on the aquation of $Co(NH_3)_5Y^{2+}$, Y being Cl^-, Br^- or I^- (ref. 4). In the latter case the accelerating effect is due to the high affinity of halogen and mercuric ions, as is shown by the increase of the rate in the order $Cl^- > Br^- > I^-$ (ref. 4).

Table 1. SUMMARY OF RATE CONSTANTS FROM EQUATIONS (1) AND (2)

Solution: 1 M HNO_3 + $NaNO_3$ up to $\mu = 2$ M. ${}_0k_e$, ${}_Mk_e$ at 0° C, k_H, k_{Th} at 20·5° C. ${}_0k_e$, ${}_Mk'_e$ related to the potential of 0·1 M calomel electrode at 0° C

Complex	${}_0k_e$	${}_{Th}k'_e$	${}_{La}k'_e$	${}_{Th}k_e : {}_0k_e$	k_H (s^{-1})	k_{Th} (s^{-1} mol^{-1} l.)
$Co(NH_3)_5F^{2+}$	$1·4 \times 10^{-6}$	$9·7 \times 10^{-3}$	$5·7 \times 10^{-5}$	6,800	$7·0 \pm 0·2 \times 10^{-5}$	$3·1 \times 10^{-4}$
$Co(NH_3)_5SO_4^+$	$9·55 \times 10^{-6}$	$5·3 \times 10^{-4}$	$1·06 \times 10^{-5}$	56	—	—
$Co(NH_3)_5H_2O^{3+}$	4×10^{-6}	$6·6 \times 10^{-6}$	—	1·5	—	—

Dimensions: ${}_0k_e$ = cm × s^{-1}; ${}_Mk_e$ = cm × s^{-1} × l.mole^{-1}.

These experiments show that an association of the complex cation with the metallic cation occurs, the ligand *X* acting as a bridge between the two metals. In the ion-pair formed a certain fraction of electron density is transferred to the bond *M*–*X*, so that the bond *X*–Co is loosened which facilitates the aquation. The electrochemical reduction of the ion-pair does not proceed via the aquated ion or via a particle with the co-ordination number 5, for the rate of reduction is higher than it would correspond to a process preceded by a homogeneous splitting off the ligand *X*.

Evaporation of Langmuir – Blodgett Monolayers in Vacuum

While there is an extensive literature on the methods of depositing monomolecular films of fatty substances on solid surfaces by the Langmuir–Blodgett method[1], there seems to be little information available on the stability of the films once prepared. Gregg and Widdowson[2] studied the evaporation of built-up multilayers of fatty acids, but their results were restricted to layers many molecules thick. More recently, Karle[3] and Menter and Tabor[4] have obtained some evidence of the evaporation of fatty acid and soap molecules from monomolecular films in electron diffraction investigations.

The availability of radioactively labelled fatty acids in recent years has permitted a more direct approach to assessing the stability of such deposited monolayers. We have recently reported observations on the stability *in vacuo* of stearic acid and barium–copper stearate monolayers deposited on quartz, soft glass and gold[5]. The monolayers were labelled with carbon-14, and the rate at which they were desorbed at room temperature and a pressure of ~10^{-8} torr was measured radiometrically. The barium–copper stearate films on soft glass lost about 10 per cent of their initial activity in 90 h pumping; stearic acid films on gold, on the other hand, were about half removed after 5 h evacuation. These investigations have now been extended.

The most stable monolayers which we have prepared are those of *n*-octadecylamine hydrochloride, deposited on either mica or evaporated gold films from the surface of 10^{-3} N hydrochloric acid. Such monolayers retain more than 90 per cent of their initial activity after 40 h of evacuation. Autoradiographs of these monolayers, both before and after evacuation, show a uniform density of activity over the entire sample. We have found the deposition of *n*-octadecylamine hydrochloride monolayers, however, to be more erratic than that of the stearates, perhaps partly due to the greater tendency to expansion of the amine hydrochloride monolayers on the aqueous surface[6]; we have also found evidence of slow solution of these monolayers while spread on the acid subphase. In several cases, we have obtained transferred monolayers, the initial activity of which was appreciably below that to be expected from a homogeneous monolayer; autoradiographs of the samples show an inhomogeneous distribution of activity over the surface. The free amine, spread on 10^{-3} N sodium hydroxide solutions, should form a more compact monolayer[7]. We have prepared a few samples of free *n*-octadecylamine monolayers on gold, quartz, and mica, and their stability in vacuum appears to be appreciably lower than that of the corresponding amine hydrochloride films. This result is not surprising, since the free amines have much lower melting points and higher vapour pressures than do their salts.

For many types of experiments, only short-term stability to vacuum exposure may be required. The removal of the first small fraction of a monomolecular film may be governed by factors quite different from those controlling the removal of the major portion of the monolayer. In the case of soap monolayers, for example, it is possible that any free fatty acid in the film would evaporate more readily than the soap itself[7].

Table 1. SHORT-TERM STABILITY OF MONOLAYERS IN VACUUM. FRACTION OF MONOLAYER REMAINING AFTER 30 MIN PUMPING IS TABULATED. MONOLAYERS WERE DEPOSITED UNDER 17 DYNES/CM SURFACE PRESSURE

Substrate Monolayer	Quartz	Mica	Soft glass	Gold on quartz	Gold on mica
Barium–copper stearate	0·93 ± 0·02 (4)	0·97 ± 0·03 (5)	0·96 ± 0·02 (3)	0·94 ± 0·01 (3)	0·91 ± 0·04 (3)
Stearic acid	0·31 ± 0·04 (2)	—	—	0·85 ± 0·01 (2)	—
n-Octadecylamine hydrochloride	—	1·00 ± 0·02 (4)	—	—	0·96 ± 0·01 (4)

Figures in brackets indicate number of samples.

In order to investigate this behaviour, we examined a number of samples after they had been exposed to vacuum for 30 min. The results are presented in Table 1. Both barium–copper stearate and *n*-octadecylamine hydrochloride monolayers are fairly stable over this short period; stearic acid films have already lost an appreciable amount of their activity in 30 min. Mica substrates seem to show the highest resistance to desorption of the solids which we have used, although the differences observed with the barium–copper stearate and *n*-octyldecylamine hydrochloride monolayers are small.

Schmidt Reaction

Since the advent of commercial polyphosphoric acid, a number of novel procedures have been developed for the Schmidt reaction using polyphosphoric acid as the solvent and catalyst[1–3].

It was interesting to note that in nearly all the reactions run, temperatures of 100° or higher were used. One of these[3] reported that benzoic acid gave aniline in 48 per cent yield, along with a considerable amount of diphenylurea, while *p*-nitrobenzoic acid failed to react. The conditions of these reactions were not clearly defined.

We found that aromatic carboxylic acids can be converted to the corresponding amines at room temperature (25°) in good yields using polyphosphoric acid and excess sodium azide. Table 1 shows our results. The yields are in agreement with the fact that acids with electron donator groups give better yields and have faster rates[4].

Table 1

Acid	Product	Yield (%)	Derivative	Melting point	Infra-red
Benzoic	Aniline	71·2	Benzamide	161–162°	2·82, 2·91, 3·08, 6·19, 7·68µ (film)
p-Nitro-benzoic	*p*-Nitro-aniline	48·2	—	146°	2·82, 2·94, 3·09, 6·19, 7·72µ (Nujol mull)
p-Methoxy-benzoic	*p*-Methoxy-aniline	79·7	—	55–56°	2·82, 2·91, 3·07, 6·17, 7·70µ (Nujol mull)
Mesitoic	Mesidine	90·6	Benzamide	203°	2·83, 2·90, 3·07, 6·18, 7·70µ (film)

Apparently no side-reaction occurred, such as urea formation, because the amine products, which were solid, melted sharply within two degrees of the reported melting points[7] without recrystallization. Those amines which were liquids were also uncontaminated because their infra-red curves[8] were identical to original samples.

It appears that urea formation is decreased to a considerable degree when the Schmidt reaction is run at room temperatures. Furthermore, the increase of yields in polyphosphoric acid over conventional methods seems to imply the formation of the more reactive oxocarbonium ion in this medium.

Effect of Naphthalene on the Quenching of Liquid Scintillation Solutions

IN liquid scintillation counting the passage of β-particles through the phosphor solution results in a complex series of events, the useful ones culminating in the emission of photoelectrons at the photocathode of the photomultiplier. A number of parasitic events occur concomitantly that lead to a lowering of the yield, or total loss of the photoelectrons, that is, quenching. Possible sequences for these events, which occur during a time-interval of approximately 10^{-9} sec, have been outlined by several authors[1-3]. The addition of naphthalene to some liquid phosphors improves their counting characteristics. The enhancement in counting efficiency has been ascribed by Fust and Kallmann[4] to the ability of the naphthalene to act as an intermediate solvent that is capable of transmitting the energy from the primary solvent to the scintillators, thereby by-passing the quenching agent. If this is true the series of events leading to photoelectron production could be outlined as follows: (*A*) emission of β-particle; (*B*) excitation of primary solvent molecules (toluene); (*C*) excitation of secondary solvent molecules (naphthalene); (*D*) excitation of primary solute molecules (PPO); (*E*) excitation of secondary solute molecules (POPOP); (*F*) production of photons.

I have found that the addition of naphthalene to some liquid scintillator systems containing tritium can have a marked effect on the quenching curves. The effect depends entirely on the chemical nature of the quenching agent. With some substances the quenching effect is almost entirely removed; with others, it is enhanced.

The continuous curves shown in Figs. 1 and 2 were prepared by adding inactive benzoic acid and methyl benzoate to a liquid scintillator (4 g/l. PPO and 0·04 g/l. POPOP in toluene) containing approximately 10^{-8} g of tritiated benzoic acid. The broken curves were prepared by repeating the experiments with the same liquid phosphor solutions containing in addition 100 g/l. of purified naphthalene.

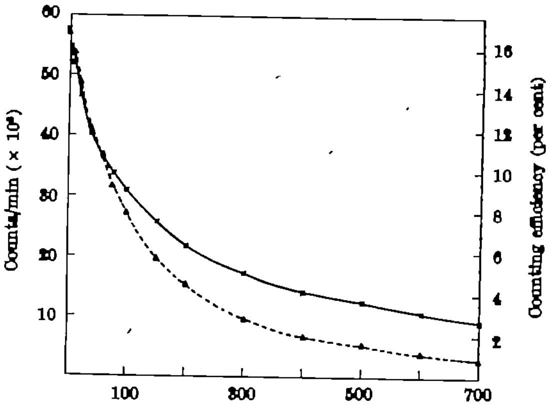

Fig. 1. Graph showing the effect on the count-rate of adding inactive benzoic acid to liquid scintillators containing a very small quantity of tritiated benzoic acid. ×, Normal scintillator solution; ▲, scintillator plus naphthalene

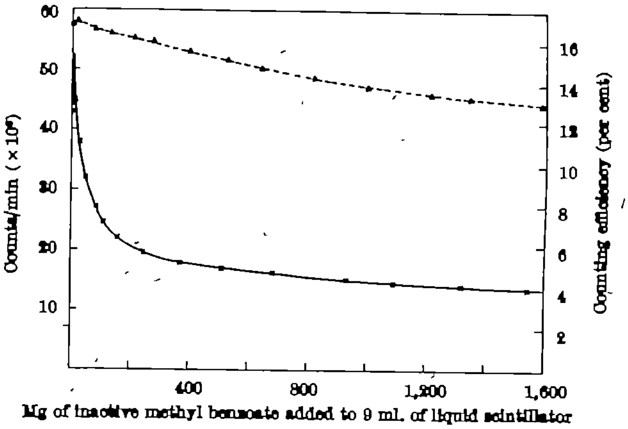

Fig. 2. Graph showing the effect of adding naphthalene to the scintillator on the tritium–methyl benzoate quenching curve. The small increase in count-rate recorded on the broken curve for very small amounts of methyl benzoate is due to desorption of active tritiated benzoic acid from the walls of counting vessel (ref. 5). ×, Normal scintillator; ▲, scintillator plus naphthalene

It can be seen from the results that addition of naphthalene to the liquid scintillator containing benzoic acid results in a small increase in counting efficiency at low concentrations of benzoic acid, and a decrease in efficiency at high concentrations. The addition of naphthalene to a benzoate-quenched solution, on the other hand, results in a considerable increase in counting efficiency at all quencher concentrations.

These results would seem to indicate that the quenching effects of benzoic acid and methyl benzoate are basically different. Two possible explanations are: (*a*) that the quenching phenomena for the two quenching agents occur at different points in the chain of events outlined here; or (*b*) that the quenching phenomena operate at the same stage in the scintillation process (between events *B* and *D*) and are the result of different rates of energy transfer. Thus, if quenching occurs between events *B* and *C* the rate of transfer of energy from the primary solvent to benzoic acid is greater than its rate of transfer to naphthalene, which in turn is greater than the transfer rate to methyl benzoate. If, however, quenching occurs between events *C* and *D*, the rates of energy transfer from naphthalene would be in the order benzoic acid > PPO > methyl benzoate.

Use of Modified 'Bentone-34' for the Gas Chromatographic Separation of Aromatic Hydrocarbons

The use of 'Bentone-34' (dimethyldioctadecylammonium bentonite) for the separation of aromatic hydrocarbons has been described previously[1-3], but the chromatograms published have either exhibited considerable tailing[3] or, where symmetrical peaks have been shown, these have been obtained using small sample volumes (about 0·02 µl.) and ionization detectors[3,4].

In an effort to obtain a stable column packing suitable for use with µl. samples and thermal conductivity detection the performance of 'Bentone-34' when modified with silicone oil and dispersed on 'Celite' has been investigated.

Equal parts by weight of 'Bentone-34' (F. W. Berk and Co., Ltd.) and 'Silicone Oil *MS 555*' (Midland Silicones, Ltd.) were dispersed in benzene and added to 10 parts by weight of 'Celite' (60–100 mesh). The resulting mixture was evaporated to dryness, sieved to break up any lumps present, and was packed into a 12-ft. copper column (internal diameter $\frac{1}{8}$ in.) at a packing density of 1·85 g/ft. A chromatogram, obtained using this column at 70° C, illustrating the separation of the C_8 aromatics and other hydrocarbons is shown in Fig. 1. The separation of the xylenes was completed in less than 30 min and symmetrical peaks were obtained. It will be noted, however, that the elution order of the *m*- and *o*-xylenes was the reverse of that normally obtained using 'Bentone-34'/'Celite' columns[3]. The relative retention volumes for seventeen hydrocarbons are given in Table 1.

The same column has been used at 90° C to separate all but two of the C_8–C_9 aromatics and the relative retention volumes obtained are given in Table 1. The inlet pressure was as before, that is, 22 lb./in.^{2}, but the flow-rate 106 ml./min.

X-ray examination of the 'Bentone-34' before and after modification indicates that the basal spacing of the organo-clay has been expanded from 12·3 Å to 38·5 Å. Thus, in the modified column packing the 'Bentone-34' is likely to be present as a thixotropic gel. With a 1 : 1 mixture of 'Bentone-34' and silicone oil the separation factor for the *meta*- and *para*-xylenes is 1·13 at 70° C and, as the proportion of silicone oil is decreased, the separation factor increases but the basal spacing remains unchanged. It would appear, therefore, that the inter-lamellar distances within the clay complex play only a minor part in the separation of the xylene isomers but the need for the xylenes to expand the lattice prior to adsorption may explain the serious tailing experienced when using the unmodified 'Bentone-34'.

Other modifying solvents have been used successfully including squalane and polyethyleneglycol and it appears that the separation possible can be controlled by careful selection of the type and proportion of the modifying solvent. Also, there seems no reason why the technique should be limited to modified organo-bentonites and other

easily expandable clays possessing exchangeable interlamellar cations should be equally applicable.

It is clear that the use of modified organo-clays as gas chromatographic stationary phases may have wide possibilities. Their application is certainly not limited to the separation of the C_6–C_8 aromatics described here, and many naphthenic and substituted hydrocarbon mixtures for which separation by conventional gas liquid partition chromatography has involved extended retention times may be more rapidly resolved on columns containing modified organo-clay packings.

Thin Layer Chromatography of the Gibberellins

PAPER chromatography of the gibberellins has been investigated by many investigators but no comprehensive study of all the known gibberellins has been reported. MacMillan, Seaton and Suter[1] described four solvent systems which separate gibberellins A_5, A_6, A_8 and A_9 but not the pairs gibberellin A_1 and gibberellic acid (A_3) or gibberellins A_4 and A_7. The solvent systems used by Takahashi *et al.*[2] and Phinney *et al.*[3] do not separate gibberellins A_1, A_2 and A_3. Gibberellins A_1 and A_3 can be separated on paper which is developed by overflow elution with benzene/acetic acid/water (4 : 1 : 2); this method is lengthy when conducted under gravity as described by Bird and Pugh[4] and resolution is poor when development is hastened by centrifugal force[5].

Thin layer chromatography of gibberellins A_1 and A_3 has been described by Kutacek, Rosmus and Deyl[5]; good resolution was obtained on a layer of aluminium oxide, developed by overflow elution with benzene/acetic acid (100 : 23).

We have found that the nine known gibberellins can be separated by thin layer chromatography (Table 1).

Table 1. R_F VALUES OF THE GIBBERELLINS

Gibberellin	Silica gel Solvent system 1	Silica gel Solvent system 2	Kieselguhr Solvent system 3	Kieselguhr Solvent system 2
A_1	0·11	0·0	0·54	0·26
A_2	0·04	0·0	0·64	0·30
A_3	0·11	0·0	0·42	0·18
A_4	0·37	0·82	1·0	1·0
A_5	0·31	0·85	1·0	0·88
A_6	0·25	0·21	0·95	0·76
A_7	0·37	0·70	1·0	1·0
A_8	0·04	0·0	0·28	0·06
A_9	0·75	1·0	1·0	1·0

For solvent systems, see legend to Table 2.

Thin layers of silica-gel *G* or kieselguhr *G* were prepared[6] on glass plates; they were spotted with not more than 10 μg gibberellic acid and the solvent was run for 15 cm at room temperature (17°–21° C). Running times for solvent system 1 were 25–50 min and for solvent systems 2 and 3 were 45–70 min. With solvent systems 2 and 3 plates were equilibrated overnight with lower phase then developed with upper phase.

Two sprays were used: (*a*) ethanol/concentrated sulphuric acid (95 : 5); (*b*) water/concentrated sulphuric acid (30 : 70).

After spraying with (*a*) the plates are heated at 120° for 10 min. The gibberellins are then visible in ultra-violet light. Gibberellins A_1, A_3, A_5, A_6 and A_8, which possess a 7-hydroxyl group, give blue fluorescent spots of different intensities; gibberellins A_2, A_4, A_7 and A_9, which have no 7-hydroxyl group, give purple spots.

With spray (*b*) gibberellins A_3 and A_7 are visible in ultra-violet light as yellow-green fluorescent spots before heating. After heating at 120° for 10 min, all are visible in ultra-violet light. Gibberellins A_1, A_5, A_6 and A_8 give green-blue fluorescent spots; gibberellins A_2, A_4 and A_9 give blue-purple fluorescent spots; gibberellins A_3 and A_7 are exceptions and give light yellow and brown fluorescent spots respectively.

Both sprays show similar sensitivity ranging from 0·00025 μg gibberellin A_3 to 0·01 μg gibberellin A_8. In mixtures 0·5 per cent gibberellin A_1 can be detected in 1 μg gibberellin A_3 and 0·05 per cent gibberellin A_1 in 10 μg gibberellin A_3. Similar quantities of gibberellin A_4 can be detected in gibberellin A_7.

Methyl esters (Table 2) give the same coloured spots as the corresponding acids but with weaker fluorescence.

Table 2. R_F VALUES OF METHYL ESTERS OF GIBBERELLINS

Methyl ester	A_1	A_2	A_3	A_4	A_5	A_6	A_7	A_8	A_9
Solvent system 2	0·33	0·34	0·26	1·0	1·0	1·0	1·0	0·1	1·0
Solvent system 1 (2% for 5% acetic acid)	0·18	0·08	0·16	0·50	0·38	0·31	0·48	0·08	0·60

Solvent systems: (1) Di-isopropyl ether/acetic acid (95 : 5); (2) Benzene/acetic acid/water (8 : 3 : 5); (3) Benzene/propionic acid/water (8 : 3 : 5).

No one solvent system separates all the gibberellins or their methyl esters. Gibberellin A_5, A_6 and A_9 are separated from each other and from the unresolved pairs gibberellins A_2 and A_8, A_1 and A_3, and A_4 and A_7.

Gibberellins A_4 and A_7 are separated on silica-gel *G* by solvent system 2. The pairs, gibberellins A_2 and A_8 and gibberellins A_1 and A_3, are separated on kieselguhr *G* by solvent system 2; all four (A_1, A_2, A_3 and A_8) are separated on kieselguhr *G* by solvent system 3; but this system is unreliable since streaking of the plates frequently occurs for reasons unknown.

Gibberellins A_3 and A_7 can be further distinguished from the other gibberellins by means of spray (*b*); they give characteristic yellow-green fluorescent spots without heating while the other gibberellins fluoresce only after heating for 10 min at 120°.

Indolyl-3-acetic acid has an R_F value of 0·60 on silica gel in solvent system 1 and so can be separated from the gibberellins.

All methyl esters except those of gibberellins A_4 and A_7 can be resolved on silica-gel *G* using solvent systems 1 and 2.

Advantages of these methods are convenience, speed and sensitivity. The sulphuric acid sprays, which cannot be applied to paper chromatograms, are to be preferred to the perchloric acid spray[5] and are more sensitive and specific than the 0·5 per cent aqueous potassium permanganate spray[1]. The latter reagent does not detect gibberellin A_9 or less than 5 μg of the other gibberellins.

CERAMICS

Deformation of Quartz Crystals at the Transformation Temperature

The recent demonstration by Gorum, Parker and Pask[1] that magnesium oxide crystals could be bent plastically at room temperature has stimulated considerable interest in ductile ceramics. The plastic behaviour of alumina crystals at elevated temperatures as shown by Wachtman and Maxwell[2] and Kronberg[3] also directed attention to the fundamental behaviour of refractory oxides.

No data concerning deformation of quartz appear to have been published. This communication describes attempts to deform this material at the α ⇌ β transformation temperatures (571° and 573° C).

The specimen was cycled between two temperatures, 565° and 585° C, as the exact transformation temperatures could not be maintained for a period of time.

Rectangular bars (approximately 2·5 cm × 0·180 cm × 0·17 cm) of single-crystal quartz of random orientation were loaded in a three-point bending device, the details of which will be published elsewhere[4]. Each specimen, subjected to a maximum fibre stress of 5,000 lb./in.^{2} (occasionally 7,000 lb./in.^{2}), was cycled several times between 565° and 585° C with a very slow rate of heating and cooling. A typical curve is shown in Fig. 1 for one cycle of heating and cooling. The temperature at the maximum point of deflexion was found to be 573° C on the heating cycle and 571° C on the cooling cycle for all specimens. The specimen had apparently deformed. Assuming the complete reversibility of the transformation process, this may be considered as a true plastic deformation. The appearance of the samples under a polarizing microscope was the same before and after testing. The total permanent deformation was calculated from the difference of the original and final reading at 565° C. Similar calculation considering 585° C as the line of reference was not so successful, due to the drift on the line at 585° C (Fig. 2). This drift probably was produced by the temperature gradient existing across the furnace wall to the ceramic thrust column and was more pronounced in the heating cycle. However, calculation, if made on the basis of the dotted line (Fig. 2, drawn from the points at which drifting started) as the true base line at 585° C, produced results which are in good agreement with those obtained from 565° C as the line of reference.

In addition to the direct measurement of the deformation, the data were analysed as follows. The maximum deflexion (as in Figs. 1 and 2) is a cumulative effect of the change of elastic modulus with temperature (which exhibits a minimum value at the transformation temperature) and the change of volume accompanying the transformation and permanent deformation. After approximately the fourth cycle of heating and cooling, no further permanent deformation was observed and the total deflexion was found to be constant for the heating as well as for the cooling cycles. The deflexion produced by the change of elastic modulus was reduced during heating due to volume expansion. It was increased by the same magnitude during cooling due to volume shrinkage. Knowing the values of deflexion at the heating and cooling cycles, the deflexions due to the change of modulus of elasticity and change of volume were calculated. Then, subtracting from the total deflexion those constant contributions produced by the elastic modulus and volume change, values for the permanent deformation in first, second and third cycle were obtained.

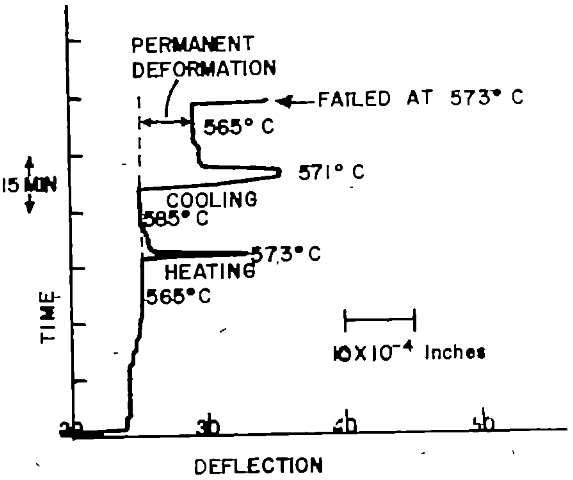

Fig. 1. Temperature cycling-deflexion curve of quartz under a maximum fibre stress of 5,000 lb./in.^{2}

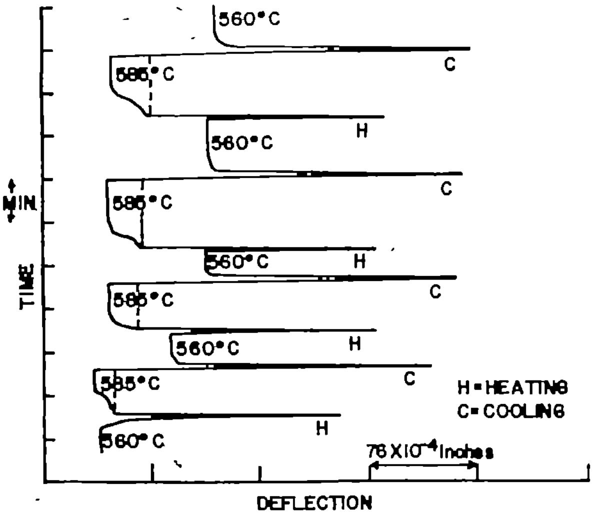

Fig. 2. Effect of temperature cycling on the permanent strain of quartz under a maximum fibre stress of 5,000 lb./in.^{2}

The modulus of elasticity and the per cent linear expansion or contraction were also calculated for different specimens. Typical values are shown in Table 1.

The values for the modulus of elasticity are in quite good agreement with those obtained by other workers[5].

The residual strain was found to vary from 0·055 to 0·030 per cent for different specimens on the first cycle. This variation is possibly due to the different orientation of crystals in respect to the direction of the applied stress. A somewhat higher permanent strain was obtained (as much as 0·07 per cent) with a maximum fibre stress of 7,000 lb./in.^{2}. However, frequent failure of the specimen under this load at the transformation temperature restricted further investigation.

Fig. 2 shows the effect of successive cycling of heating and cooling on the permanent deformation. The residual strain was very similar for all the specimens tested for the second and third cycles, being 0·013 and 0·004 per cent respectively. Permanent deformation of 0·002 per cent could be calculated in the fourth cycle in some cases. However, in most cases no noticeable deformation could be observed in the fourth or succeeding cycles.

Table 1

Specimen No.	Total deflexion (in.) Heating (average of three cycles)	Total deflexion (in.) Cooling (average of three cycles)	Deflexion due to change of elastic modulus (in.)	Deflexion due to volume change (in.)	Linear change (%)	Modulus of elasticity (lb./in.^{2}) 565° C.	Modulus of elasticity (lb./in.^{2}) 573° C
1	$13·6 \times 10^{-4}$	$26·2 \times 10^{-4}$	$20·0 \times 10^{-4}$	$6·2 \times 10^{-4}$	1·0	$8·0 \times 10^{6}$	$4·2 \times 10^{6}$
2	$14·8 \times 10^{-4}$	$25·8 \times 10^{-4}$	$20·3 \times 10^{-4}$	$5·5 \times 10^{-4}$	0·83	$10·2 \times 10^{6}$	$3·7 \times 10^{6}$

This effect was further studied by successively cycling a specimen (6 times) with an applied maximum fibre stress of 5,000 lb./in.² to obtain complete hardening. Afterwards, another series of temperature cycling was carried out with the same specimen at 7,000 lb./in.². A permanent strain of 0·035 per cent was obtained on the first cycle at 7,000 lb./in.² for the hardened specimen. However, with continued cycling at 7,000 lb./in.² the specimen again lost its ductility.

Annealing of the strained specimen for 15 h at 800° C completely restored the original ductility. However, no recovery of its original ductility was observed with a similar annealing treatment of the strained specimen below the transformation temperature.

I thank Mr. W. R. Irvine for his help in carrying out the experiments and Dr. E. Teghtsoonian for advice.

BIOCHEMISTRY

Succinic Dehydrogenase Activity and Oxidative Phosphorylation of the Mitochondria in the Crystalline Lens of Bovines

It is well established that only a small amount of the glucose consumed by the eye lens supplies carbon dioxide. The part played by the Krebs cycle in this oxidization and even the presence of the enzyme of this cycle have given rise to much controversy. According to Kinsey[1] oxidative degradation occurs almost exclusively in the epithelium. However, the report of succinic dehydrogenase activity in eye lens homogenates[2] and the inhibition of energy production in the fibres by potassium cyanide[3] suggests the possible presence of an oxidative process outside the epithelium.

In the course of an earlier investigation[4] we established the presence of mitochondria in the various zones of the lens and attempted the study of their metabolic activity. This communication attempts to define the succinic dehydrogenase activity of the mitochondria in the various zones of the lens and particularly the aptitude to oxidative phosphorylation of the mitochondria in the anterior (*E*) and cortical equatorial (*CE*) zones.

Our experiments have been carried out on lenses of calves, taken from the animals immediately after death and placed into a container at 0°. Various zones of the lens were separated by dissection at 0°: an anterior zone comprising the capsule, the epithelium and some fibres (*E*), an equatorial cortical zone (*CE*), an anterior cortical zone (*CA*) and a posterior cortical zone (*CP*); the central part which remained frozen during the manipulation was then rejected. The various zones were homogenized for 5 min, after the addition of nine volumes of 0·3 M sucrose containing 10^{-4} M of ethylenediamine tetraacetic acid. Subcellular fractionation was carried out by differential centrifugation according to the technique of Hogeboom, Schneider and Pallade[5], as modified by Aldridge and Johnson[6]. The combined mitochondrial fractions were washed in 0·3 M sucrose and 10^{-4} M ethylenediamine tetraacetic acid.

In a previous investigation we established by electron microscopy the presence of mitochondria in the pellets thus isolated; we found that these mitochondria were very few in number, more or less swollen, but recognizable by their peripheral cristae.

An incubation mixture almost similar to Aldridge's[7] (see legend, Table 3) was adopted, but we had to add cytochrome *c*. The choice of the incubation mixture allowed us to eliminate the inhibition of succinic dehydrogenase by endogenous oxaloacetate or by that produced by the degradation of sodium succinate[8]. The quantity of oxygen consumed by the mitochondrial fractions was determined according to the classic manometric method of Warburg. Incubations were performed for 1 h at 37° and in the presence of air[9]. Finally we evaluated the quantity of adenosine triphosphate (ATP) produced, by measuring the amount of mineral phosphorus which had disappeared from the incubation mixture[10]. The technique for evaluating the quantity of ATP by enzymatic dosage of glucose-6-phosphate[11] could not be applied because of the glucose-6-phosphate dehydrogenase activity of the lens[12,13]. For phosphorus assay we used the technique of Martin and Doty[14].

Our results are presented in Tables 1, 2 and 3.

Table 1. ACTION OF CYTOCHROME *c* AND INHIBITORS ON SUCCINIC DEHYDROGENASE ACTIVITY OF CALF LENS MITOCHONDRIA

Incubation mixture	Q_{O_2} μl /g wet weight
Sodium succinate 5×10^{-2} M + cytochrome *c* 1×10^{-4} M	3·46
Sodium succinate 5×10^{-2} M without cytochrome *c*	0
Sodium succinate 5×10^{-2} M + cytochrome *c* 1×10^{-4} M + Na malonate 5×10^{-2} M	0
Sodium succinate 5×10^{-2} M + cytochrome *c* 1×10^{-4} M + potassium cyanide 1×10^{-3} M	0

Incubation mixture, see Table 3.

Table 3. OXYGEN CONSUMPTION, ATP PRODUCTION AND P/O RATIO OF ISOLATED MITOCHONDRIA FROM EPITHELIAL AND CORTICAL ZONES OF BOVINE LENSES

Exp.	μm ATP produced (μatom g P)	μatom g O	P/O
1	3·00	2·67	1·12
2	3·55	2·75	1·29
3	2·18	1·70	1·28
4	3·55	2·85	1·25

ADP, 0·0025 M; ATP, 0·0006 M; KCl, 0·044 M; $MgCl_2$, 0·006 M; PO_4H_2Na and PO_4HNa_2, 0·0008 M; cytochrome *c*, 0·0004 M; KF, 0·025 M; glucose, 0·06 M; sodium succinate, 0·03 M, in main vessel, volume 2·3 ml, Hexokinase 200 u., 0·3 ml. in side-arm and 0·2 ml. NaOH 10 per cent in the centre well.

A survey of Tables 1 and 2 shows that the addition of cytochrome *c* is necessary to demonstrate the succinic dehydrogenase activity of the mitochondria *in vitro*. This, undoubtedly, is a consequence of the very small quantity of cytochrome *c* in the lens[15], a fraction of which has probably been lost during preparatory work; cytochrome thus appears as a limiting factor in the evaluation of respiration of the lens.

It is noticeable, moreover, that classic inhibitors such as that of the succinic dehydrogenase, sodium malonate, and that of electron carriers, potassium cyanide, suppress this respiration. But, and this is an essential fact, the succinic dehydrogenase activity actually exists in all the zones studied: in the epithelium where it is clearly highest as well as in equatorial, anterior or posterior fibres.

The parallel analysis of oxygen consumption and ATP production gives an average value of 1·2 for P/O. Now, the theoretical P/O ratio admitted for the succinic fumarate stage is two[16]. This figure, however, represents the maximum yield possible in optima conditions of coupling of the phosphorylations and oxidization. Experimental figures show the average yield of a preparation for a given tissue; they are generally inferior to 2 and oscillate between values approximating 1, obtained for sarcosomes, and 1·7, given by the same authors for the mitochondria in the liver[17].

We think that our comparatively small values can be explained by damage done to the mitochondria the separation of which from the lens is relatively long and difficult because in each experiment the zones of 120 crystalline lenses were used and separated. Thus taking into account these preparatory conditions which favour the uncoupling of phosphorylations and oxidations, we may admit that the P/O values *in vivo* are superior to those found *in vitro*.

In any event, our experiments indicate the actual existence of a reaction chain of the Krebs cycle in the lens fibres; it is more active in the epithelium, but is not negligible in the other zones of the lens; our P/O value can be considered as satisfactory considering the damages done to mitochondria.

Axial Period of Fibrinogen and Fibrin

X-RAY diffraction was first applied to the analysis of blood clotting by Bailey, Astbury and Rudall[1]. The apparent persistence of the α-type wide-angle X-ray diagram when fibrinogen is converted to fibrin led these investigators to conclude that "fibrinogen is no other than an insoluble modification of fibrin without any fundamental change in molecular plan".

More recent investigations have given new insight into the structural basis of the α-diagram. This pattern may be interpreted as due to a coiled-coil conformation of α-helices[2,3]. In general, however, the wide-angle X-ray diffraction pattern of a polymer gives information about the chain configuration of ordered regions only. An estimate of α-helix content may be made by optical rotatory dispersion measurements: on this basis, fibrinogen has a helix content of about 30 per cent[4]. Thus, the coiled-coil region characterizes only a small part of the total molecular structure, so that conclusions on the clotting mechanism based solely on the wide-angle diagram are not rigorous.

Support for the picture of fibrinogen as a more complex molecule comes from the electron microscope observations by Hall and Slayter[5,6]. These investigators have proposed a model for the molecule consisting of three globular units about 60 Å in diameter, separated by a thin strand. This picture is consistent with a molecular weight of about 300,000[7]. The average length of dried fibrinogen monomer varies with pH from about 270 to 400 Å when measured in electron micrographs[8]. Light scattering measurements[8] at pH 6·2 and 8·2 give a radius of gyration for fibrinogen monomer of 150 Å. Assuming the general model proposed by Hall and Slayter this would correspond to an overall length of about 400 Å upwards, depending on the exact relative sizes of the three globular units, and the rigidity of the interconnecting strand. It has been postulated[9] that the thin rod seen in the electron microscope may have the coiled-coil conformation.

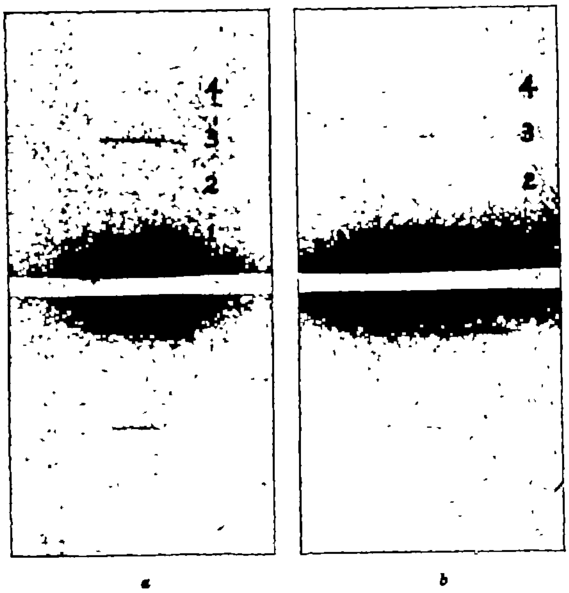

Fig. 1. *a*, Fibrinogen gel; *b*, fibrin clot. The specimen to film distances and magnifications are identical in these two photographs. The defining slit was longer in Fig. 1*b* than in Fig. 1*a*

In order to obtain further information on the structural basis of the clotting mechanism, low-angle X-ray diffraction investigations were begun. This technique reveals significant large-scale structural features; it may be carried out on hydrated 'native' specimens; and it affords the possibility of a quantitative determination of electron density. Here we report our preliminary observations.

Bovine fibrinogen ('Pentex Fraction I') was formed into gels by high-speed centrifugation of a 1–2 per cent purified solution in 0·3 M potassium chloride at pH 8–9. A portion of the birefringent pellet was aspirated into a thin-walled 1 mm diameter quartz capillary; second-order interference colours and good extinction were often observed. Fibrin was formed by the addition of bovine thrombin (Parke-Davis) to a fibrinogen solution in 0·3 M potassium chloride at pH 5–7. The clot was packed by centrifugation and a portion of the birefringent pellet inserted into a capillary. Most of the X-ray diagrams were obtained with nickel-filtered copper $K\alpha$-radiation and a low-angle camera with slit collimation, giving very high resolution along the meridian. Pictures were also taken using a bent quartz crystal focusing monochromator which gave more uniform overall resolution.

The low-angle diagrams of fibrinogen and fibrin gels both show four orders of a 226 ± 3 Å axial repeat (Fig. 1). There is some variation of the intensity distribution among different specimens, but the trend is similar in the two materials (Table 1). Pinhole collimation pictures show that the four layer lines have greatest intensity on the meridian. The patterns are characterized by very sharp layer lines indicating a considerable degree of crystallinity along the fibre axis; and very little arcing of the layer lines, indicating good orientation of the crystallites with respect to the fibre axis. The equator has no discrete low-angle reflexions.

Fibrin stained with phosphotungstic acid also shows a 230 Å period, and a characteristic striation in the electron microscope[10,11]. This period has been interpreted by some

Table 1. QUALITATIVE ASSIGNMENT OF INTENSITIES IN FIBRINOGEN AND FIBRIN GELS

Order (period 226 Å)	Fibrinogen	Fibrin
1	Strong	Strong to very strong
2	Very weak	Very weak or absent
3	Medium	Medium
4	Weak	Weak

authors[4] as directly representing the length of the fibrinogen monomer. By this hypothesis, an intramolecular contraction or folding must occur on clotting, since the monomer seen under the electron microscope is often longer than 230 Å. Our X-ray diffraction results make it appear more likely that the fibrin period represents some staggered arrangement of the fibrinogen monomer. For example, if the length of the fibrinogen monomer were 460 Å, a half-staggered arrangement would give the observed 230 Å period for fibrin.

The identity of the axial period of the fibrinogen gels and fibrin clots, and the similar trend of thoi diffracted intensities, strongly suggest that there is no major internal rearrangement of the monomer in the clotting process. This finding thus provides a more rigorous foundation for the original interpretation given by Bailey *et al.*[1].

We thank Mr. J. Kucera for some of the fibrinogen and fibrin preparations.

Replacement of Thymidylic Acid by Deoxyuridylic Acid in the Deoxyribonucleic Acid of a Transducing Phage for *Bacillus subtilis*

THE findings that the thermal denaturation temperature (T_m) of DNA from a wide variety of bacterial, plant and animal sources as well as the buoyant density in a caesium chloride gradient are linearly related to the guanine plus cytosine (G plus C) base composition[1,2] have made it possible to search for the existence of DNA samples which would show an anomalous behaviour with respect to these two parameters. Native DNA preparations which show no correlation between their buoyant density and T_m would be expected to have components other than those usually encountered in DNA[3]; this situation might arise with a high degree of probability in the DNA isolated from bacteriophages or viruses, which because of their specialized behaviour would be expected to possess distinctive structural features.

Bacteriophages *PBS*1 and *PBS*2 have been shown to transduce several genetic markers among strains of *Bacillus subtilis*[4,5]. The DNA's from these phages were very similar in their chemical composition and physical properties. Consequently only the data obtained with *PBS*2 will be presented in this communication. When native DNA from this phage was examined, it was found that its T_m in 0·15 M sodium chloride plus 0·015 M sodium citrate was 76·5° (corresponding to 17·5 per cent G plus C) and its buoyant density was 1·722 g/c.c. (corresponding to 62 per cent G plus C). This discrepancy prompted a chemical analysis of the nucleic acid constituents.

Purified *PBS*2 DNA was hydrolysed in 12 N perchloric acid for 60 min at 100° and liberated bases were separated by paper chromatography. Four spots were obtained by two-dimensional chromatography with solvents *A* and *B* and also with solvents *B* and *C* (Table 1). Three spots were identified as adenine, guanine and cytosine. Thymine was absent from the chromatograms. The designation of the fourth base as uracil was suggested by chromatographic and also spectrophotometric comparison with other pyrimidines (Tables 1 and 2). Further, this identification was supported by the fact that a uracil requiring *B. subtilis* strain (*A* 26) could grow on a minimal medium containing the compound eluted from the fourth spot but not on thymine.

* The data for the reference compounds were taken from the literature; the data for deoxyuridylate (Sigma) were obtained in our laboratory.
† Obtained from purified *PBS*2 DNA either by perchloric acid hydrolysis or by snake venom phosphodiesterase hydrolysis.
‡ Reference compounds.

Enzymatic hydrolysis of thermally denatured *PBS*2 DNA with snake venom phosphodiesterase (Worthington) was carried out and the mononucleotides were separated by chromatography on 'Dowex-1' (formate form) and elution carried out with formate and bicarbonate[6]. The uracil-containing nucleotide was eluted from the column with 0·2 M ammonium bicarbonate (which normally elutes thymidylate). The spectrophotometric data of this nucleotide together with those of other pyrimidine deoxynucleotides are summarized in Table 2. The ultra-violet absorption spectrum of deoxyuridylate is indistinguishable from that of uridylate and additional tests were carried out to identify the sugar component. The nucleotide was treated with prostatic phosphomonoesterase. The uracil-containing nucleoside[7] thus obtained migrated with authentic deoxyuridine but not with the faster moving uridine in paper electrophoresis with 0·1 M borate buffer at *p*H 9·2. Furthermore, the sugar moiety of the nucleoside was identified as deoxyribose by the method described by Waravdekar and Saslaw[8] after an incubation with deoxynucleoside transglycosidase and adenine[7]. Thus the possibility that the uracil spot found in the paper chromatograms of perchloric acid hydrolysed *PBS*2 DNA might be a degradation product could be eliminated.

In addition to the replacement of thymine by uracil, the DNA from *PBS*2 has another unusual feature. The mole per cent base composition of *PBS*2 DNA determined by paper chromatography (average of 4 independent experiments) was adenine, 35·9; uracil, 35·9; guanine, 13·4; cytosine, 14·7 (G plus C : 28 per cent). This base composition differs significantly from that of the host DNA (G plus C : 43 per cent). The DNA's of known transducing phages such as *P*22 and λ have been shown to possess a base composition similar to that of bacterial host DNA[8,9]. This suggests that the mechanism by which *PBS*1 and *PBS*2 transfer the bacterial genome might be somewhat different from that in other transducing systems. Phages *PBS*1 and *PBS*2, therefore, may offer a unique situation not only for studying the biosynthesis of phage DNA but also the genetics and the DNA base sequence homology of host–virus relationships.

We thank Dr. L. Grossman for his advice and for supplying chemicals and enzyme preparations. One of us (J. M.) received support from the National Science Foundation and the U.S. Public Health Service.

Changes in the Ribonucleoproteins of the Nucleolus following Inhibition of Synthesis of Deoxyribonucleic Acid

BY means of an improved toluidine blue–molybdate staining procedure[1] two types of ribonucleoprotein (RNP) can be very clearly demonstrated in the nucleolus. One type is the pars amorpha and the other consists of minute granules or hollow spheres and appears to correspond to the nucleolini of classical cytologists[2]. Enlargement of the nucleolini has been observed in cells infected with viruses and in cells in which the onset of mitosis is blocked by large doses of colchicine[3]. The relationship between the changes in the nucleolini and nucleic acid metabolism is not clear in these systems. An examination of the nucleolar RNP was therefore undertaken in cells treated with 5-fluorodeoxyuridine (FUDR) since the metabolic changes produced by this antimetabolite have been extensively studied. FUDR inhibits synthesis of deoxyribonucleic acid (DNA) by blocking the formation of thymidylic acid[4,5]. When cells in tissue culture are treated with FUDR, DNA synthesis is prevented, cell division is arrested and the metabolism of ribonucleic acid (RNA) is disturbed[6,7]. During one generation time of HeLa cells, the DNA per cell remains constant, the cytoplasmic RNP doubles and the nuclear RNP is unchanged. Salzman and Sebring provide evidence that the effect of FUDR on RNA metabolism of HeLa cells is mediated through its effect on DNA synthesis since the process is reversed by thymidine, but not by uridine[7].

In the present work, a clone of *S*3 HeLa cells (kindly provided by Dr. N. P. Salzman) was grown in ring cultures[8] in Eagle's minimal essential medium containing 1 per cent glutamine and 8 per cent horse serum. Cell growth was inhibited by the addition of 10^{-6} M FUDR, which was changed daily (Fig. 1). The inhibitory effect was reversed by removal of the analogue and the addition of equimolar thymidine (Fig. 1). Examination of preparations stained to demonstrate the nucleolar RNP[1] indicated that the changes in the cells were not synchronous. FUDR inhibited the onset of prophase and exerted a *C*-mitotic effect on dividing cells. The earliest change in the nucleolus was noted in a few cells 4 h after addition of the inhibitor and consisted of fusion of the nucleolini to form large RNP bodies. Afterwards, the number of cells showing this change increased. During the succeeding 21 h, two processes occurred contemporaneously. The intensity of staining of the nucleolini decreased and many were extruded from the pars amorpha into the nucleoplasm until most of the nucleoli contained few or no nucleolini. Fragments of RNP staining like the nucleolini were seen in the nucleoplasm and, occasionally, even in the cytoplasm of some cells. In many cells the nucleoplasm appeared empty. 3–6 h after addition of thymidine numerous prominent nucleolini were reformed in the pars amorpha. Shortly afterwards, mitotic division was restored to normal (Fig. 1). In the cultures which remained exposed to the inhibitor mitosis was completely blocked and the nucleolini progressively disappeared, leaving only the pars amorpha surrounded by an empty nucleoplasm in which occasional RNP bodies remained.

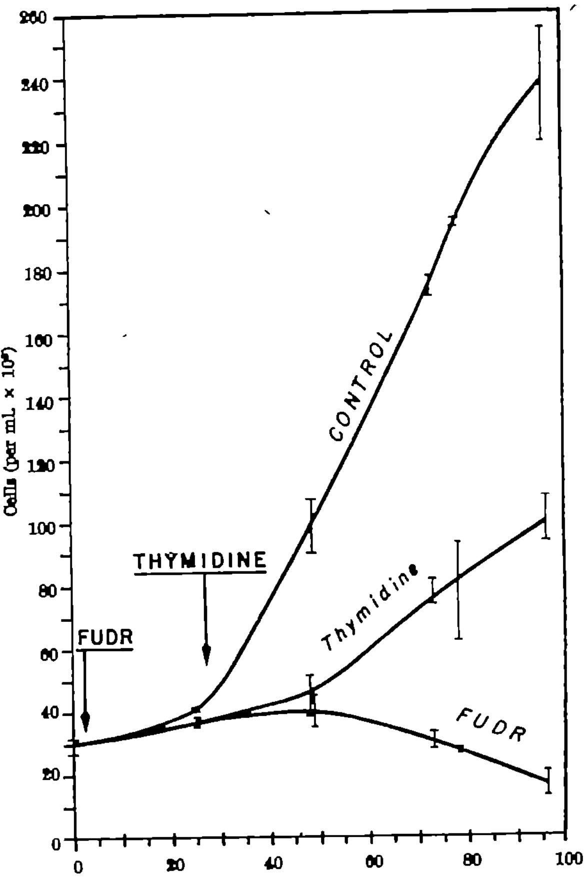

Fig. 1. Effect of 10^{-6} M 5-fluorodeoxyuridine on growth of HeLa cells and reversal by thymidine. The medium was changed daily on the control cultures. 10^{-6} M 5-fluorodeoxyuridine was applied to the experimental groups for the first 25 h. At this time, and daily thereafter, the medium was replaced by medium containing 10^{-6} M fluorodeoxyuridine or thymidine. The range of two replicate counts is indicated by the vertical bars

The mechanism of action of FUDR on RNP metabolism is indicated by reversal studies. The inhibitory effect of FUDR on cell growth and on the formation of RNP of the nucleolini was prevented by equimolar thymidine, but not by a 100-fold greater concentration of uridine in the FUDR solution. Since exogenous thymidine is incorporated solely into DNA thymine in HeLa cells[8], the reversal of the effect of FUDR on the RNP by thymidine appears to be secondary to reversal of the inhibition of DNA synthesis. Some FUDR is converted to fluorouracil; this in turn forms fluorouridylic acid which is incorporated into RNA[4,5,7]. If the inhibition of RNA synthesis were due to a block in the synthesis of uridylic acid by fluorouracil, it should have been reversed by exogenous uridine, which is a precursor of RNA uracil[9] and which reverses the effect of fluorouracil on *Candida albicans*[10]. Thus, the formation of RNP in the nucleolini appears to be dependent on DNA synthesis.

In normal cells, the nucleolini were small and numerous and occasional small granules of similarly staining RNP were present in the nucleoplasm. When DNA synthesis and mitosis were blocked by FUDR, the nucleolini and the granular RNP of the nucleoplasm were enlarged and occasional granules of similar RNP were seen in the cytoplasm. Afterwards, this RNP disappeared, first from the nucleolus and then from the nucleoplasm and cytoplasm. This would suggest the RNP of the nucleolini was passing from the nucleolus to the cytoplasm, probably in the same way as it does in the normal cell. When mitosis is blocked in cells infected with viruses or by treatment with colchicine or FUDR, the RNP may not be utilized normally or may move more slowly and accumulate in larger masses than in the normal cell. In the absence of further synthesis of RNP of the nucleolini type, this RNP disappears first from its site of formation, the nucleolus, and then from the nucleoplasm. The dependence of the synthesis of the RNP of the nucleolini upon DNA synthesis would suggest that its RNA may be the 'nucleolar' RNA II fraction which has been shown to have a high rate of synthesis and a base composition resembling DNA[11]. Further experiments are in progress to determine whether the RNA of the nucleolini may be the 'messenger' RNA which has been described by Sirlin *et al.* in the nucleolus[12].

We wish to thank Hoffmann-LaRoche Inc. for the supply of FUDR. This work was supported by grant *CA*-05402-03 *VR* from the National Institutes of Health.

A Possible Role for Minor Bases in Ribonucleic Acid

MOST discussions on the nature of the code between RNA and protein have given consideration only to the four major bases and have ignored the existence of the minor bases known to occur in RNA. Bergquist and Matthews[1] have suggested on the basis of analytical data on RNA fractions from various tissues that all the methylated purines occur in soluble RNA and that the small proportion of these bases found in other fractions, for example ribosomal RNA, may be due to transfer RNA functionally associated with these particles at the time of extraction. We also calculated that there may be roughly 1–2 methylated purine residues in each molecule of *p*H 5·2 precipitate RNA, but at that time we could see no special function for such bases. However, two recent papers[2,3] on RNA make it possible to suggest such a function.

First, Spencer *et al.*[2] have described a structure for transfer RNA. The bulk of the molecule is made up of a regular double helix with hydrogen-bonded base pairing. Methylated bases would be unlikely to occur in this region of the molecule. They suggested that a coding triplet of nucleotides with bases exposed for hydrogen bonding might occur in the short non-helical region of the chain they describe. Secondly, Woese[3] suggested that only the 2′ and 6′ positions in the four major bases may be involved in coding; and that of the triplet of bases concerned with one amino acid, one base codes according to both the 2′ and 6′ position, one according to the 2′ position only, and one according to the 6′ position only. This scheme accounts nicely for a number of experimental observations.

I now wish to suggest that in the triplet of bases in transfer RNA, which may be at the non-helical end of the molecule, and which might hydrogen bond specifically with the appropriate triplet in the template RNA on the ribosome, two of the bases are methylated purines or one of the minor pyrimidine components. The structural differences in these bases might serve to block the reading of the redundant 2′ or 6′ positions suggested by Woese. If there was a unique minor base in transfer RNA for each of the 2′ or 6′ positions on the template bases that are read singly in Woese's scheme, then 5 different minor bases would be required as follows: three which are incapable of bonding with the 6′ position in the template base but distinguished between $=O$, $-NH_2$ or $-H$ on the 2′ position; and two that are incapable of bonding with the 2′ in the template base but distinguished between $-NH_2$ and $=O$ on the 6′ position. For example, 6-hydroxy-2-dimethyl-aminopurine would be unable to donate hydrogen from the 2′ position, but the $=O$ at position 6′ would be available as a hydrogen acceptor. The following minor bases have been found in soluble RNA from various sources: 6-amino-2-methylpurine[1,4–6], 6-methylaminopurine[1,4–6], 6-dimethyl-aminopurine[1,4], 6-amino-1-methylpurine[6], 2-amino-6-hydroxy-1-methylpurine[1,5,6], 6-hydroxy-2-methylaminopurine[1,5], 6-hydroxy-2-dimethylaminopurine[1,5], pseudouridine[6,7], thymine[4,6] and 5-methylcytosine[4,6].

Available analytical data are inadequate in several ways. All these bases have not been reported from all sources tested, but some may have occurred below the level of detection in the analyses. On the other hand, most analyses have been carried out either on whole soluble RNA or on unfractionated *p*H 5·2 precipitate RNA. The RNA in the supernatant fluid after precipitation of transfer RNA at *p*H 5·2 is richer in many of these bases than is the precipitated RNA[1]. Thus many of the published values may be higher than the actual proportions in transfer RNA. Further, there is the possibility that certain of the bases may arise by rearrangement from another base during hydrolysis of the RNA (for example, 6-methylaminopurine from 6-amino-1-methylpurine during alkaline hydrolysis[10].

Testing of the hypothesis outlined here could be made along two lines. First, more accurate analyses could be made on purified transfer RNA. The hypothesis predicts 2 minor base residues per 80 nucleotides, and if a transfer RNA specific for one amino-acid were analysed then there should be either 2 residues of one base per 80 nucleotides or one residue of each of two different bases, unless some of the bases function interchangeably or have some other function. Base sequence analysis on purified single transfer RNAs, when possible, should show whether two minor bases occur in the expected location near the centre of the chain.

Secondly, model-building, based on the structure of Spencer *et al.*[2] with two minor bases in the supposed coding triplet, and opposed to appropriate triplet sequences of major bases in a model or models of template RNA might reveal whether anything approaching the expected specificity can be obtained. A major base in the centre of the transfer RNA triplet flanked by two minor bases might tend to arrange the proposed four specific hydrogen bonding sites in the most effective pattern to give maximum stability to a molecule 100 Å long held by one end to the template and holding an activated amino-acid in line at the other.

Comparison of the Caseins of Buffalo's and Cow's Milk

By comparing the major non-casein proteins of the milk of the Indian buffalo (*Bubalus bubalis*) with those of cow's milk, it has been found[1] that the single β-lactoglobulin component produced by the buffalo is very similar in properties to one (*B*) of the two genetically controlled variants (*A* and *B*)[2,3] produced by the cow. Likewise, the single α-lactalbumin of buffalo milk resembles one (*A*) of the two variants (*A* and *B*) of this protein which occur in the milk of African[4] and Indian humped (zebu) cattle[5]. (Non-zebu cows have only one α-lactalbumin which is like the *B*-variant of zebu milk.) Thus there are striking similarities in the corresponding non-casein milk proteins of buffalo and cattle, two species incapable of cross-breeding.

We have now extended the comparison to the casein complex to see whether such similarities might also pertain to the components of the principal milk protein. Milk samples from individual buffaloes, zebus, Jersey cows and some zebu–Jersey F_1 crosses were prepared for, and subjected to, paper electrophoresis in the manner recently described for cow's milk[6]. Examination of the results, of which an example is given in Fig. 1, showed that two of the three major components, β- and κ-casein, were of comparable electrophoretic mobilities. (The apparent slower movement of the Jersey β-casein in Fig. 1 is fortuitous: the particular animal happened to be homozygous for the slower-moving *B*-variant occurring in Jersey milks.) No evidence of β-casein polymorphism was seen with any of the buffalo and zebu milks, but too few samples were examined to exclude the possibility that variants exist. In contrast to the β- and κ-components, the α-caseins showed quite marked differences in their rates of migration, not only between buffalo and cattle but also, more surprisingly, between zebu and non-zebu cows. The differences are larger than those due to the α-casein polymorphism recently observed in the milk of Holstein cows[7], differences which cannot be resolved by the paper-electrophoretic technique as applied here.

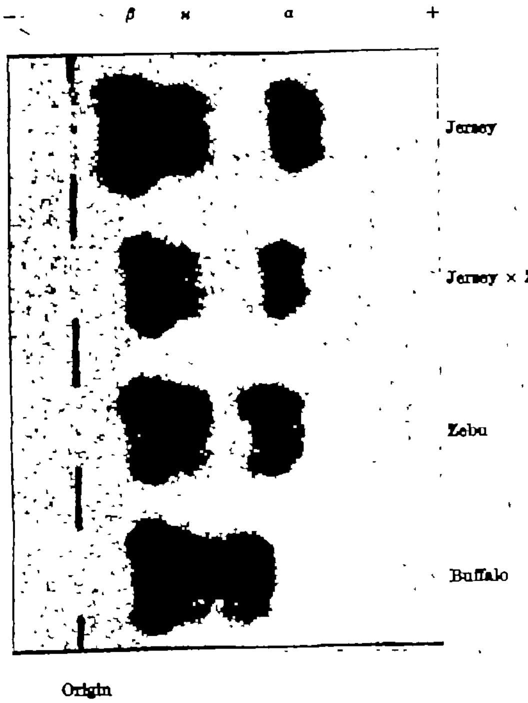

Fig. 1. Bovine caseins. Paper electrophoresis at pH 7·15

This preliminary study has shown that each of the main protein components of cow's milk has its counterpart in buffalo milk. More detailed physico-chemical studies are needed to establish the identity or near-identity of the isolated constituents, a finding which would lend support to the attractive hypothesis of a common origin of the bovine genera under discussion. Such a hypothesis might hold in spite of the non-identity of the α-caseins, since the difference in electrophoretic mobility between zebu and buffalo seems to be no greater than that between zebu and non-zebu cattle.

Inherited α-Lactalbumin and β-Lactoglobulin Polymorphism in Indian Zebu Cattle. Comparison of Zebu and Buffalo α-Lactalbumins

It has been shown by paper electrophoresis that genetically different types of β-lactoglobulin[1,2] and α-lactalbumin[3,4] occur in cow's milk. While genetic polymorphism of β-lactoglobulin is general among the cattle of different countries, that of α-lactalbumin has only been observed in two breeds of African zebus, the Nigerian White Fulani[3] and the boran[4] cattle of Kenya, but not in Icelandic, British[3], Danish[5] and North American[6] (Holstein) cattle. Blumberg and Tombs[3] noted the Nigerian White Fulani cattle to be similar in appearance to the 'Brahmin' cattle of the East, which were probably brought into Africa by the nomadic Fulani people, and suggested that α-lactalbumin-*A* might serve as a marker by which the affinities of the zebu cattle, and indirectly of the Fulani people associated with them, could be traced. We have now examined the α-lactalbumin and β-lactoglobulin polymorphism in Indian zebu cattle with the view of getting further information on this aspect.

Moreover, from a comparison of electrophoretic patterns of non-casein proteins of African zebu[5] and Indian buffalo milk[7], the mobilities of zebu α-lactalbumin-*A* and of the single buffalo α-lactalbumin appeared to be approximately the same. This indicated that these two proteins might have closely similar physico-chemical properties as has been observed[7–9] in the case of cow β-lactoglobulin-*B* and the single buffalo β-lactoglobulin.

The cows are described according to the nomenclature of Aschaffenburg and Drewry[3,4] as of phenotypes β-lactoglobulin *A*/*A*, *B*/*B* and *A*/*B* and α-lactalbumin *A*/*A*, *B*/*B* and *A*/*B* and the proteins as β-*A*, β-*B* and β-*AB* and α-*A*, α-*B* and α-*AB*.

Samples of milk from 138 zebu cows of different breeds and from 15 crosses between Jersey sires and Hariana dams were examined. Interestingly, the crosses, all belonging to the F_1 generation, were humpless, resembling European cattle. The samples were prepared according to the method of Aschaffenburg and Drewry[3] and tested at *p*H 8·6 by vertical or horizontal strip paper electrophoresis in veronal buffer, $I = 0·05$, on Whatman *3MM* paper applying a voltage of 240 V for 17 h.

The distribution of α-lactalbumin and β-lactoglobulin phenotypes among different breeds is shown in Tables 1*a* and *b* respectively. The agreement between the observed and expected frequencies shows that the Hardy–Weinberg law applies quite well throughout. Except in the case of Hariana, however, the results may not be very significant owing to the small number of samples available for testing. Nevertheless, it is seen that the gene frequency for α-*A* (Table 1*a*) is the lowest in the crosses and that for β-*A* (Table 1*b*) the highest. Since the α-lactalbumin *A*-gene is not found in British breeds[5], a relatively lower gene frequency for α-*A* is expected in the Hariana–Jersey crosses than in the total Hariana or zebu populations. In the case of β-lactoglobulin-*A*, the gene frequency in British breeds has been shown[3] to be 28 per cent, which is a significantly higher figure than the 9·4 per cent found by us for the total zebu population. Therefore, the gene frequency of β-*A* in the crosses should be higher than that in the total zebu population. This seems to be the case from Table 1*b*.

There were 31 dam daughter pairs in the Hariana population. Separate estimates of gene frequencies from this relationship gave frequencies of α-*A* and α-*B* of 0·181 and 0·819 (*S.E.* 0·0422) respectively and of β-*A* and β-*B* of 0·090 and 0·910 (*S.E.* 0·0303), frequencies which agree reasonably well with those obtained by the application of the Hardy–Weinberg formula.

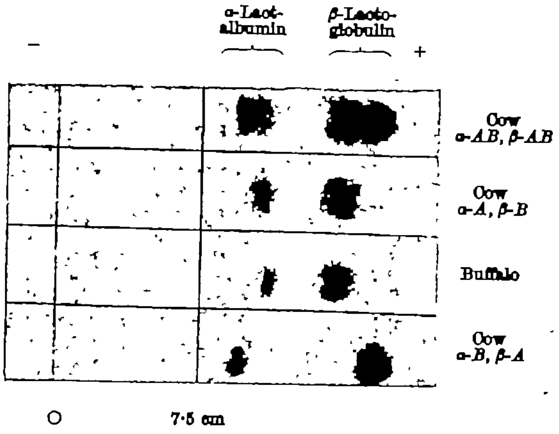

Fig. 1. Whey proteins of buffalo's and different types of cow's milk. O, Origin; bromo-phenol blue staining

Table 2 lists the gene frequencies of α-lactalbumin and β-lactoglobulin of cattle of different countries. The frequency of the *A*-gene of α-lactalbumin has the highest value in Indian zebu cattle with the African breeds having intermediate and the European breeds zero values. On the other hand, the frequency of the *A*-gene of β-lactoglobulin follows a reverse order with the Indian zebu cattle having the minimum and the European breeds the maximum value. The difference between the gene frequencies of α-*A* among Indian and African zebu cattle, though fairly large, is not significant according to the χ^2 test. The gene frequency of β-*A* for White Fulani, however, is significantly higher than that of the Indian zebu cattle. These observations appear to support the view[5] that the zebu cattle were probably brought into Africa by nomadic people.

Out of 7 α-*A* homozygotes, 4 had the combination of α-*A*, β-*B*. The electrophoretic patterns of buffalo whey proteins and cow whey proteins of types α-*AB*, β-*AB*; α-*A*, β-*B*; and α-*B*, β-*A* are shown in Fig. 1. The patterns

* From Table 1 *a* and *b*.

of whey proteins of buffalo's milk, and cow's milk with α-*A*, β-*B* seem to be almost identical, α-*A* migrating approximately the same distance as buffalo α-lactalbumin. Thus, α-lactalbumin polymorphism and existence of combinations such as α-*A*, β-*B* in zebu milk rule out the possibility of differentiation of cow's and buffalo's milk in a mixture, as previously suggested[7].

Cow α-lactalbumin-*A*, purified and crystallized by the method[10,11] used for α-*B*, and buffalo α-lactalbumin show, as expected, very similar mobilities (u) and shapes of patterns in free electrophoresis at *p*H 6·0, 7·58 and 8·6. The values of u (descending) for cow α-*A* and buffalo α-lactalbumin are $-2·40 \times 10^{-5}$ and $-2·43 \times 10^{-5}$ cm²/sec/V (*p*H 6), $-4·92 \times 10^{-5}$ and $-4·70 \times 10^{-5}$ cm²/sec/V (*p*H 7·58) and $-4·40 \times 10^{-5}$ and $-4·40 \times 10^{-5}$ cm²/sec/V (*p*H 8·6) respectively. In respect of other physical chemical properties, cow α-*A*, α-*B* and buffalo α-lactalbumin show close parallelism. They appear to have the same crystalline form, similar nitrogen contents, specific extinction coefficients at 280 mμ and tyrosine and tryptophan contents. Their sedimentation coefficients ($s_{20,w}$) fall within the range $1·87 \times 10^{-13}$ sec and $1·99 \times 10^{-13}$ sec. The molecular weight of buffalo α-lactalbumin, 16,200 g/mole, calculated from sedimentation and diffusion data is also close to that of the values[11,12] reported for cow α-lactalbumin. Some of the protein preparations, even after several recrystallizations, show the presence of a faster moving minor component (4–6 per cent) in electrophoresis and sedimentation, the mobilities and s values of which indicate it to be probably the serum albumin contaminant.

Thus, it is interesting to observe that cow α-*A* and buffalo α-lactalbumin show close similarity in their properties in almost the same manner as shown by cow β-*B* and buffalo β-lactoglobulin, which have approximately the same molecular weights[9] and are practically indistinguishable in crystal form[7], electrophoresis[9], sedimentation and ultra-violet absorption[9].

We thank Dr. R. Aschaffenburg, of the National Institute for Research in Dairying, Reading, for suggesting the work on α-lactalbumin polymorphism in Indian zebu cattle and for valuable criticism, and Dr. S. Bhattacharya and M. R. Konar of the Haringhata farm for discussions and help in collecting the samples and identification of breeds.

Significance of the Michaelis Constant

THE Michaelis–Menten[1] equation relating initial velocity of a simple enzyme-catalysed reaction to initial substrate concentration is:

$$v = \frac{k_3 es}{K + s} \tag{1}$$

where v is the initial velocity of reaction, e is the initial enzyme concentration, s is the initial substrate concentration, k_3 is the velocity constant of the breakdown of the enzyme-substrate compound into enzyme and product of the catalysed reaction and K is the substrate concentration at which v is half-maximal.

Michaelis and Menten[1] supposed K to be the equilibrium constant of the reversible reaction between enzyme and substrate. Briggs and Haldane[2] derived an expression showing it to be the ratio of the sum of the two monomolecular velocity constants governing breakdown of the enzyme-substrate compound to the bimolecular constant governing association.

Both pairs of workers based their derivations on the equation:

$$(e - p)s = Kp \tag{2}$$

where p is the initial equilibrium or steady-state concentration of enzyme-substrate compound. The full equation is:

$$(e - p)(s - p) = Kp \tag{3}$$

and the assumption was made in both cases that p was negligible relative to s. However, there are now known numerous cases in which the half-saturation concentration of the enzyme is very low. For example, the half-saturation concentration of D-amino-acid oxidase with flavin adenine dinucleotide (FAD) was reported by Warburg and Christian[3] to be in the region of 10^{-7} M. Since this means that the practicable range of substrate concentrations that can be used for kinetic studies will extend over about one order either side of this, the validity of equation (2) in all cases as an approximation to equation (3) seems doubtful.

The purpose of this communication is to point out that when the quadratic (3) is solved for p, one of the roots gives a solution which approximates to the form of equation (1), but K is replaced by $(K + e)$.

It would seem wise, therefore, in experiments with enzymes of unknown molar concentration, which have low half-saturation concentrations of substrate, to perform at least two series of experiments at different enzyme concentrations before equating the half-saturation concentration with the Briggs–Haldane[2] K. Where the enzyme concentration is known, an approximate idea of the error involved in ignoring enzyme concentration can be obtained by inspection.

When the original data of Warburg and Christian[3] are re-examined using modern techniques of fitting the Michaelis–Menten[1] relation it is found that the fit is very close and that the original estimates of K and $k_3 e$ are fully confirmed. Using more modern data for the half-saturation concentration for alanine, the second substrate used by Warburg and Christian[3], and for the turnover number of the pure enzyme (corresponding to k_3) which are given by Long[4], it can be calculated that the enzyme concentration used was roughly $1·4 \times 10^{-7}$ M. Since the half-saturation concentration for FAD was found to be $2·5 \times 10^{-7}$ M, it follows that the Briggs–Haldane[2] constant is about half the published value for K_m.

PHYSIOLOGY

Electrophoretic Behaviour of an Aminopeptidase of Human Tissues and Serum

A SERUM aminopeptidase[1] (LAP) that hydrolyses L-leucyl-β-naphthylamide migrates as a single component to the α_1-globulin region in the electrophoretic pattern of normal serum and the serum of the first and second trimesters of pregnancy. Additional components of LAP which migrate to other areas have been found in the serum of many patients with hepatobiliary and pancreatic diseases and in the third trimester of pregnancy[1-3]. The origin of these 'isoenzymes' of serum LAP was sought in an examination of the electrophoretic mobility of LAP from various tissues which exhibited high specific activity of this enzyme.

Crude extracts of apparently normal human liver, pancreas, kidney and placenta obtained at operation or immediately post-mortem were prepared by homogenizing each tissue in approximately 5 times its weight of distilled water (2° C) in a *TRI-R, STIR-R* homogenizer. The more fibrous tissues were prehomogenized in a 'Virtis 45' homogenizer. The homogenates were centrifuged at 5,000 r.p.m. (1,900*g*) for 30 min at 2° C. The residue was discarded and the supernatant centrifuged at 17,000 r.p.m. (20,000*g*) for 30 min at 2° C. The residue was again discarded and solid ammonium sulphate was then added to the supernatant (I) to yield a 65 per cent saturated solution. This solution was centrifuged at 10,000 r.p.m. (7,500*g*), the supernatant (II) separated and the residue suspended in cold distilled water (III) to a final volume equal to that of the original solution. Fractions I, II, and III were assayed for LAP activity[4] and the electrophoretic behaviour of the enzyme was determined on cellulose acetate strips.

For electrophoresis 10 μl. of solution were placed along the centre line of a 2·5 × 10 cm strip of cellulose acetate, which was divided into twenty equal sections by vertical pencil lines drawn at 0·5-cm intervals along the length of the strip. The strips were contained in a Shandon Universal electrophoresis apparatus. The samples were electrophoresed for 3 h in veronal buffer *p*H 8·6, ionic strength 0·075, at a constant current of 0·4 m.amp/cm width of paper. Samples of normal serum and serum treated as here with ammonium sulphate were electrophoresed simultaneously with the tissue extracts for comparison. Following electrophoresis LAP activity was localized on the cellulose acetate strips by a method described elsewhere for paper strips[5].

The electrophoretic mobilities of LAP in normal liver and serum were identical and coincided with that of the serum α_1-globulin (Fig. 1*A* and *B*). This observation supports the view that the liver is a primary source of serum LAP[1].

The pancreatic enzyme exhibited two overlapping peaks of activity, a major peak in the vicinity of the serum γ-globulin, and a minor peak in the region of the β-globulin (Fig. 1*C*). The latter peak has been observed in the serum of most patients with cancer of the head of the pancreas[3].

Placental LAP migrated as an α_2-globulin, as did the serum LAP in late pregnancy (Fig. 1*D*).

Crude kidney extract (I) displayed a broad peak of LAP activity in the α_2- and β-globulin regions (Fig. 1*E*). Kidney supernatant (II), unlike that of liver, pancreas, and placenta, showed considerable LAP activity. Electrophoresis of this supernatant (II) and of the resuspended residue (III) showed that the single broad peak consisted of two peaks, that of the soluble component in the

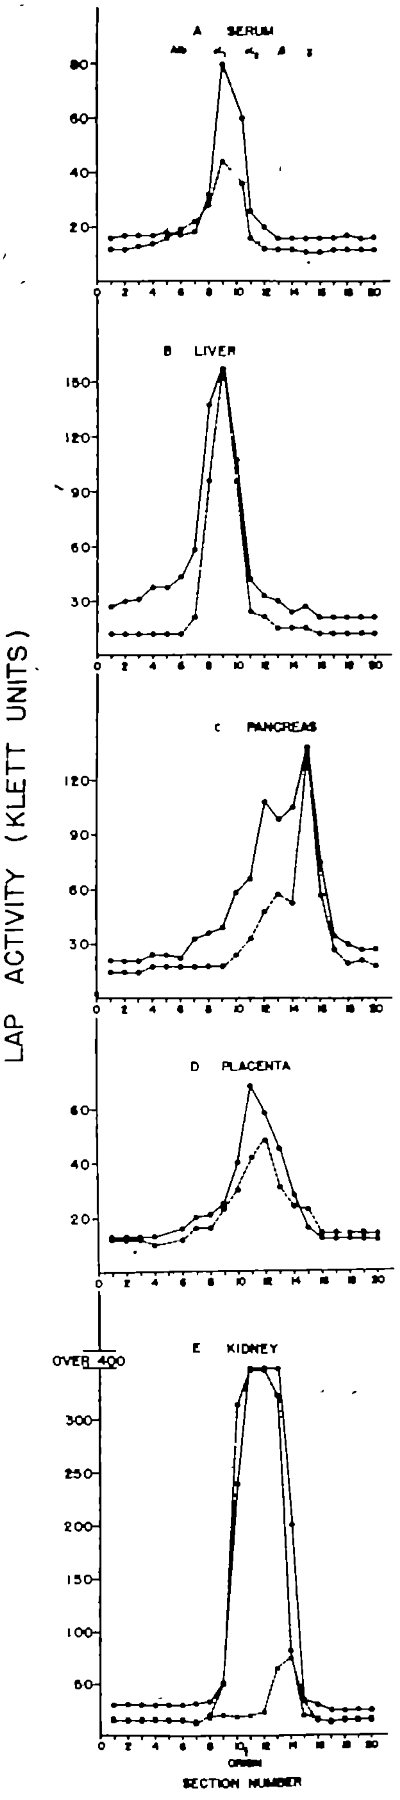

Fig. 1. Electrophoretic localization of leucine aminopeptidase in serum and tissue extracts before (solid line) and after (broken line) ammonium sulphate fractionation. The small peak in Fig. 1*E* represents kidney LAP soluble at 65 per cent ammonium sulphate saturation

β-globulin region and that of the insoluble enzyme in the α_2-globulin region. Preliminary studies showed that the LAP in normal urine migrates to the α_2-globulin region.

In a single observation, LAP from a breast cancer metastasis to the liver migrated as a β-globulin, whereas the enzyme from adjacent liver parenchyma migrated as an α_1-globulin. This finding suggests that the abnormal (β-globulin) LAP component in the serum of most patients with metastatic cancer of the liver[4,5] may be derived from the cancer rather than the liver parenchyma.

Since the results indicated different types of LAP in different tissues, the appearance in the serum of types other than the usual one may prove to be a useful indicator of disease.

Sex Differences in the Pattern of Radio-iodine Excretion in the Urine of Intact Stilbœstrol-treated Guinea Pigs

The effects of œstrogen on intra-thyroidal iodine metabolism have been widely investigated[1-4], but very little is known about its influence on the excretion of iodine in urine. In thyroidectomized castrated male rats on a daily maintenance dose of *dl*-thyroxine there is some indication that 50 µg of œstradiol benzoate daily for one week causes a slight retention of radioiodine[1]. Feldman[2] has observed a decreased renal clearance of iodine-131 in both castrated and hypophysectomized rats receiving 500 I.U. of œstrone daily, but the decrease was not significant when compared with controls. It is most likely[1,4] that œstrogen influences thyroidal activity by depression of renal excretion of iodine-131. It has also been reported that œstrogen influences the distribution of radioiodine in castrated male rats[5].

In the experiments reported here, however, intact guinea pigs were used in order to observe physiological differences in reactivity to stilbœstrol dependent on sex and dose of œstrogen, which it is believed have not hitherto been described. Since the 24-h renal excretion test gives incomplete information about the course of iodine metabolism during this period the method of fractional urine examination was used[6].

Three groups, each containing 7 male and 7 female guinea pigs, were used in the experiment. All animals were fed *ad libitum* with bulky wet food. Stilbœstrol was injected in oil intramuscularly in doses of 0·5 mg/day for three days (group II) and 1·25 mg/day for five days (group III). The animals of the control group (group I) were injected intramuscularly with saline. These two doses of stilbœstrol were assumed to stimulate and depress thyroid activity respectively[7]. 24-h after the last injection of hormone the animals were given an intraperitoneal injection of 28 µc. of carrier-free $Na^{131}I$ in 0·5 ml. of saline. It was previously established that the most favourable fractionation of urine for the required observation should be 0–8 h, 8–14 h and 14–24 h (zero time = time of radioiodine injection). The daily volumes of excreted urine per animal were: 67–140 ml. in controls (group 1); 12–91 ml. (group II) and 17–104 ml. (group III). Following the addition of potassium iodide solution as carrier the radioactivity of the dried urine samples was estimated using the β-ray Geiger–Müller counter. A summary of the results is given in Table 1.

It will be noted that retention of radioiodine was greater in female guinea pigs (including controls) than males. This difference was statistically significant, and therefore comparison with the controls was possible only within each sex.

The 24-h test of urinary excretion used previously gives only slight information about the influence of stilbœstrol on the retention of radioiodine in the body. With the adoption of the method of fractionated urine examination it has become possible to observe differences between groups. Relative contents of radioiodine in separate fractions of urine show the largest differences between groups in the first fraction (0–8 h). The second fraction (8–14 h) does not show any significant inter-group differences. In the last fraction (14–24) there was a marked change in the urine excretion in the male but to a lesser degree in the female. In general, there was a decreased excretion of radioiodine in females, but only at the 1·25 mg dosage of stilbœstrol was the difference statistically significant ($P < 0·05$).

Table 1. Effect of Stilbœstrol on the Excretion of Radioiodine to Sex and Dose in Intact Guinea Pigs

No. of animals	Sex	Treatment	Body-weight (g)		Percentage of administered ^{131}I excreted in urine

* Significantly different from control at 1 per cent level. † Significantly different from control at 5 per cent level.

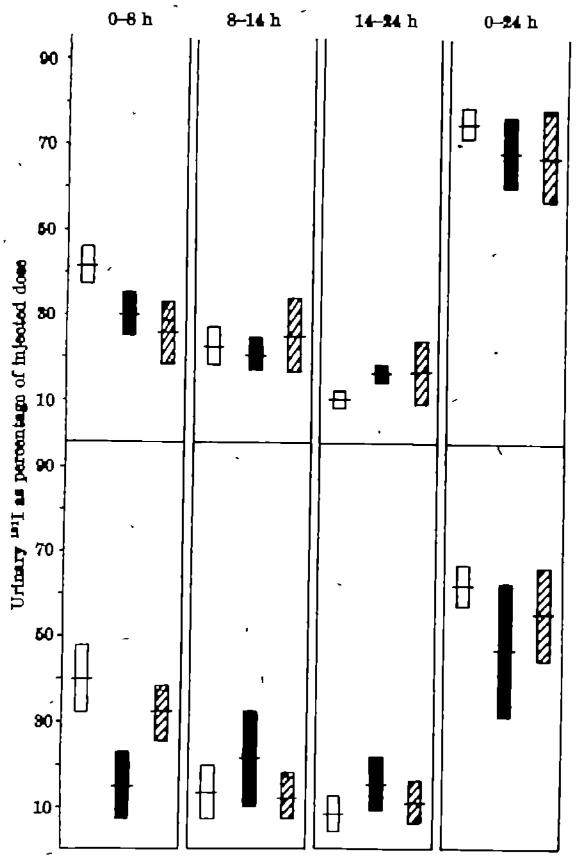

Fig. 1. Results obtained by the method of fractionated urine examination of Arnott *et al.* (ref. 6). Horizontal line and bar indicate the group mean and the limits of ± *S.D.* respectively. White, controls; shaded, stilbœstrol-treated 0 5 mg/day; black, stilbœstrol-treated 1·25 mg/day

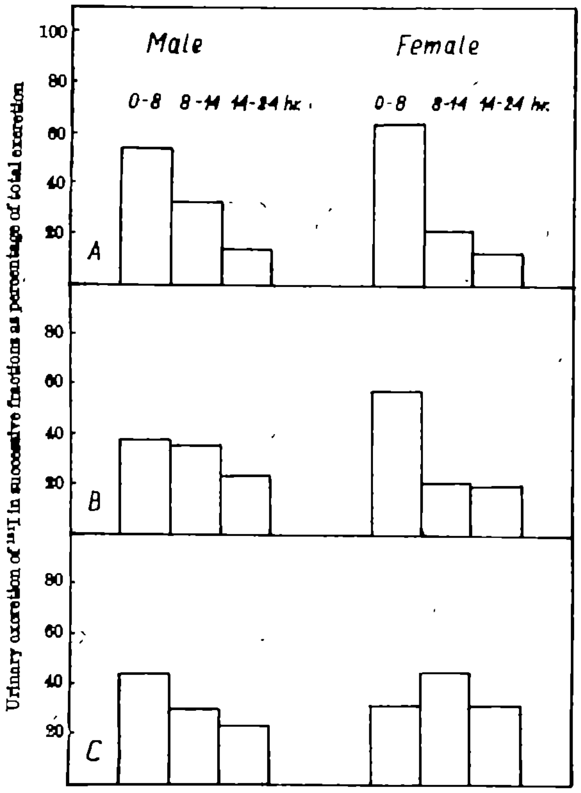

Fig. 2. Inhibitory effect of stilbœstrol on the excretion and excretion pattern of radioiodine in intact male and female guinea pigs. *A*, Controls; *B*, stilbœstrol-treated 0·5 mg/day; *C*, stilbœstrol-treated 1·25 mg/day

From Figs. 1 and 2 it can be concluded that the urinary excretion of radioiodine is greatest in the first hour after administration and thereafter gradually decreases. Stilbœstrol in a dose of 1·25 mg alters this pattern in the intact female, more than in the male, especially with respect to the first fraction. Administered at the rate of 0·5 mg per day, stilbœstrol affects the retention of radioiodine in the body; in the female, however, this effect is not statistically significant. Both the aforementioned doses give a significant change of retention of radioiodine in the male as assessed from examination of the third fraction (14–24 h).

From this evidence it appears that the female is more stimulated by large doses of stilbœstrol and returns more quickly to the normal condition than does the male. On the other hand, intact female guinea pigs are not so much affected as the male by the administration of small doses of stilbœstrol.

The volume of urine excreted per animal per day was in general significantly less after stilbœstrol administration. This was probably due in part to the decreased appetite of the experimental animals, with consequent decreased water intake, and in part to the recognized effect of œstrogens in promoting water-retention[8]. Nevertheless, the values calculated for the regression equations and coefficients of correlations show that there is no correlation between the volume of urine and the amount of radioiodine excreted in the male, but that the correlation is statistically significant at the 1·25 mg dose of stilbœstrol in the female ($P < 0.05$).

In vitro Measurements of Oxygen Consumption of Human Heart Muscle

HYPOTHERMIA has been used extensively in medicine to depress the metabolism of the body tissues[1,2]. Frequent studies have been made of the reduction in oxygen consumption brought about by various grades of hypothermia, both in whole animals[3–5] and in isolated organs and tissues[6,7], but isolated human heart muscle has not so far been examined intensively.

We have found that small pieces of human auricular muscle, trimmed from the appendage submitted for pathological examination at mitral valvotomy, will undergo rhythmic contractions for several hours when placed in a Burn–Dale bath[8]. This observation led us to consider the possibilities of using such material for the *in vitro* examination of various aspects of human cardiac metabolism. This communication deals with the preliminary studies which have been made of human cardiac metabolism at normothermia and at various grades of hypothermia.

Small pieces of auricular muscle were received, in the operating theatre, into Krebs–Ringer phosphate solution and transported rapidly to the laboratory where tissue slices, 0·2 mm thick, were made, and these were placed in Warburg respirometer flasks each containing 2·5 ml. of Krebs–Ringer phosphate solution and 0·5 ml. of 0·02 molar succinic acid in the side-arm. It was usually possible to obtain sufficient material from each operation specimen to supply six Warburg flasks, three of which were placed

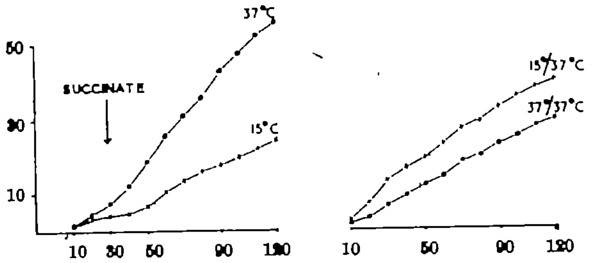

Fig. 1. Results of an experiment at 15° C, showing depression of oxygen consumption of hypothermic tissue followed by increase in oxygen consumption after rewarming.

in one Warburg apparatus, maintained constantly at 37° C, while the other three flasks were placed in a second Warburg apparatus which was at the temperature under investigation.

Endogenous metabolism was examined for 30 min and the succinate was then added from the side-arm and the oxygen uptake measured for the next 90 min. The flasks from the hypothermic bath were then placed in the bath at 37° C and after 15 min for temperature equilibrium the uptake of oxygen of all the flasks in the bath at 37° C was measured for a further 120 min. At the end of the experiment the material from each of the flasks was estimated for nitrogen by the micro-Kjeldahl technique[9], and the results finally expressed in terms of microlitres of oxygen consumed per mg nitrogen in the tissue.

At each of the temperatures selected, namely, 26° C, 15° C, and 8° C, two different specimens were examined and the results are thus from observations on auricular muscle from six different individuals.

Fig. 1 shows the results obtained from one of the experiments at 15° C, and the reduction in oxygen consumption brought about by maintaining the tissue at 15° C can be seen in the first 2-h period, against the oxygen consumption of the control tissue at 37° C. The results obtained during the second 2-h period, when all the flasks were in the bath at 37° C, show that the increased oxygen consumption of the tissue from the cold bath lies presumably in the extra supply of substrate which it has at the end of the first 2-h period compared with its control, which has been undergoing more active metabolism during the preceding 2 h.

Table 1 shows the results obtained from each of the two specimens of tissue tested at each of the temperatures under investigation. The results are expressed in terms of the percentage reduction in oxygen consumption obtained when each specimen is compared with its own control at 37° C. The oxygen consumption is reduced to 72 per cent of the value obtained at 37° C when the tissue is maintained at 26° C and to 40 and 30 per cent when maintained at 15° C and 8° C respectively. The lower part of Table 1 shows the results obtained during the second 2-h period when all the tissue was in the bath at 37° C. In all cases there is an increase in oxygen consumption of the tissue from the hypothermic bath, compared with that in the bath at 37° C throughout, and the mean value indicates an increase of some 50 per cent in oxygen consumption. Thus in all cases it was possible to metabolize succinate following the 2-h period in the hypothermic bath.

Table 1. The Oxygen Consumption at Various Temperatures when each Specimen is compared with its own Control at 37° C is shown in the Upper Part and again in the Lower Part after Rewarming

	Temperature ° C		
	26 % O_2 consumption	15 % O_2 consumption	8 % O_2 consumption
	72	38	28
	72	42	32
Mean	72	40	30
	26° C/37° C % O_2 consumption	15° C/37° C % O_2 consumption	8° C/37° C % O_2 consumption
	188	136	109
	117	147	203
Mean	153	142	156

In Table 2 can be seen the oxygen consumption in each of the experiments during the first 30 min of endogenous metabolism and then during the second 30-min period after the succinate had been added. At 37° C the addition of succinate caused the oxygen consumption to be doubled during the second 30-min period; but this stimulation is reduced as the temperature falls, being only slightly reduced at 26° C, much more at 15° C, while at 8° C it is apparent that succinate is not being metabolized at all.

Table 2. Oxygen Consumption at Various Temperatures Before and After Addition of Succinate

Time min	37° C μl. O_2		26° C μl. O_2		15° C μl. O_2		8° C μl. O_2	
	1	2	3	4	5	6	7	8
0–30	16	15	12	9	4	4	8	5
30–60	32	30	18	19	5	7	3	4

This preparation of human heart muscle appears to function in a stable and reproducible manner, and when many more specimens have been examined it should be possible to give a Q_{10} for human heart muscle. The results of the preliminary experiments show a reduction in oxygen consumption to 72 per cent of the value obtained at 37° C when the tissue is maintained at 26° C and to 40 and 30 per cent of the value obtained at 37° C when the tissue is maintained at 15° C and 8° C respectively. The ability to metabolize succinate decreases with declining temperature and has been arrested by the time 8° C is reached. Both the specimens from bath at 8° C, however, showed a rapid return of ability to metabolize succinate when placed in the bath at 37° C.

Utilization of Proline during Healing of Fractures

Summer[1] has recently demonstrated that following oral administration of proline the level of serum proline was lower in children afflicted with osteogenesis imperfecta than in normal children. Since this effect was shown not to be due to urinary excretion, it seemed that the relative rate of proline disappearance from the blood system (proline 'tolerance') could serve as an index of connective tissue metabolism. To determine the validity of this concept, the serum proline concentration was measured by the method of Troll and Lindsey[2], at two intervals after an intravenous injection of proline into normal rabbits and into rabbits with healing fractures.

Ten New Zealand white female rabbits were fasted overnight and subjected to a proline 'tolerance' test. Blood samples were withdrawn by heart puncture, prior to and 30 and 60 min after the intravenous administration of 65 mg proline/kg body-weight. After a day's rest the same rabbits were anaesthetized with ether and one femur was snapped with the aid of a pipe wrench. The fractures were not reduced or immobilized. After 10 and 34 days the proline 'tolerance' test was repeated. The fracture site

Table 1. EFFECT OF FRACTURE HEALING ON THE REMOVAL OF PROLINE FROM THE BLOOD

Min. after intravenous injection of 65 mg proline/kg	Serum proline-level (g/mL.) 10 days of healing		Prior to fracture		30 days of healing
